## Abstract

Experiments on extremely steep waves generated in a large wave tank by focusing of a broad-banded wave train serve as a motivation for the theoretical analysis of the conditions leading to wave breaking. Particular attention is given to the crest of the steepest wave where both the horizontal velocity and the vertical acceleration attain their maxima. Analysis is carried out up to the 3rd order in wave steepness. The apparent, Eulerian and Lagrangian accelerations are computed for wave parameters observed in experiments. It is demonstrated that for a wave group with a wide spectrum, the crest propagation velocity differs significantly from both the phase and the group velocities of the peak wave. Conclusions are drawn regarding the applicability of various criteria for wave breaking.

## 1 Introduction

Three main factors determine the wave energy balance: input due to the action of wind, wave energy dissipation, and nonlinear interactions among waves. The nonlinear interactions among waves are fairly well understood; the interaction between wind and waves can be modelled effectively. In spite of the fact that breaking constitutes the dominant wave energy damping mechanism, it is not yet understood properly, so that the wave breaking constitutes one of the most challenging problems in physical oceanography.

During the wave breaking process substantial part of the wave energy is dissipated, mostly to turbulent kinetic energy of water velocity fluctuations and eventually to heat. The detailed mechanism of wave breaking and the exact conditions required for waves to break remain largely unknown. The breaking criteria suggested over the years may be divided in a broad sense into three types: geometric, kinematic and dynamic (Gemmrich, 2005; Babanin, 2011). A number of geometric criteria related to the wave shape on the verge of breaking were suggested, such as maximum steepness

( $a k \approx 0.443$ for Stokes wave, where $a$ and $k$ are the amplitude and the wave number, respectively), wave asymmetry in either horizontal or vertical direction, as well as maximum instantaneous surface slope (Longuet-Higgins and Fox, 1977). The kinematic criteria for wave breaking predict that the wave breaks if the orbital velocity at its crest exceeds either the phase or the group velocity of the wave. although recent experiments by Grue and Jensen (2012) seem to demonstrate that the maximum velocity at the crest of breaking wave does not exceed significantly $0.4 c$, where the wave phase velocity $c$ is computed taking into account nonlinear and current effects. Phillips (1958) offered a dynamic breaking criterion arguing that since for gravity water waves the gravity is the only restoring force, the maximum possible negative value of the vertical acceleration at the free surface $a_{v}=-g$. Although straightforward and physically convincing, this criterion remains unsupported neither experimentally nor numerically. Longuet-Higgins (1985) noticed that the maximum negative value of the vertical acceleration in the steepest Stokes wave where $120^{\circ}$ corner flow exists at the crest is only $a_{v}=-g / 2$. In some field experiments the measured values close to $a_{v}=-g / 2$ were reported, but most experiments yield wave breaking at downward acceleration values less than $g / 2$ (Jensen et al., 2007).

It should be stressed that when experimental verification of the dynamic criterion by Phillips is considered, distinction should be made between the "apparent" acceleration defined by Longuet-Higgins (1985) as $\partial^{2} \zeta / \partial t^{2}$, the Eulerian vertical acceleration $a_{\mathrm{E}}=\partial w / \partial t$, and the Lagrangian acceleration of the fluid particle, $a_{\mathrm{L}}$. While in linear approximation all these accelerations are identical; they can differ essentially when nonlinear terms are accounted for. For unidirectional waves, the velocity $\boldsymbol{v}=(u, w)$ at the free surface $\zeta=\zeta(x, t)$ is related to $\zeta$ by the kinematic boundary condition
$w=\partial \zeta / \partial t+u \partial \zeta / \partial x \quad$ at $z=\zeta(x, y)$.
It is evident from (1) that at higher orders the Eulerian vertical acceleration $a_{\mathrm{E}} \neq$ $\partial^{2} \zeta / \partial t^{2}$. The "apparent" acceleration $\partial^{2} \zeta / \partial t^{2}$ can be measured relatively simply; the experimental determination of $a_{\mathrm{E}}$ however is significantly more complicated since it

Interactive Discussion

requires simultaneous measurements of the horizontal component of the instantaneous surface velocity and of the surface slope. The Phillips dynamic criterion is based on the Lagrangian vertical acceleration $a_{\mathrm{L}}$, a quantity that is even more difficult to measure. In this respect it should be noted that the contribution of higher order (bound) 5 waves is essential not only to the material acceleration of the water particle, but also to the velocity components (Johannessen, 2010).

