## Abstract

Volcanic fallout deposits from the June 2011 Cordón Caulle eruption in Central Patagonia were remobilized in several occasions months after their emplacement. In particular, during 14–18 October 2011, an intense outbreak episode generated huge volcanic clouds that were dispersed across Argentina, causing multiple impacts in the environment, affecting the air quality and disrupting airports. Fine ash particles in volcanic fallout deposits can be resuspended under favourable meteorological conditions, particularly during strong wind episodes in arid environments having low soil moisture and poor vegetation coverage. In opposition to eruption-formed ash clouds, modeling of resuspension-formed ash clouds has received little attention. In consequence, there are no emission schemes specially developed and calibrated for volcanic ash, and no operational product exists to model and forecast the formation and dispersal of resuspension ash clouds. Here we implement three dust emission schemes of increasing complexity in the FALL3D tephra dispersal model and use the 14–18 October 2011 outbreak episode as a model test case. We calibrate the emission schemes and validate the results of the coupled WRF-ARW/FALL3D modeling system using satellite imagery and measurements of visibility (a quantity related to total suspended particle concentration at surface) and particulate matter ( $PM_{10}$ ) concentration at several meteorological and air quality stations sparse across Argentina and Uruguay. Our final goal is to test the capability of the modeling system to become, in the near future, an operational forecast product for volcanic ash resuspension events.

## 1 Introduction

Resuspension and dispersal of volcanic ash by wind is of concern to human health and environment. Micron-size ash particles suspended at low atmospheric levels deteriorate the quality of air and cause severe impacts on local population and animals, causing irritation of mucosae, chronic respiratory symptoms resulting from inhalation of

Interactive Discussion

ash, and dispersion of toxic chemicals (e.g. Baxter, 1999). Other hazards include affection to ground transportation systems and disruption of airports (e.g. Guffanti et al., 2009). All these impacts can occur far away from the original deposit region because, like dust clouds, resuspended ash clouds can be dispersed at large distances. The lift of ash and subsequent formation of clouds is enhanced under particular meteorological (strong winds and surface friction velocities) and ambient (low soil moisture, no vegetation) conditions, and can occur in both fresh and relic ash fallout deposits. For example, a combination adequate meteorological conditions during 20–21 September 2003 originated continuous resuspension of relic volcanic ash from the Katmai volcano and formation of ash clouds that were transported up to 230 km into the Gulf of Alaska, affecting operations at Kodiak airport (Hadley et al., 2004). Other examples include resuspension of ash from fresh deposits of Mount St. Helens in US (Hobbs et al., 1983), Soufriere Hills in Montserrat (Hincks et al., 2006), Mount Hudson in Southern Patagonia (Wilson et al., 2011), Eyjafjallajökull in Iceland (Thorsteinsson et al., 2012; Leadbetter et al., 2012), or Cordón Caulle in Central Patagonia, which is addressed in this paper.

Modeling of atmospheric dispersal and sedimentation of ash clouds from volcanic eruptions has been an active topic of research during the last two decades, and very specially in the aftermath of the major civil aviation outbreaks following the 2010 Eyjafjallajökull and the 2011 Cordón Caulle eruptions. Several Tephra Transport and Dispersal Models (TTDM) (e.g. Folch, 2012) run operationally at the Volcanic Ash Advisory Centers (VAACs) and other institutions for forecasting purposes, and the underlying modeling strategies are being substantially reviewed and improved (Bonadonna et al., 2011). In contrast, modeling of resuspended ash clouds has received little attention. This is surprising because, even if potentially less hazardous, resuspension-formed clouds can also trigger substantial impacts (see Sect. 4). In fact, modeling of resuspended ash has been recognized as a research priority during a recent joint WMO-VAAC modeling workshop (NOAA, Washington DC, 5–9 November 2012). At present, no TTDM is used operationally to forecast ash resuspension events. Regarding mod-

Interactive Discussion

eling of resuspended ash clouds, the examples in literature are very scarce. Barsotti et al. (2010) proposed a simple fit based on data from Hincks et al. (2006) to estimate resuspended  $\text{PM}_{10}$  surface concentrations at various populated locations around Etna volcano. More recently, Leadbetter et al. (2012) modelled resuspension events from the 2010 Eyjafjallajökull deposits using the UK Met Office Lagrangian dispersion model NAME-III. Given the similarities between volcanic ash and mineral dust, Leadbetter et al. (2012) considered a simple dust emission scheme to compute the mass flux of resuspended ash depending on the wind friction velocity.

