Abstract

One of the most important tasks of modern volcanology is the construction of hazard maps simulating different eruptive scenarios that can be used in risk-based decision-making in land-use planning and emergency management. The first step in the quantitative assessment of volcanic hazards is the development of susceptibility maps, i.e. the spatial probability of a future vent opening given the past eruptive activity of a volcano. This challenging issue is generally tackled using probabilistic methods that use the calculation of a kernel function at each data location to estimate probability density functions (PDFs). The smoothness and the modeling ability of the kernel function are controlled by the smoothing parameter, also known as the bandwidth. Here we present a new tool, QVAST, part of the open-source Geographic Information System Quantum GIS, that is designed to create user-friendly quantitative assessments of volcanic susceptibility. QVAST allows to select an appropriate method for evaluating the bandwidth for the kernel function on the basis of the input parameters and the shapefile geometry, and can also evaluate the PDF with the Gaussian kernel. When different input datasets are available for the area, the total susceptibility map is obtained by assigning different weights to each of the PDFs, which are then combined via a weighted summation and modeled in a non-homogeneous Poisson process. The potential of QVAST, developed in a free and user-friendly environment, is here shown through its application in the volcanic fields of Lanzarote (Canary Islands) and La Garrotxa (NE Spain).

1 Introduction

Volcano susceptibility is defined as the spatial probability of vent opening (Martí and Felpeto, 2010) and constitutes one of the first steps in the assessment of volcanic hazards and the construction of hazard maps of eruptive products (e.g. lava flows, ash, and pyroclastic density currents). The exact site of a new eruption – a central vent or a vent located on the flanks of a stratovolcano, or at any other apparently randomly distributed

Interactive Discussion

point in a larger monogenetic volcanic field – is of critical importance in determining the potential outcome of an eruption. For the same eruption, different eruption scenarios and, consequently, different potential impacts are to be expected depending on the exact location of the vent and on the geographic and demographic characteristics of the area. Hence, evaluating where future eruptive vents are most likely to open greatly influences volcanic hazard assessment (Cappello et al., 2011a, b).

The exact path that the over-pressurized magma will take from its accumulation site to the Earth's surface – and hence the site of any new vent – will be determined by geological structure and stress distribution inside the crust. We know that the energetic investment by the magma on this path will be the minimum and that it will be parallel to the trajectory of the main principal stress and normal to the minimum principal stress (Gudmundsson, 2008, 2012). However, we do not have any direct criteria that enable us to determine this route a priori since we lack detailed 3-D knowledge of the stress field of the area. In the long term it is possible to base some approaches on the location of previous eruptions and on the structural characteristics of the volcano or the volcanic area. On the other hand, in the short term it is also possible to take into account monitoring data from the volcanic field. Therefore, the estimation of the most probable vent site is not an impossible task and can be undertaken as part of volcanic hazard assessment. This is a less difficult task in stratovolcanoes for which good knowledge of past eruptive history exists and where real-time volcano monitoring is currently being performed. However, volcano susceptibility assessment is more complex in monogenetic volcanic fields, as has been shown by the recent eruption at El Hierro (Martí et al., 2013), where stress conditions may change from one eruption to another.

Published work in this field (Connor and Hill, 1995; Felpeto et al., 2007; Jaquet et al., 2008; Martí and Felpeto, 2010; Favalli et al., 2011; Connor et al., 2012; Cappello et al., 2012, 2013) reports the use of kernel density functions to evaluate susceptibility. However, this technique is based mainly on the assumption that new vents will not form far from existing ones (Martin et al., 2004; Jaquet et al., 2008). This is an a priori

hypothesis for long-term hazard assessment, in which the use of volcano-structural alignments (eruptive fissures, fractures, dykes) and the location of past centers of emission assumes implicitly that the general stress field has not changed significantly since the formation of these structures. Conversely, when dealing with short-term hazard assessment, monitoring data (Martí and Felpeto, 2010) – which provides important information regarding the evolution of magma migration and its ascent to the surface – play a major role in determining volcanic susceptibility.