The present study that considers broad-banded wave groups was motivated by an observation made during experiments on unidirectional random water waves in a large wave tank (Shemer et al., 2010). In the course of that study it was noticed that for a fixed wave peak frequency and steepness, maximum accelerations and velocities of the wavemaker piston required for excitation of the prescribed wave field depend on the spectral shape and increase strongly as the spectrum gets wider. This observation led to a plausible assumption that while the negative vertical acceleration remains significantly below gravitational acceleration $g$ even for the steepest possible Stokes wave, the situation may differ for a wave field with a wider spectrum. The horizontal velocities at crests of steep waves in a broad-banded wave field may also exceed significantly estimates based on a single dominant mode. Moreover, both the vertical accelerations and the horizontal velocities of fluid particles at the free surface of extreme waves that are essentially nonlinear, differ significantly from those predicted by the linear wave theory. Previous experiments (Shemer et al., 2007) provided records of deterministic breaking and non-breaking steep focused waves with a wide spectrum under controlled conditions. Since direct measurements of water particle velocities and accelerations at the crest of the steepest wave are extremely difficult to perform, these parameters are computed here taking into account nonlinear contributions up to the 3rd order.

## 2 Theoretical and experimental background

The spatial evolution of a nonlinear unidirectional wave field that takes into account 3rd order (quartet) interactions can be described by the spatial version of the Zakharov

equation (1968) as suggested by Kit and Shemer (2002) and Shemer et al. (2007). The evolution equation is written in terms of scaled amplitudes $B_{j}=B\left(\omega_{j}, x\right)$ that are related to the generalized complex "amplitudes" $a_{j}(x)=\left(\omega_{j}, x\right)$ composed of the Fourier transforms of the surface elevation $\hat{\zeta}_{j}(x)=\hat{\zeta}\left(\omega_{j}, x\right)$ and of the velocity potential at the free surface $\hat{\varphi}_{j}^{s}(x)=\hat{\varphi}^{s}\left(\omega_{j}, x\right)$ :
$a_{j}(x)=\left(\frac{g}{2 \omega_{j}}\right)^{1 / 2} \widehat{\zeta}_{j}(x)+i\left(\frac{\omega_{j}}{2 g}\right)^{1 / 2} \widehat{\varphi}_{j}^{s}(x)$.
The amplitudes $a_{j}(x)$ in (2) can be seen as consisting of a sum of free and the bound waves:
$a_{j}=\left[\varepsilon B_{j}(x)+\varepsilon^{2} B_{j}^{\prime}(x)+\varepsilon^{3} B_{j}^{\prime \prime}(x)+\ldots\right] \exp \left(-i \omega_{j} t\right)$.
10 The amplitudes $B_{j}$ denote the so-called "free" waves that satisfy the dispersion relation for gravity waves in water of intermediate depth $h: \omega^{2}=k g \bullet \tanh (k h) ; B_{j}$ and $B_{j}^{\prime \prime}$ correspond to the 2nd and 3rd order, respectively, 'bound' waves. The small parameter in the decomposition (3) $\varepsilon=k a$, where $k$ and a represent the characteristic wave number and amplitude. The higher order bound components $B^{\prime}, B^{\prime \prime}$, etc., are computed for a given free wave packet $B_{j,} j=1, \ldots, N$, following Stiassnie and Shemer (1987), see also Krasitskii (1994). The 2nd order bound waves $B_{n}{ }_{n}$ generated by harmonics $i$ and $j$ and their frequencies $\omega_{n}$ and wave numbers $k_{n}$ be computed using the relations
$B_{n}^{\prime(1)}=A_{n j l}^{(1)} B_{j} B_{l} ; k_{n}=k_{j}+k_{l} ; \omega_{n}=\omega_{j}+\omega_{l}$,
${ }^{20} \quad B_{n}^{\prime(2)}=A_{n j l}^{(2)} B_{j}^{*} B_{l} ; k_{n}=-k_{j}+k_{l} ; \omega_{n}=-\omega_{j}+\omega_{l}$,

$B_{n}^{\prime(3)}=A_{n j l}^{(3)} B_{j}^{*} B_{l}^{*} ; k_{n}=-k_{j}-k_{l} ; \omega_{n}=-\omega_{j}-\omega_{l}$.