The objective of this paper is to test different dust emission schemes of increasing complexity for implementation in volcanic ash transport models. To this purpose, we implement three different schemes in the FALL3D model (Costa et al., 2006; Folch et al., 2009) and consider the Cordón Caulle 14–18 October 2011 outbreak episode as a test case. We use a meteorological station located at Buenos Aires (1380 km from the volcano) to calibrate the emission of ash. This is necessary because uncertainties exist regarding the source strength for different reasons, including that the emission schemes have been originally developed for mineral dust rather than for volcanic ash, or poor constraints on the properties and grain size distribution of ash particles in the deposit. Once calibrated, we compare the model results with satellite retrievals and particulate matter surface concentrations inferred from observations at different meteorological and air quality stations across Argentina. The final goal is to test the modeling strategy before its implementation as an operational forecast product at the Argentinean National Meteorological Service (SMN) and Buenos Aires VAAC.

## 2 Previous considerations on modeling volcanic ash resuspension

Modeling of volcanic ash resuspension requires the implementation of emission schemes in TTDMs. Emission schemes give the mass flux of resuspended (ash) particles depending on meteorological conditions, soil moisture, terrain roughness, and characteristics of the fallout deposit (size and density of particles, grain-size distribu-

tion, deposit thickness). Typically, soil moisture is obtained from the Numerical Weather Prediction (NWP) model driving the TTDM (WRF-ARW in our case). This can introduce a considerable uncertainty because NWP models do not include updated information about recent fallout deposits, which can alter substantially moisture and roughness of the original soil. On the other hand, fallout deposits are heterogeneous, introducing a second source of uncertainty regarding granulometric properties. Heterogeneities in grain-size distribution and particle properties exist because the variation of settling velocity with particle size and density (causing strong granulometric variations along the dispersal axis), occurrence of different eruptive phases (e.g. variable eruption rates, column heights, degree of magma fragmentation, etc.), or transport under unsteady heterogeneous wind fields. Moreover, even if a fallout deposit is well characterized through dedicated field studies information is rarely available in a regular grid, but rather across transects or along the most accessible parts of the deposit (e.g. along roads). It follows that, from a modeling perspective and in practical terms, an option to obtain the granulometric characteristics at all deposit grid points is to run a preliminary simulation for the fallout using the total grain size distribution, typically reconstructed from field data.

### 3 Dust emission schemes

Saltation impact represents the most effective mechanism for resuspension of smaller-size particles in soils (Shao et al., 1993). When the intensity of wind blowing across a granular soil exceeds a certain threshold, grain particles begin to saltate. Experiments with sand-sized particles show that the impact of saltating mid-size grains (larger than about 50  $\mu\text{m}$ ) when falling back to ground breaks the cohesive forces of smaller particles enhancing their suspension. For this reason, the emission rate (vertical flux of particles), defined as the mass emitted per unit of area and time, strongly depends on the horizontal (saltation) flux of larger particles. In recent years, various emission schemes for mineral dust have been proposed and implemented in atmospheric trans-

port models to simulate long-range transport and deposition of mineral dust. This section summarizes different dust emission schemes that we will test for volcanic ash. We follow an approach similar to that of Darменова et al. (2009) and Kang et al. (2012), who tested different dust emission schemes in the WRF and WRF/Chem models respectively.

### 3.1 Threshold friction velocity

The threshold friction velocity, defined as the wind friction velocity at which soil erosion initiates, depends on properties of soil particles and on surface conditions such as soil moisture and roughness. Soil moisture reinforces soil particle cohesion and therefore inhibits erosion and resuspension. The presence of rough elements at ground (e.g. non erodible rocks, vegetation, etc.) also decreases the emission rate of particles because the elements act as wind shelters and absorb part of the momentum of wind. A precise quantification of the friction velocity is challenging and requires of data on soil properties and meteorological conditions which are often unavailable on a local scale.