A kernel function is a density function used to obtain the intensity of volcanic events. It is based on the distance from nearby volcanoes and a smoothing constant h (Martin et al., 2004), which indicates the spatial probability that a new eruptive vent will form. A Gaussian kernel is a kernel function describing a normal distribution that is used in volcanology to estimate local volcanic event densities in volcanic fields (Martin et al., 2004; Connor et al., 2012; Cappello et al., 2012).

The aim of this work is to (i) analyze different approaches to evaluating the smoothing parameter h (also known as the bandwidth), (ii) estimate for each approach the corresponding probability density function (PDF) and (iii) assess long-term spatial susceptibility in monogenetic volcanic fields. We describe here a new user-friendly plugin known as QVAST (**Q**GIS for **V**olc**A**nic **S**uscep**T**ibility) for the free Geographic Information System Quantum GIS (QGIS), which can make these calculations and help users to choose the best option in each particular case (Fig. 1). We describe the QVAST interface step-by-step via two different applications: the first in Lanzarote (Canary Islands, Spain) and the second in La Garrotxa (NE Spain). These two case studies show QVAST's great flexibility and its ability to identify the most likely zones to host new eruptions in monogenetic volcanic fields.

2 Optimal bandwidth in kernel density estimation

The probability distribution in a kernel technique is strongly influenced by a smoothing parameter or bandwidth, which determines how probabilities are distributed in terms

Interactive Discussion

of the distance from the volcanic structures or vents. The smoothness of the kernel density estimate is evident compared to the discreteness of the histogram, as bin width of a histogram, for continuous random variables (Scott, 1979). An optimal smoothing bandwidth is based on the clustering behavior of the volcanic structures and varies proportionally with the volcanic field size and vent density. Indeed, narrow bandwidths accentuate densities near the locations of past events. Conversely, broad bandwidths may oversmooth the density estimate, resulting in unreasonably low density estimates near clusters of past events, or overestimate densities at greater distances from past events. In a Gaussian kernel function, the bandwidth is equivalent to the variance of the kernel (Connor et al., 2012).

In volcanic hazard applications, the choice of the optimal bandwidth is difficult and will depend on the field size and degree of cluster and will determine the probability distribution at distance from volcanic structures or eruptive vents.

QVAST provides a number of different methods for estimating optimal bandwidths: the Least Square Cross Validation, LSCV (Worton, 1995; Cappello et al., 2012) for the volcanic structures with linear geometries (e.g. dykes, eruptive fissures, faults) and three further methods for non-linear eruptive vents, LSCV, the \hat{h} score (Silverman, 1986) and the SAMSE selector H (Connor et al., 2012).

The value assigned to the bandwidth parameter in a kernel function has a substantial effect on results. When choosing small values for the bandwidth, the kernel function gives high probability estimates in the vicinity of existing volcanic structures. Conversely, when high values are assigned, probability estimates are distributed in a more homogeneous way throughout all of the studied area.

2.1 Least Square Cross Validation (Cappello et al., 2012)

Least Square Cross Validation (LSCV) is a procedure that uses an iterative approach to determine the optimal bandwidth for fixed kernel functions. Initially proposed by Rudemo (1982) and Bowman (1984), the LSCV uses the minimization of the integrated square error between the estimated distribution and the true distribution.

In our QGIS plugin, we used the version proposed by Worton (1995), defined as:

$$\text{LSCV}_h = \frac{1}{\pi h^2 n} + \frac{1}{4\pi h^2 n^2} \times \sum_{i=1}^n \sum_{j=1}^n \left(\exp \left[\frac{-d_{ij}^2}{4h^2} \right] - 4 \exp \left[\frac{-d_{ij}^2}{2h^2} \right] \right) \quad (1)$$

5 where h is the smoothing factor, n is the total number of historical data and d_{ij} is the Euclidean distance between the i th and the j th points, when dealing with eruptive vents.