The 3rd order bound waves $B^{\prime \prime}{ }_{n}$ generated by free harmonics $i, j$ and $m$ are determined by
$B_{n}^{\prime \prime(1)}=C_{j / m}^{(1)} B_{j} B_{l} B_{m} ; k_{n}=k_{j}+k_{l}+k_{m} ; \omega_{n}=\omega_{j}+\omega_{l}+\omega_{m}$,
${ }^{5} \quad B_{n}^{\prime \prime(2)}=C_{j / m}^{(2)} B_{j}^{*} B_{l} B_{m} ; k_{n}=-k_{j}+k_{l}+k_{m} ; \omega_{n}=-\omega_{j}+\omega_{l}+\omega_{m}$,
$B_{n}^{\prime \prime(3)}=C_{j / m}^{(3)} B_{j}^{*} B_{l}^{*} B_{m} ; k_{n}=-k_{j}-k_{l}+k_{m} ; \omega_{n}=-\omega_{j}-\omega_{l}+\omega_{m}$,
$B_{n}^{\prime \prime(4)}=C_{j l m}^{(4)} B_{j}^{*} B_{l}^{*} B_{m}^{*} ; k_{n}=-k_{j}-k_{l}-k_{m} ; \omega_{n}=-\omega_{j}-\omega_{l}-\omega_{m}$.
10 The coefficients $A$ in (4) and $C$ in (5) are given in the Appendix of Stiassnie and Shemer (1987). As can be seen from (4) and (5), the phase velocities $c_{n}=\omega_{n} / k_{n}$ of higher order bound waves are not defined by the free waves' dispersion relation, but rather by frequencies and wave numbers of the "parent" free waves. The complex amplitudes $a_{j}$ that contain both free and bond waves' contributions for any prescribed wave frequency spectrum allow to compute the temporal variation of the surface elevation
$\zeta(x, t)=\frac{1}{\pi} \operatorname{Re}\left\{\sum_{j=1}^{N} \sqrt{\frac{\omega_{j}}{2 g}} a_{j}(x) \exp \left[i\left(k_{j} x-\omega_{j} t\right)\right]\right\}$
and of the velocity potential at the free surface
$\phi^{s}(x, t)=\frac{1}{\pi} / m\left\{\sum_{j=1}^{N} \sqrt{\frac{g}{2 \omega_{j}}} a_{j}(x) \exp \left[i\left(k_{j} x-\omega_{j} t\right)\right]\right\}$.

The surface elevation $\zeta$, the full velocity potential $\phi$ and the horizontal $u=\partial \phi / \partial x(z=$ $\zeta(x, t))$ and the vertical $w=\partial \phi / \partial z(z=\zeta(x, t))$ velocity components at the free surface can thus be computed to the needed order.

In experiments of Shemer et al. $(2002,2007)$ the following Gaussian temporal varia-
tion of the surface elevation was prescribed:
$\zeta(t)=\zeta_{o} \exp -\left(\frac{t}{m T_{0}}\right)^{2} \cos \left(\omega_{o} t\right)$,
where $\omega_{0}=2 \pi / T_{0}$ is the carrier wave frequency, $\zeta_{0}$ is the maximum wave amplitude in the group attained at $t=0$, and the parameter $m$ defines the width of the group. The free wave frequency spectrum of the surface elevation given by (7) is also Gaussian. Higher values of $m$ correspond to a wider group with a narrow spectrum, decrease in $m$ renders the group narrower and the frequency spectrum wider. It was demonstrated in Shemer et al. (2007) that for $m=0.6$, the wave group (7) contains only a single wave and thus has a wide spectrum. The small parameter representing the magnitude of nonlinearity $\varepsilon$ is the maximum wave steepness $\varepsilon=\zeta_{0} k_{0}$. The prescribed temporal variation of the surface elevation (7) at the focusing location takes into account the contribution of free waves only.