Simplest dust emission schemes assume a constant threshold friction velocity over the region of interest regardless of the particle size. For example, Leadbetter et al. (2012) modelled the resuspension of ash after the 2010 Eyjafjallajökull eruption in Iceland assuming a threshold friction velocity of  $0.4 \text{ ms}^{-1}$  for all particle diameters in the range  $1\text{--}10 \mu\text{m}$  combined with a precipitation rate cut-off of  $0.01 \text{ mm h}^{-1}$  (the cut-off accounts for a critical soil moisture above which the emission of particles is assumed to be inhibited). However, the constant friction velocity approach can be inadequate over large areas because particle properties and soil characteristics are likely to vary substantially in space. For example, in the particular case of volcanic deposits, a decrease in the mean particle size is expected as the distance to the volcano increases. In order to account for heterogeneous particle and soil characteristics, the threshold friction velocity  $u_{*t}$  can be expressed at each point as (Shao, 2001):

$$u_{*t}(d, w, \lambda) = u_{*ts}(d)f_w(w)f_\lambda(\lambda) \quad (1)$$

Interactive Discussion

where  $u_{*ts}(d)$  is the threshold friction velocity on a bare dry surface for particles of size  $d$  (for irregular particles  $d$  is assumed to be the equivalent particle diameter), and  $f_w(w)$  and  $f_\lambda(\lambda)$  are correction functions for soil moisture  $w$  and surface roughness  $\lambda$  respectively ( $f_w(w) \geq 1$  and  $f_\lambda(\lambda) \geq 1$ ). A number of experimental and theoretical studies have determined parameterizations for threshold friction velocities on bare dry surfaces. Marticorena and Bergametti (1995) fitted experimental data obtained in wind tunnels involving various particle densities (from 210 to 1135 kg m<sup>-3</sup>) and diameters (from 12 to 1290 μm) (Iversen and White, 1982) and derived the following expression for  $u_{*ts}$  depending on particle size and density:

$$u_{*ts} = \begin{cases} \frac{0.129K}{(1.928Re^{0.092}-1)^{0.5}} & 0.03 < Re \leq 10 \\ 0.129K(1 - 0.0858e^{-0.0617(Re-10)}) & Re > 10 \end{cases} \quad (2)$$

with  $K = \sqrt{\frac{\rho_p g d}{\rho_a} \left(1 + \frac{0.006}{\rho_p g d^{2.5}}\right)}$  and  $Re = 1331 \times d^{1.56}$  (the lower bound of the fit corresponds to particles of  $\approx 10 \mu\text{m}$  in size). In the expressions above,  $\rho_p$  and  $\rho_a$  are particle and air densities (expressed in g cm<sup>-3</sup>),  $g$  is gravity (in cm s<sup>-2</sup>),  $d$  is the particle size (in cm),  $Re$  is the Reynolds number parameterized as a function of the particle size, and  $u_{*ts}$  is given in cm s<sup>-1</sup>. In turn, Shao and Lu (2000) derived an expression for  $u_{*ts}$  considering spherical particles with a cohesion force proportional to particle size:

$$u_{*ts} = \sqrt{0.0123 \left( \frac{\rho_p g d}{\rho_a} + \frac{\gamma}{\rho_a d} \right)} \quad (3)$$

where  $\gamma$  is a parameter ranging between  $1.65 \times 10^{-4}$  and  $5 \times 10^{-4}$  kg s<sup>-2</sup> (a value of  $3 \times 10^{-4}$  kg s<sup>-2</sup> is assumed here).