Conversely, if historical data consists of broken lines containing a number of linear segments, QVAST uses a modified version of LSCV (Cappello et al., 2012; Becerril et al., 2013; Cappello et al., 2013), where d_{ij} is the “minimax distance”, i.e. the minimum
10 value of the maximum distances between each end points of the i th volcanic structure and all the end points of the j th volcanic structure.

2.2 The h_{opt} score (Silverman, 1986)

The Silverman method determines the optimal bandwidth h based on the assumption that the location of the vent opening is a random variable. The generalization of the
15 Silverman’s rule-of-thumb (Silverman, 1986) in the multivariate case is as follows (also known as Scott’s rule; Scott, 1992; Härdle et al., 2004):

$$\hat{h} = n^{1/(d+4)} \hat{\sigma} \quad (2)$$

in the bivariate case $d = 2$, n is the length of the samples (x and y are the Cartesian coordinates), and $\hat{\sigma}$ is the standard deviation. Thus, we obtain:

$$\hat{h} = n^{1/6} \sqrt{\frac{\sigma_x^2 + \sigma_y^2}{2}} \quad (3)$$

where σ_x and σ_y are the standard deviations of the x and y coordinates, respectively.

Interactive Discussion

2.3 The SAMSE selector (Connor et al., 2012)

The SAMSE pilot bandwidth selector is a modified asymptotic mean integrated squared error (AMISE) method developed by Duong and Hazelton (2003) to evaluate the optimal bandwidth in kernel density estimation.

5 Despite their mathematical complexity, SAMSE bivariate bandwidth selectors can help find optimal bandwidths using actual data locations and so remove subjectivity from the process (Connor et al., 2012). In Duong and Hazelton (2003), the bivariate kernel density is defined by:

$$\hat{f}(\mathbf{x}; \mathbf{H}) = n^{-1} \sum_{i=1}^n K_{\mathbf{H}}(\mathbf{x} - \mathbf{x}_i) \quad (4)$$

where n is the sample size, $\mathbf{x} = (x_1, x_2)^T$, $\mathbf{X}_i = (X_{i1}, X_{i2})^T$, for $i = 1, 2, \dots, n$, and K is the bivariate kernel that depends on \mathbf{H} , the bandwidth matrix that is symmetric and positive-definite. To measure the performance of \hat{f} , a SAMSE (Sum of Asymptotic Mean Squared Error) pilot selector is used, which is simpler and more parsimonious than the AMISE selectors.

15 The SAMSE selector is freely available within the “ks” Package of the R Project for
Statistical Computing (Duong, 2007; Hornik, 2009) and can be expressed as follows:

$$H = Hpi(x, nstage, pilot='samse', pre='sphere') \quad (5)$$

where x is a vector or matrix of data (vents), $nstage$ is the number of stages in the plugin bandwidth selector, $pilot$ indicates the pilot estimation, and pre concerns the pre-transformations.

The spatial density estimates are based on the distribution of past events within a volcanic field and the time period under consideration, and can be used as the basis for estimating the probability of the opening of new vents within a region. Connor et al. (2012) defines an event as the opening of a new vent at a new location during a new episode of volcanic activity.

The optimal bandwidth matrix obtained using Eq. (5) represents smoothing in E–W and N–S directions, the upper left and lower right diagonal elements, respectively.

3 Kernel density estimation

Kernel density estimation is a well-known, non-parametric approach to the estimation of probability density functions using a finite number of samples. The shape of kernel function – be it Cauchy kernel (Martin et al., 2004), Epanechnikov kernel (Lutz and Gutmann, 1995) or Gaussian kernel (Connor and Hill, 1995) – is important in probability calculations, even if it is less relevant than for other parameters (Connor and Hill, 1995; Lutz and Gutmann, 1995).