Experiments were carried out in the Large Wave Channel (GWK) in Hannover, Germany that is 300 m long, 5 m wide 7 m deep, with water depth set at 5 m . The pistontype wavemaker was driven by a computer-generated signal that was obtained by integration of the spatial version of the Zakharov equation from the focusing location back to the wvameker, see Shemer et al. (2007). The focusing location in all experiments was set at 120 m from the wavemaker. Two peak wave periods were used: $T_{0}=2.8 \mathrm{~s}$, corresponding to wave length of $\lambda_{0}=2 \pi / k_{0}=12.5 \mathrm{~m}$ and nearly deep water conditions ( $k_{0} h=2.6$ ), and $T_{0}=4.32 \mathrm{~s}\left(\lambda_{0}=25.0 \mathrm{~m}\right)$, corresponding to intermediate water depth 25 with $k_{0} h=1.26$. The experiments were carried out for the width parameter $\mathrm{m}=0.6$ at the values of the nonlinearity coefficient $\varepsilon=\zeta_{0} k_{0}$ ranging from 0.1 (corresponding to nearly linear wave regime) to those exceeding $\varepsilon=0.3$ for strongly nonlinear and

Interactive Discussion
breaking waves. The approach adopted in the experiments thus enabled generating either a single breaking wave, or a wave on the verge of breaking, at a prescribed location in the wave tank. In all experiments where breaking was observed it ocurred at the crest of the steepest wave in close vicinity of the focusing location. In particular, 5 it was observed that the wave with $\varepsilon=0.3$ and $T_{0}=2.8 \mathrm{~s}$ does not break, while the longer wave with $T_{0}=4.34 \mathrm{~s}$ and the same steepness undergoes breaking. When the maximum steepness was reduced to $\varepsilon=0.27$ while retaining the same dominant wave period, no breaking was observed.

## 3 Numerical simulations

In view of these experimental observations, computations of the surface elevation variation with time, as well as the horizontal and vertical components of velocity and accelerations were carried out for conditions corresponding to the focused waves in the experiments. The computations of wave shapes at the focusing location with the free wave (linear) surface elevation variation with time given by (7) were performed up to 15 the 3rd order in wave steepness $\varepsilon$, using Eqs. (4)-(6). The resulting contributions to the instantaneous surface elevation of the 1st order (proportional to $B$ ), 2nd order ( $\sim B^{\prime}$ ) and 3rd order ( $\sim B^{\prime \prime}$ ), as well as the total surface elevation $\zeta(t)$ at the 3rd order are plotted in Fig. 1 for $\varepsilon=0.3$. The nonlinear bound waves are clearly visible in this figure; they manifest themselves in higher and sharper crests and shallower troughs of the focused wave. The effect of this variation of the wave's shape on the velocities and accelerations is now studied.

The temporal variation of two components of water velocity at the focusing location is plotted in Fig. 2. The contributions to the total horizontal velocity at all orders attain maximum at the crest $(t=0)$; as expected, all vertical velocity contributions at the crest vanish. Higher order contributions to horizontal velocity are relatively more significant than those for the wave shape in Fig. 1. Note also that for the conditions of Fig. 2, the 3rd order contribution to the horizontal velocity $u$ in the vicinity of the crest is not

Interactive Discussion
very different from that at the 2 nd order. For longer dominant wave period, $T_{0}=4.34 \mathrm{~s}$, corresponding to effectively shallower water, and the same steepness of $\varepsilon=0.3$, the contributions of the 2 nd and 3 rd order to the horizontal velocity at the crest are practically equal and even more important, each contributing to the total horizontal velocity at the crest more than $25 \%$ of the leading order order part. For a wave group in water of intermediate depth the extreme value of the horizontal velocity is thus increased by more than $50 \%$ as compared to the linear solution.