Using experimental data from literature, Fecan et al. (1999) parameterized the increase in the threshold friction velocity due to soil moisture in arid and semi-arid re-

gions and derived the following expression:

$$f_w(w) = \begin{cases} 1 & w_g \leq w' \text{ (dry soil)} \\ \sqrt{1 + 1.21(w_g - w')^{0.68}} & w_g > w' \text{ (wet soil)} \end{cases} \quad (4)$$

where  $w'$  is the maximum amount of absorbed water (depending on soil texture) and  $w_g$  is the gravimetric soil moisture,  $w_g = w\rho_w/\rho_b$  with  $\rho_w$  and  $\rho_b$  being the water and soil bulk densities respectively, and  $w$  is the soil moisture in % (given by the NWP model). The value of  $w'$  ranges from 0 % for sand to  $\approx 30$  % for pure clay (Fecan et al., 1999). It is difficult to give a value of  $w'$  for volcanic fallout deposits because the amount of water absorbed strongly depends on porosity which, in turn, depends on variable factors controlling tephra formation (e.g. magma reology, degree of fragmentation, amount of volatiles in magma, etc). In this study we assume that  $w' = 10$  %. Figure 1 shows the dependency of the threshold friction velocity  $u_{*t}$  on particle size with and without soil moisture correction. Note that particles more easily suspended by saltation are in the range 30–200  $\mu\text{m}$ .

On the other hand, several parameterizations have been proposed for the so-called drag partition coefficient, the inverse of  $f_\lambda(\lambda)$  (e.g. Marticorena and Bergametti, 1995), depending on the roughness length over a smooth surface and the aeolian roughness length. However, it is very difficult to assess these parameters in the case of ash fallout deposits. An obvious difficulty is that the deposition of ash modifies the underlying surface (to an extent that depends on the thickness of deposit) affecting any information embedded in the land modules of NWP models (e.g. roughness length). For this reason the influence of terrain roughness on the threshold friction velocity will not be considered in this study.

### 3.2 Horizontal (saltation) flux

The horizontal flux of saltating particles, i.e. the stream-wise flux of saltating particles integrated along the vertical, measures the “intensity” of saltation, which strongly

Interactive Discussion

affects the emission rate of smaller-size particles. Following the theory of saltation and experimental results from Owen (1964), Shao et al. (1993) proposed the following parameterization:

$$F_H(d_s) = \begin{cases} 0 & u_* < u_{*t}(d_s) \\ c_o \frac{\rho_a u_*^3}{g} \left(1 - \frac{u_{*t}^2(d_s)}{u_*^2}\right) & u_* \geq u_{*t}(d_s) \end{cases} \quad (5)$$

- 5 where  $F_H$  is the horizontal (saltation) flux (units of  $\text{kg m}^{-1} \text{s}^{-1}$ ) of saltating particles of size  $d_s$ , and  $c_o$  is an empirical dimensionless constant close to 1. A similar expression was proposed by Marticorena and Bergametti (1995) and Marticorena et al. (1997a) after the seminal work of White (1979):

$$F_H(d_s) = \begin{cases} 0 & u_* < u_{*t}(d_s) \\ c_w \frac{\rho_a u_*^3}{g} \left(1 + \frac{u_{*t}(d_s)}{u_*}\right) \left(1 - \frac{u_{*t}^2(d_s)}{u_*^2}\right) & u_* \geq u_{*t}(d_s) \end{cases} \quad (6)$$

- 10 with  $c_w = 2.61$  according to the original wind tunnel experiments (White, 1979) and  $c_w \approx 1$  according to successive corrections (Marticorena et al., 1997a).

### 3.3 Vertical flux (emission rate)

Simplest dust emission parameterizations depend only on meteorological conditions (typically on a power of the friction velocity). For example, Westphal et al. (1987) measured the vertical flux of aerosol dust particles ( $< 10 \mu\text{m}$  radius) from sandy, loamy, and clay soils depending on the friction velocity and obtained the following least square fit:

$$F_V = \begin{cases} 0 & u_* < u_{*t} \\ 10^{-5} u_*^4 & u_* \geq u_{*t} \end{cases} \quad (7)$$

where  $F_V$  is the vertical flux (in  $\text{kg m}^{-2} \text{s}^{-1}$ ), occurring only above a (constant) threshold friction velocity of  $u_{*t} = 0.3 \text{ ms}^{-1}$  in the particular experiment of Westphal et al. (1987).

An important limitation of Eq. (7) is that the vertical flux does not depend on particle size or soil moisture. Although very simplistic, this parameterization can be useful when information on soil characteristics (e.g. particle sizes and densities, moisture, roughness, etc.) is poorly constrained or unavailable.