In the general case, if X_i denote samples of size n , then the kernel density estimate of λ in the point x is given by:

$$\lambda(x) = \frac{1}{n} \sum_{i=1}^n K_h(x, X_i) \quad (6)$$

where K_h is a kernel function with bandwidth h , satisfying the condition that $\int K_h(x, \cdot) dx = 1$ to ensure that $\lambda(x)$ is a density. In the Gaussian formulation,

$$\lambda(x) = \frac{1}{2\pi nh^2} \sum_{i=1}^n \exp\left(-\frac{d_i^2}{2h^2}\right). \quad (7)$$

4 Interface and tools of QVAST

Available open-source desktop GIS have notable differences in quality and performance (Sherman, 2008; Chen et al., 2010). Quantum GIS (QGIS) is a free, open-source software (available at www.qgis.org) that can be run on a number of operating

systems. It includes all of the common GIS functions and features and possesses an intuitive and user-friendly environment. One of the great advantages of QGIS is the availability of plugins from official and third-party repositories that provide a large number of additional functions. These features suggest that QGIS is the most appropriate software for our plugin.

QVAST was developed in Python script, an interpreted, general-purpose, high-level programming language, whose codes can be packaged into standalone executable programs (using sub-process calls to R and C++ codes). A graphical user interface (GUI) was created to provide users with a dynamic graphical window in QGIS.

QVAST includes different methods for choosing the optimal value for the bandwidth, which will depend on the size of the volcanic field and the degree of clustering in the available data. The PDF is constructed using a kernel density estimator, which is a function centered at each data sample location that exerts an influence on the surrounding region (Diggle, 1985). It is employed to estimate how the density of new vent openings varies across a study area in accordance with the distribution of past eruptions and the bandwidth. Different types of kernels can be used to describe the spatial density, e.g. the Cauchy (Martin et al., 2004), Epanechnikov (Lutz and Gutmann, 1995), Gaussian (Connor and Hill, 1995), or elliptical (Kiyosugi et al., 2010) kernels. Here we use the Gaussian kernel, which responds well to the clustering phenomena commonly observed in volcanic distributions (Weller et al., 2006).

Long-term spatial susceptibility is obtained through a non-homogeneous Poisson process (NHPP), where the PDFs and their relative weights are combined through a weighted sum. QVAST allows users to assign different weights to each of the PDFs depending on the relevance and reliability of datasets. Once the user has installed the plugin in the QGIS plugins folder, a new option called “Volcano” appears in the QGIS menu bar where the QVAST model is installed.

The QVAST structure consists of three main modules (Fig. 2):

1. estimation of the optimal bandwidth starting from different geometric layers (points and polylines);

Printer-friendly Version

Interactive Discussion

2. evaluation of the Gaussian kernel and generation of the PDF in the volcanic area under study;
3. calculation of the susceptibility map from one or more PDFs. In this latter case, QVAST allows users to assign different weights to each layer.

5 The first window that appears after launching the plugin is the evaluation of the bandwidth. A dropdown menu contains the shapefile layers added in the “Layers” menu in the QGIS project. To estimate the optimal bandwidth in case of a group of sample points (e.g. eruptive vents), QVAST offers three different methods: LSCV, the \hat{h} score and the SAMSE selector H . If the GIS layer consists of linear volcanic structures (e.g. dykes, eruptive fissures, or faults), only the LSVC score can be used. Otherwise, the plugin
10 allows the user to introduce the optimal value for the bandwidth by hand (if known) and continue directly to the construction of the PDF.

Once the layer and the method for evaluating the bandwidth have been selected, the value of the smoothing parameter is calculated using the “CALCULATE BANDWIDTH”
15 button.

The second window enables the PDF with the Gaussian Kernel to be evaluated using the calculated optimal bandwidth. To evaluate the Gaussian kernel on the selected layer, QVAST needs the following input parameters: the surface area on which the calculation (raster layer) is to be performed, the grid resolution (that should be clearly
20 smaller than the size of the volcanic area under study), the bandwidth value, the output name, and the output path where the results are to be saved. The surface area can be less than the entire Digital Elevation Model (DEM) if the user is only interested in a particular area. The result of the Gaussian kernel is a PDF in GeoTIFF raster format, which is automatically added as a new layer to the active QGIS project. The
25 results shows the distribution of the PDF in the volcanic area related to the input layer selected.