The computed horizontal velocities at the wave crest for the nonlinearity parameter $\varepsilon=0.3$ are $u_{\max }=1.69 \mathrm{~m} \mathrm{~s}^{-1}$ for the wave group with shorter dominant wave, $T_{0}=2.8 \mathrm{~s}$, and $u_{\max }=3.09 \mathrm{~m} \mathrm{~s}^{-1}$ for $T_{0}=4.34 \mathrm{~s}$. These results can be compared with the corresponding wave propagation velocities. For relatively deep water case of $T_{0}=2.8 \mathrm{~s}$, the dominant wave's phase velocity is $c_{p}=4.32 \mathrm{~m} \mathrm{~s}^{-1}$, and the group velocity only slightly exceeds the deep water relation $c_{\mathrm{g}}=c_{\mathrm{p}} / 2$; the calculated for this wave period $c_{\mathrm{g}}=2.29 \mathrm{~m} \mathrm{~s}^{-1}$. The corresponding values of the longer wave ( $T_{0}=4.34 \mathrm{~s}$ ) are $c_{\mathrm{p}}=5.76 \mathrm{~m} \mathrm{~s}^{-1}$ and $c_{\mathrm{g}}=4.06 \mathrm{~m} \mathrm{~s}^{-1}$. The phase and group velocities, however, can serve as characterizing parameters only for wave groups with narrow spectra. As stressed in Shemer et al. (2007), appearance of extremely steep waves by focusing mechanism is a result of constructive interference of numerous harmonics and thus requires broad spectrum. Therefore both phase $c_{\mathrm{p}}$ and group $c_{\mathrm{g}}$ velocities calculated for the dominant wave are not directly related to the actual crest propagation velocities $u_{\mathrm{cr}}$. As can be seen from Fig. 1, the higher order contributions do not affect the instant at which the steepest wave appears. The velocity of the crest was therefore determined by computing the instantaneous wave forms at several instants in the vicinity of the focusing at $t=0$ at the leading order yielding $c_{\mathrm{cr}}=3.6 \mathrm{~m} \mathrm{~s}^{-1}$ for $T_{0}=2.8 \mathrm{~s}$ and $c_{\mathrm{cr}}=5.0 \mathrm{~m} \mathrm{~s}^{-1}$ for $T_{0}=4.34 \mathrm{~s}$. In both these cases the crest velocity $c_{c r}$ of the broad-spectrum wave group is signficantly different from both the phase $c_{\mathrm{p}}$ and the group $c_{\mathrm{g}}$ velocities of the dominant wave and satisfy the condition $c_{\mathrm{g}}<c_{\mathrm{cr}}<c_{\mathrm{p}}$. For the dominant wave lengths considered, the maximum velocities at the crest containing terms up to the 3rd order

are significantly lower than $c_{\text {cr }}: u_{\text {max }} / c_{\text {cr }}=0.47$ for $T_{0}=2.8 \mathrm{~s}$ and $u_{\max } / c_{\text {cr }}=0.62$ for shallower water with $T_{0}=4.34 \mathrm{~s}$.

Vertical accelerations are considered next. Since the emphasis of this study is on nonlinear effects that are more pronounced in intermediate depth, the results corresonding to the longer wave case are mainly presented in sequel. It is instructive to compare different relevant accelerations quantitatively. The contributions at different orders to the "apparent" vertical acceleration $\partial^{2} \zeta / \partial t^{2}$ that can be relatively easily estimated in experiments from the data recorded by a fixed wave gauge are plotted plotted in Fig. 3a. A similar plot of the Eulerian vertical acceleration component $a_{\mathrm{E}}=\partial w / \partial t$ is presented in Fig. 3b. In the linear approximation these two accelerations are indeed identical. Higher order contributions, however, are quite different in Fig. 3a and b and are comparable with the linear term, in particular in Fig. 3a. The importance of higher order terms in computations of acceleration stems from the even more significant role of the high the frequency part of the spectrum as compared to the nonlinear contributions to the total velocity in Fig. 2. The "apparent" and the Eulerian accelerations accurate to the 3rd order differ considerably, both qualitatively and quantitatively. The negative "apparent" acceleration at the wave crest exceeds $8 \mathrm{~m} \mathrm{~s}^{-2}$, quite close to the acceleration of gravity $g$. The value of $a_{\mathrm{E}}$ in Fig. 3 b is only about $-5.5 \mathrm{~m} \mathrm{~s}^{-2}$ at this instant; it should be stressed though that it still exceeds $g / 2$.