- 5 A slightly more sophisticated approach consists on modeling the emission rate as a function of the difference between the friction velocity and the threshold friction velocity. This embeds all the information on soil properties within the threshold friction velocity and allows to compute fluxes depending on particle size. For example, from the parametrization in Marticorena et al. (1997b):

$$10 F_V(d) = \begin{cases} 0 & u_* < u_{*t}(d) \\ \frac{K\rho_a u_*}{g} (u_*^2 - u_{*t}^2(d)) & u_* \geq u_{*t}(d) \end{cases} \quad (8)$$

where  $K$  is a soil texture coefficient equal to  $K = 5.4 \times 10^{-4} \text{m}^{-1}$  from the experiments of Gillette et al. (1997). This parameterization has been used, among others, by Draxler et al. (2001) to simulate  $\text{PM}_{10}$  concentrations from dust storms using the HYSPLIT model.

- 15 Finally, more sophisticated emission schemes consider particle-particle interaction by saltation bombardment and, in some cases, by aggregates disintegration (e.g. Shao, 2001). Shao et al. (1993) considered that the vertical flux (emission rate) of particles of size  $d$  caused by the saltation bombardment of particles of size  $d_s$  ( $d_s \geq d$ ) is proportional to the horizontal flux of saltating particles:

$$20 F_V(d, d_s) = \frac{\alpha(d, d_s)}{u_{*t}^2(d)} F_H(d_s) \quad (9)$$

where  $\alpha$  (units of  $\text{m s}^{-2}$ ) is a coefficient of blasting efficiency determined experimentally (Shao and Leslie, 1997; Shao, 2001):

$$\alpha(d, d_s) = (0.6 \log(d_s) + 1.6) \exp(-140d) \quad (10)$$

Interactive Discussion

with  $d$  and  $d_s$  expressed in mm. Given the particle grain size distribution  $p(d)$  at each point of the deposit and assuming a discretization in a series of bins ( $\sum p(d_{\text{bin}}) = 1$ ), the emission rate of particles of size  $d$  can be obtained by summing up the contribution from saltating particles of all sizes equal or larger than  $d$ :

$$F_V(d) = \sum_{d_s=d}^{d_s=d_{\max}} \frac{\alpha(d, d_s)}{u_{*t}^2(d)} p(d_s) F_H(d_s) \quad (11)$$

where  $d_{\max}$  is the maximum considered size (typically few hundreds of  $\mu\text{m}$ ). Note that, when  $u_* \gg u_{*t}$ , the vertical flux  $F_V(d)$  becomes proportional to  $u_*^3$  in both parameterizations (Eqs. 8 and 11) (with  $F_H$  given by either Eqs. 5 or 6).

### 3.4 Tested emission schemes

In this study we test three different emission schemes (of increasing sophistication) for the case of volcanic ash:

- Emission scheme 1, hereafter referred as the WE scheme. Consists on computing the emission rate using Eq. (7) and a threshold friction velocity  $u_{*t}$  independent of particle size (Westphal et al., 1987).
- Emission scheme 2, hereafter referred as the MB scheme. Consists on computing the emission rate using Eq. (8) and the threshold friction velocity  $u_{*t}(d)$  using Eq. (2) (Marticorena and Bergametti, 1995; Marticorena et al., 1997a).
- Emission scheme 3, hereafter referred as the SH scheme. Consists on computing the emission rate using Eqs. (11) and (5) and the threshold friction velocity  $u_{*t}(d)$  using Eq. (3) (Shao et al., 1993; Shao and Leslie, 1997; Shao and Lu, 2000).

Given that these schemes have been developed theoretically and calibrated experimentally for mineral dust rather than for volcanic ash, we multiply the emission rates by a correction factor  $\phi$  that will be determined comparing model with observations, in our case from the Cordon Caulle 14–18 October 2011 outbreak episode.