The third window enables users to simultaneously consider different layers to which they can assign different weights and thus calculate the final susceptibility map. Once

Interactive Discussion

the grid size and the weight for each PDF have been defined, QVAST calculates the weighted sum and evaluates the final raster map that represents the spatial susceptibility. The map is presented in a GeoTIFF raster format and is added to the layer.

Hence, the steps needed to obtain the final susceptibility can be summarized as follows (Fig. 1):

1. gathering of all volcano-structural data available;
2. optimal bandwidth selection using different methods;
3. application of the Gaussian Kernel to obtain the PDF;
4. assignment of a relative weight to each PDF;
5. creation of the susceptibility map with a NHPP.

The functionality and flexibility provided by QVAST have been demonstrated in the Lanzarote volcanic area and La Garrotxa volcanic field. Different methods were used to identify the optimal bandwidth and different results were obtained when different weights to the PDFs were assigned.

5 Applying QVAST: Lanzarote (Canary Islands, Spain) and La Garrotxa (NE Spain)

5.1 Lanzarote: geological context

Lanzarote lies in the northeast of the Canary Islands archipelago (Fig. 3). It forms the emergent part of the so-called East Canary Ridge (ECR), a NNE–SSW linear volcanic structure located on atypical oceanic crust, at least 11 km thick (Banda et al., 1981), lying between the continental rise and the Canary basin.

The geological evolution of Lanzarote involves two main stages, the first pre-erosional during the Miocene-Pliocene and the second – divided into two periods of volcanic activity – post-erosional during the Quaternary (Marinoni and Pasquaré, 1992).

Interactive Discussion

Sub-aerial volcanic activity has been almost continuous during the past 20 Myr and reveals that these islands are part of a sector of the lithosphere in which the thermal and dynamic anomalies that lead to the production and ascent of alkaline basaltic magmas have persisted for an exceptionally long period (Coello et al., 1992; Blanco-Montenegro et al., 2005).

In historical time eruptions on Lanzarote took place during the eighteenth and nineteenth centuries. The eruption between 1730 and 1736 was one of the Earth's biggest ever historical eruptions. A large number of volcanic cones were formed along an around 15 km long fissure. During the eruption 3–5 km³ of lava were emitted, covering an area of approximately 200 km² (Carracedo et al., 1992; Felpeto et al., 2001).

The structural evolution results from a complex interaction between the magmatism and both the regional stress field and the local stress field generated during the growth of the island itself. Hence, the present structural architecture is the result of a complex magmatic and tectonic evolution characterized by variations in the stress field that have been at work from the Miocene to the present day (Camacho et al., 1991).

5.2 La Garrotxa: geological context

The Catalan Volcanic Zone (CVZ) (NE Iberian Peninsula) is one of the alkaline Quaternary volcanic provinces that form part of the European rift system (Fig. 4). The age of its volcanism has not yet been fully defined. Available data indicate that volcanic activity started over 12 Ma ago and continued up to the beginning of the Holocene. Despite being significant in both extension and volume, this volcanism – whose eruptions continued up to the Holocene – is poorly known in comparison to the contemporaneous alkaline volcanism in other parts of Western and Central Europe. Volcanism in the CVZ lies predominantly in a NW–SE direction corresponding to the graben system present in the area. Various vents in the area can be aligned in the same NW–SE direction in parallel to the local fault systems. The volcanism younger than 0.5 Ma is mostly concentrated in an area of about 100 km² located between the cities of Olot and Girona. This basaltic volcanic field exhibits scoria cones, lava flows, tuff rings, and maars. Magmatic

Interactive Discussion

eruptions range from Hawaiian to violent Strombolian. Phreatomagmatism is also common and has contributed to the construction of more than half of the region's volcanic edifices. It is frequently associated with Strombolian activity but has also acted independently, thereby giving rise to a large variety of different types of eruptive sequences (Martí et al., 2011).