As stressed above, the physical reasoning behind the dynamic criterion by Phillips implies that the negative vertical acceleration of any water particle cannot exceed $g$. To verify wherther this criterion is applicable for the experimental conditions considered, Lagrangian acceleration $a_{L}$ has to be calculated. For unidirectional waves, $a_{L}$ is a sum of $a_{\mathrm{E}}$ and the convective acceleration:
$a_{\mathrm{L}}=D w / D t=\partial w / \partial t+u \partial w / \partial x+w \partial w / \partial z$
The convective acceleration only contributes at the 2nd order and higher. To compute the corresponding terms with the 3rd order accuracy, it is sufficient to calculate both velocity components and their spatial derivatives have up to the 2nd order. The convective

Interactive Discussion

acceleration terms in (8) at the 2nd and the 3rd order are plotted in Fig. 4. The indices in the legends denote the order of the corresponding terms. It is obvious that in general, in spite of the fact that the convective acceleration is a quantity of higher order, for steep waves it cannot be disregarded. Although the contribution of the term $w \partial w / \partial z$ at the wave crest is zero at all orders, see Fig. 4b, since the vertical velocity vanishes at $t=0$, this term may become quite larger at other instants. Even more important for the present discussion is the fact that at $t=0$ the contributions at all terms to $u \partial w / \partial x$ in Fig. 4a are positive and relatively large. The essentially positive convectional acceleration at the wave crest therefore reduces considerably the maximum value of the negative vertical acceleration as compared to $a_{\mathrm{E}}$. It is also worth noting that at $t=0$, the contribution of the 2 nd order term $u_{1}(\partial w / \partial x)_{1}$ is nearly identical to the total 3rd order term $u_{1}(\partial w / \partial x)_{2}+u_{2}(\partial w / \partial x)_{1}$.

The computed Lagrangian accelerations at the focusing location are plotted in Fig. 5 for both wave periods in the experiments. The extreme negative value of the vertical component of the Lagrangian acceleration attained at the wave crest accurate to the 3rd order in both cases is close to about $g / 3$, well below the value predicted by the Phillips dynamic criterion. Although higher order corrections are essential in computations of the "apparent", Eulerian and convective accelerations, see Figs. 3 and 4, their respective contributions effectively cancel out in computation of the Lagrangian acceleration, so that the resulting temporal variation of $a_{\mathrm{L}}$ does not differ substantially from the linear solution. A qualitative and relatively minor difference can be noticed between the accelerations in the vicinity of the crest in Fig. 5 a and b . For $k_{0} h=2.6$ in Fig. 5a, the total negative Lagrangian acceleration at $t=0$ is smaller than the linear value, while for shallower water with $k_{0} h=1.26$ in Fig. 5b the opposite is correct. This dissimilarity can be attributed to the increasing contribution of higher order bound waves with decreasing dimensionless depth $k_{0} h$, cf. Fig. 2a and b.

## 4 Discussion and conclusions

In the present study an attempt is made to relate the kinematics of a wave group to experimentally observed wave breaking events in a tank under controlled conditions (Shemer et al., 2007). For wave steepness of $\varepsilon=0.3$, the steepest wave in a focused wave group with a wide Gaussian-shaped spectrum wave (at the leading order) was observed to be on verge of breaking for the shorter dominant wave length corresponding to $k_{0} h=2.6$, and actually underwent breaking for a longer wave with $k_{0} h=1.26$. For the temporal variation of the surface elevation corresponding to that in the experiments at the focusing location, velocities and accelerations at the surface are computed to the 3rd order. The analysis is based on the Zakharov (1968) equation and is accurate to the 3rd order in $\varepsilon$. The various orders contributions to the surface elevation as well as to the horizontal and vertical velocity components are accounted for. In general, the orbital velocities computed at the crest of steep waves close to breaking are in agreement with recent direct measurements by Grue and Jensen (2012).