## 4 The 14–18 October 2011 outbreak

The June 2011 eruption from Puyehue-Cordón Caulle Volcanic Complex (CCVC) in Chile blanketed with volcanic ash a vast area of the Argentinean Central Patagonia (Collini et al., 2013). Recurrent ash resuspension events occurred during the following months due to the strong ( $\approx 100 \text{ km h}^{-1}$ ) westerly and south-westerly winds that typically blow over Patagonia during the austral spring. The small villages sparse across the Patagonian steppe (e.g. Ing. Jacobacci in the Río Negro province, see Fig. 2) were highly affected by this phenomenon which hindered ordinary activities and forced inhabitants to remain indoors during the strongest wind episodes (Wilson et al., 2012).

By mid-October 2011, a particularly strong resuspension episode occurred during the passage of a south-western frontal system crossing northern Patagonia with surface wind speeds of  $65\text{--}85 \text{ km h}^{-1}$  and maximum gusts of about  $95 \text{ km h}^{-1}$ . As a result, a huge ash cloud reaching the 850 hPa atmospheric level (1.5 km elevation roughly) was formed and dispersed rapidly east-northeast across Argentina (G. O. Damiani, personal communication, 2011). Impacts occurred at a national level. Main routes in northern Patagonia (e.g. the famous Route 40 linking Bariloche city with the Neuquén province) were closed during 15–16 October due to very low visibility and after the occurrence of accidents. This disruption hardly harmed the transportation of persons and goods in the southern part of the country. During and after 15 October afternoon, the ash cloud reached the provinces of Río Negro, La Pampa, and west of Buenos Aires. On 16 October early morning, a dense ash cloud was clearly visible over the sky of Ciudad Autónoma de Buenos Aires (CABA), at nearly 1375 km from CCVC, and a perceptible ash layer was deposited at ground, blanketing the city. The air quality stations of the Government of CABA (GCBA) registered the ash cloud from its arrival and measured a daily-averaged  $\text{PM}_{10}$  level of  $252 \mu\text{g m}^{-3}$ . This largely exceeds the EPA NAAQS (National Ambient Air Quality Standard) as well as the national legislation standard (law 1356-GCBA) limit of  $150 \mu\text{g m}^{-3}$   $\text{PM}_{10}$  concentration for 24 h exposure. For the first time since the June 2011 CCVC eruption, the national authorities

issued warnings regarding transportation in the Buenos Aires province due to the low visibility owing to the presence of suspended ash at low atmospheric levels. Around midday, flights from Aeroparque Jorge Newbery and Ezeiza international airports were suspended, resulting in the cancellation of 146 flights only on Sunday 16th. The morning after, some scheduled flights began to depart after the cleaning of platforms and runaways but, nevertheless, the main commercial airlines did not resume their operations until Monday 17th afternoon. During this day, the ash cloud covered the south of Uruguay disrupting the Montevideo international airport (40 cancelled flights). Flight disruptions affected also the Argentinean airports of Córdoba, Mendoza and San Luis until 18 October afternoon because a branch of the ash cloud moved towards these inner provinces making the sky almost invisible.

## 5 Modeling strategy

We modelled the 14–18 October 2011 Cordón Caulle resuspension event using the FALL3D dispersal model (Costa et al., 2006; Folch et al., 2009) coupled off-line with the Weather Research and Forecasting (WRF-ARW) meteorological model (Skamarock et al., 2008). FALL3D uses 4-D meteorological fields furnished off-line and volcanological inputs to produce time-dependent variables like airborne ash concentration, ash cloud column load, or ground deposit thickness among others. The new version of the code (FALL3D-7.0) includes new capabilities to deal with a “continuum” of sources over a region, as opposed to a single point source or a set of vertical point sources typically considered for eruption columns. As already mentioned, our modeling strategy builds upon a preliminary eruption simulation run to characterize the deposit (extent, thickness and granulometry at each point) followed by the simulations of resuspension.