5.3 Datasets and bandwidth estimation

A Digital Elevation Model (DEM) created by the Instituto Geológico Nacional (IGN) for Lanzarote and by the Institut Cartogràfic de Catalunya (ICC) for La Garrotxa with a cell size of 25 × 25 m was used in these analyses. Volcano-structural data for Lanzarote were retrieved by the Instituto Geológico y Minero de España (IGME, 1988) and for La Garrotxa by the Institut Geològic de Catalunya (IGC, 2007).

Volcanic susceptibility was estimated by studying separately all structural data in order to identify different datasets that could be used for the probabilistic analysis. Using the available literature and geological maps we were able to identify vent locations, vent alignments, and dykes.

5.3.1 Application to Lanzarote

Volcanic structures on Lanzarote are shown in Fig. 5. Specifically, we considered 256 dykes and two layers of vent alignments containing 75 older vent alignments and 30 more recent vent alignments, formed during Holocene. Since both dykes and vent alignments can be represented as polyline shapefiles, QVAST used the LSCV method to calculate the optimal values for the bandwidth, which were found to be:

- 351 m for dykes;
- 3000 m for the oldest vent alignments;
- 2304 m for the most recent vent alignments.

As well, we identified a total of 187 emission centers (quaternary pyroclastic cones and eruptive vents), most of which are distributed in the central part of the island in a NE–SW direction (Marinoni and Pasquaré, 1992).

The evaluation of the bandwidth for the vent locations was performed using the three methods available in QVAST and the following results were obtained: (i) 333 m with the LSCV method; (ii) 3844 m with Silverman’s method; and (iii) 3934 m with the SAMSE selector.

The PDFs for each layer evaluated using the Gaussian kernel and a 500 m spaced grid are shown for dykes in Fig. 7, for vents alignments in Fig. 8, and for emission centers in Fig. 9.

Given that the PDF generated using the bandwidth obtained with the LSCV seems to provide the best reflection of the current clustering of the emission centers observed, we decided to use this method for the final susceptibility map.

5.3.2 Application to La Garrotxa

Volcanic structures in La Garrotxa are shown in Fig. 6. Specifically, we considered vent alignments and emission centers.

Given that the vent alignments can be represented as polyline shapefiles, QVAST used the LSCV method to calculate the optimal value for the bandwidth, which was found to be 4012 m.

In addition, we identified a total of 45 emission centers aligned in a NW–SE sense parallel to the fault systems (Martí et al., 2011).

As on Lanzarote, the evaluation of the bandwidth for the vent locations was performed using the three methods available in QVAST, which gave the following results: (i) 2002 m with the LSCV method; (ii) 1774 m with Silverman’s method; and (iii) 1567 m with the SAMSE selector.

The PDFs for each layer evaluated using the Gaussian kernel and a 500 m spaced grid are shown for vents alignments in Fig. 10 and for emission centers in Fig. 11.

Interactive Discussion

The PDFs obtained for the vent locations using different bandwidth values generate similar local intensity results. Taking into account isolated vents, we decided to use Silverman's method for the final susceptibility map since it seems to provide the best reflection of the degree of clustering currently observed.

5.4 Susceptibility map

The spatial probability of future vent openings is obtained by applying a NHPP to each potential vent (x, y) as follows:

$$\text{susc}(x, y) = 1 - \exp(-\Lambda(x, y)\Delta x\Delta y) \tag{8}$$

where $\Delta x\Delta y$ is the size of the grid cell (500 m \times 500 m) and $\Lambda(x, y)$ is the weighted sum of the four PDFs and their relative weights.

QVAST provides the opportunities for assigning the weights that reflect the importance and reliability of each input dataset. The user might not assign any specific individual weight and defines the same constant value for all PDFs in the computation of the final probability map. Alternatively, weights are assigned using expert judgment on the basis of structural criteria (Aspinall, 2006; Neri et al., 2008; Martí and Felpeto, 2010), which provides initial indicative probability distributions to be associated with each PDF.