In an effort to verify the applicability of Phillips (1958) dynamic criterion for wave breaking particular attention is given in the present study to computations of the vertical acceleration, with clear distinction made between the 'apparent', Eulerian ( $a_{\mathrm{E}}$ ) and Lagrangian ( $a_{\mathrm{L}}$ ) accelerations. The time dependence of all those accelerations for the focused wave was obtained. It is shown that the extreme negative values of the 'apparent' acceleration $\partial^{2} \zeta / \partial t^{2}$ with nonlinear terms accounted for indeed exceed significantly those computed in the linear approximation. The same is true regarding the Eulerian vertical acceleration $a_{\mathrm{E}}=\partial w / \partial t$, although the extreme negative values of $a_{\mathrm{E}}$ are somewhat smaller than those of $\partial^{2} \zeta / \partial t^{2}$. The convective acceleration terms are, however, mostly positive and thus lead to even smaller negative Lagrangian acceleration $a_{\mathrm{L}}$ at the crest of a steep wave. It was observed that for the cases considered, even the value of the "apparent" negative acceleration $\partial^{2} \zeta / \partial t^{2}$ at the crest of the steepest possible wave at this order remains somewhat smaller than $g$. The nonlinear

Interactive Discussion
contributions decrease the extreme values of negative Eulerian and Lagrangian vertical accelerations as compared to $\partial^{2} \zeta / \partial t^{2}$.

The Lagrangian acceleration is of particular importance since it is the appropriate quantity in the Phillips' dynamic breaking criterion. The present results show that the extreme values of $a_{\mathrm{L}}$ for waves on the verge of breaking remain well below the gravity acceleration $g$. It appears that virtually all nonlinear additions to the maximum apparent negative vertical acceleration are effectively cancelled out by positive convective acceleration, so that the maximum negative values of the Lagrangian acceleration accurate to the 3rd order in the wave steepness $\varepsilon$ are in fact quite close to the vertical acceleration calculated in the linear approximation. This observation makes it plausible to assume that extension of computations to even higher order will not change significantly the resulting vertical component of $a_{\mathrm{L}}$. It thus appears that the Phillips criterion cannot serve for prediction of wave breaking not only for Stokes waves, as demonstrated by Longuet-Higgins (1985), but also for more realistic wide-spectra nonlinear wave groups.

This failure of the dynamic criterion prompts a closer look at the kinematic wave breaking criteria that relate the water velocities at the surface with wave propagation velocities. The kinematic condition states that wave breaks when the water particle velocity at the crest of the wave exceeds the crest velocity that is often represented by the phase velocity $c_{p}$ at the dominant wave frequency. Alternatively, since the envelope of a narrow-banded group propagates with the group velocity $c_{\mathrm{g}}$ of the peak wave, the value of $c_{\mathrm{g}}$ sometimes is taken as the characteristic wave velocity. It is demonstrated that here, however, that for a wider spectrum, neither $c_{\mathrm{p}}$ nor $c_{\mathrm{g}}$ correspond to the highest wave crest propagation velocity. The actual velocity of crest that should be used in the analysis of breaking conditions for waves with wider spectra therefore has to be either computed directly for any given complex wave spectrum, or determined experimentally.

The computed in the present study horizontal components of orbital velocity at the crest $u_{\max }$ accurate to the 3rd order remain notably smaller that the estimated

corresponding propagation velocities of crests of extreme waves, thus suggesting that the kinematic condition is also not satisfied for wave parameters considered here. Nevertheless, it should be stressed that contribution of the 3rd order terms to $u_{\text {max }}$ is relatively large and comparable to the contribution to the maximum horizontal velocity needed to determine the applicability of the kinetic criterion for wave breaking. Alternatively, direct measurements of water particle velocities at the surface in the vicinity of crest of breaking wave should be carried out.