## 5.1 Deposit characterization

As a starting point, we ran the WRF-ARF/FALL3D modeling system for the period 4–20 June 2011, during which most deposition of tephra from Cordón Caulle eruption occurred. We considered a Gaussian Total Grain Size Distribution (TGSD) discretized in 10 bins ranging from  $-1\Phi$  (2 mm) to  $8\Phi$  ( $4\mu\text{m}$ ) and a linear dependency of particle density with diameter (end-member density values of 1000 and  $2200\text{ kg m}^{-3}$ ). Note that the largest particles can not be transported substantially by resuspension but, nonetheless, we considered them because play a key role in the SH emission scheme (see Eq. 11). FALL3D-7.0 can handle ash aggregation phenomena but not particle desegregation, which typically occurs when (fragile) aggregates break when grounding. For this reason, and because our primary interest is to model subsequent resuspension, particle aggregation was not considered for the deposit simulation. This introduces some uncertainty because the real amount of fine particles in the proximal (originally fallen as aggregates and then desaggregated) can be larger than that predicted by the model. Eruption column heights in the model oscillate daily from around 10 km down to less than 3 km by 20 June 2011 (Collini et al., 2013). Figure 3 shows the modelled deposit that we consider as the potential source area for resuspension. Note that, as observed in the field, the main deposition lobe is directed SE.

## 5.2 Meteorological driver and emission schemes

We used the modelled deposit to initialize the resuspension simulations using a WRF-ARW run from 14 to 18 October 2011 as the meteorological driver. This WRF-ARW run uses  $0.5^\circ$  Global Forecast System (GFS) analysis and forecasts supplied by the National Centers for Environmental Prediction (NCEP) of the National Oceanic and Atmospheric Administration (NOAA) as initial and boundary conditions. The WRF-ARW model was configured with an horizontal resolution of 12 km, 38 vertical levels, the Ferrier scheme for microphysics, the Rapid Radiative Transfer Model (RRTM) for long wave radiation, the Dudhia model for short wave radiation, the NOAA Land surface

model, the Betts–Miller–Janjic scheme for convection, and the Mellor–Yamada–Janjic for the Planetary Boundary Layer. The computational domain on the inner WRF-ARW nest spanned between  $21^{\circ}\text{S}$ – $48^{\circ}\text{S}$ ;  $30^{\circ}\text{W}$ – $90^{\circ}\text{W}$ . For illustrative purposes, Fig. 4 compares the WRF-ARW predicted wind velocities (first model layer, 10 m above ground) with measurements at three different stations located at Bariloche (M1, 108 km from CCVC), Neuquén (M2, 386 km from CCVC) and Buenos Aires (Aeroparque airport, M13, 1379 km from CCVC). Note how two different velocity peaks, responsible for two resuspension events, are clearly visible at M1 and M2. The predictions of WRF-ARW at station M13, far from the ash emission region, show also a good agreement with measurements except during 16 October afternoon, where differences of up to  $4\text{ m s}^{-1}$  exist. This discrepancy might be due to the Río de la Plata breeze effects not well solved by the NWP model.

Figure 5 shows the emission rate integrated over the deposit as predicted by the three emission schemes along the 14–18 October 2011 period. Two major resuspension events are evident, the first starting on 14 October at around 18:00 UTC and the second, more intense, starting 24 h later. Note from Fig. 5a how these events coincide with values of  $\langle u_{*} \rangle$  (spatially averaged  $u_{*}$ ) above  $0.4\text{ m s}^{-1}$  approximately. In the MB and SH schemes,  $u_{*t}$  results from emission model parameterizations, whereas in the WE scheme this quantity is an input to be defined (see Eq. 7). Based on this previous analysis we set  $u_{*ts} = 0.25$  for the WE scheme that, once corrected for moisture, results in values of  $u_{*t} \approx 0.4\text{ m s}^{-1}$ . This agrees well with the value of  $0.4\text{ m s}^{-1}$  used by Leadbetter et al. (2012) for Eyjafjallajökull in Iceland.