In this case study, we demonstrated the flexibility of QVAST by generating two different susceptibility maps.

In the first map, the same weight (e.g. 0.25) was assigned to each PDF under the assumption that the probability of all future vent openings is influenced equally by all volcano-structural data.

In the second case, we assigned to each of the PDFs the following weights for Lanzaote:

- 0.05 for dykes;
- 0.15 for the oldest vent alignments;

- 0.3 for the most recent vent alignments;
- 0.5 for the emission centers;

and for La Garrotxa, the following weights:

- 0.3 for the vent alignments;
- 0.7 for the emission centers.

On Lanzarote, the highest weight (0.5) was assigned to the emission centers in the center of the island, where eruptions have occurred in historical times. This means that new eruptions are given the greatest likelihood of occurring close to the most recent eruptions. Decreasing importance was awarded to the most recent vent alignments, the oldest vent, alignments and dykes. Obviously, the total sum of weights is equal to 1. In La Garrotxa, the highest weight (0.7) was assigned to the emission centers.

The two final susceptibility maps for Lanzarote are shown in Fig. 12 and for La Garrotxa are shown in Fig. 13.

As is obvious, on Lanzarote the susceptibility obtained using the same weight for all PDFs (Fig. 12a) provides a very homogeneous probability distribution, with the highest values corresponding to exposed dykes. This is disputable, since these dykes are volcanic structures that are clustered as a wide swarm chiefly at the headwalls of the main landslide and have probably been buried by recent volcanic products in other areas. Hence it is not clear whether they have acted as feeders or not (Becerril et al., 2013).

Conversely, the susceptibility map obtained using different weights (Fig. 12b) would appear to be more accurate and reliable, and reflects coherently the recent distribution of alignments located in the central part of the island in a NE–SW sense.

If we change the assigned weights, results differ for Lanzarote but not for La Garrotxa. In fact, in this latter volcanic field, the susceptibility maps obtained using the same (Fig. 13a) and different weights (Fig. 13b) for the PDFs are both valid. The choice of the final technique for constructing hazard maps depends on the reliability of the method used to assign the weights.

Interactive Discussion

6 Conclusions

The elaboration of a susceptibility map based on the quantification of objective geological and geophysical data is the first and most important step in the quantitative assessment of volcanic hazard and risk. Here we present QVAST, the new tool for calculating volcanic susceptibility that works under QGIS, a free and user-friendly GIS environment.

QVAST is built to evaluate volcanic susceptibility, that is, the spatial probability of the appearance of a future vent opening, based on the activity of the volcanic area under study. The main steps involved are: (i) calculation of the bandwidth using different methods; (ii) evaluation of the PDF using a Gaussian kernel; (iii) assignment of the weights to each PDF; (iv) evaluation of the susceptibility map using a NHPP.

The comparison of different volcanic fields shows the importance of the choice of the bandwidth parameters. The strength of QVAST lies in the possibility of choosing different methods for evaluating the bandwidth parameter and for obtaining the final susceptibility map. The volcanic fields of Lanzarote and La Garrotxa are excellent case studies for learning to use this interface and for comparing the different results generated using different bandwidths for the kernel; this thus allows an optimal bandwidth for the volcanic field to be chosen.

QVAST is part of a larger project consisting of several modules (implemented in QGIS) that will interact and analyze the current situation of volcano fields as part of the task of generating hazard maps.

In the cases of Lanzarote and La Garrotxa, although data availability is somewhat restricted, the preliminary results obtained are good enough to be used as a starting point for generating eruptive scenarios that can aid local territorial planning and risk-mitigation programs. Thus, we propose that this tool should be used as a common way for determining the susceptibility of future volcanic eruptions in active regions and as a necessary tool in the reduction of volcanic risks.

Interactive Discussion

Future work will include the spatio-temporal analysis of future vent openings and the construction of volcanic hazard maps, all of which will be of great help to the governmental bodies in charge of territorial planning and the development of mitigation plans.