### 5.3 Ash transport modeling

For the resuspension runs, we set a FALL3D-7.0 domain spanning between  $30^{\circ}\text{S}$ – $46^{\circ}\text{S}$  and  $49^{\circ}\text{W}$ – $73^{\circ}\text{W}$  with an horizontal model resolution of  $0.1^{\circ}$  and 14 vertical levels ranging from 10 to 4000 m (model layers increase gradually in order to have better resolution within the atmospheric boundary layer, where the ash cloud was mostly confined). The ash emission schemes in FALL3D-7.0 assume that the ash is released

homogeneously along the vertical up to a certain height fixed by the user. Here we assume a maximum injection height of 250 m. Particle granulometry changes at each deposit grid point, as determined by interpolating results of the preliminary eruption simulation. For resuspension, we consider the same 10 particle bins but fixing the maximum particle size that can be resuspended to 250  $\mu\text{m}$ . This allows 7 particle classes to be resuspended and transported. Larger particles are kept because influence the emission rate in the SH scheme, but we assume that these can not travel significant distances. Finally, in order to perform the evaluation of the kinematic turbulent fluxes, the diagonal components of the eddy diffusivity tensor in FALL3D have been parametrized using the similarity theory option for the vertical component and the CMAQ model option for the horizontal diffusion (Byun and Schere, 2006).

## 5.4 Model calibration

Our first quantitative comparisons indicated that, in most cases, the simulations overestimated observed surface particle concentrations. There might be multiple reasons for this, including a poor characterization of the deposit, the non-consideration of the surface roughness in the computation of the threshold friction velocity, overestimation of the friction velocity by WRF-ARW, the inaccuracy of dust emission schemes when applied to volcanic ash, etc. In order to calibrate the emission rates we considered observations made at the M13 meteorological station (see Table 1), located in CABA. We determined the correction factor  $\phi$  for each emission scheme fitting simulation results to observations on this particular station. Results are shown in Fig. 6 and Table 2. Note that  $\phi > 1$  for the SH scheme and  $\phi < 1$  for WE and MB, meaning that the original SH formulation underestimated source strength whereas WE and MB overestimated. Although the factor  $\phi$  was specifically determined from measurements at CABA, the value found was consistent with observations in the rest of meteorological stations, except for those in the deposit region (see Sect. 6.2).

## 6 Results and model validation

### 6.1 Comparison with space-based measurements

In order to have a first qualitative verification of model results we used images from the Moderate Resolution Imaging Spectroradiometer (MODIS) sensor on board of AQUA/TERRA satellites using the Brightness Temperature Difference (BTD). The BTD algorithm, also known as the split window technique (Prata, 1989), computes the difference of brightness temperatures (derived from the inverse Planck's function) between the 10.7  $\mu\text{m}$  and 12  $\mu\text{m}$  frequency bands. Given the reverse absorption of volcanic ash particles (negative BTD), the technique allows discriminating between meteorological and volcanic ash clouds. The efficiency of detection increases when the ash cloud is not opaque, has low water/ice contents, and contains small particles (Prata et al., 2001). Additionally, we considered also Volcanic Ash Advisories (VAAs) issued by the Buenos Aires VAAC. These are text messages that identify the observed and forecasted positions of ash clouds (ICAO, 2011). In particular, we used Volcanic Ash Graphics (VAGs), a graphical depiction of the VAAs showing the edges of the polygons encompassing the ash cloud location. VAAs and VAGs from the Buenos Aires VAAC were based on observations from GOES-12 and NOAA-19 satellites (METAR and airline pilot reports were considered in some cases).

Figure 7 compares remote sensing observations and simulation results. The VAG polygons have been superimposed to the FALL3D predicted column mass at the appropriate times for both MB and SH schemes. Results for the WE emission scheme are very similar and are not shown. The model predicts well the formation and evolution of the cloud and show how the ash located in northern Patagonia is transported towards east and north-east reaching the coastal areas few hours after the passage of the frontal system. A large portion of central Argentina, Río de La Plata region and southern Uruguay are affected. Note from Fig. 7a how the emission of ash starts shortly after the simulation begins, as expected from our previous analysis (see Fig. 5). The larger area of the VAG polygon in Fig. 7a is explained by the occurrence of a previous

minor resuspension event, which was detected by the VAAC. This event was partially modelled because we considered a model spin-up of 6 h.

In general, we found a good qualitative agreement between model results and BT  
D images. The results of the different schemes are similar, although the SH scheme  
gives higher concentrations close to source region. It is interesting to note that, when  
the simulated cloud passes over the northeast of the Buenos Aires province (between  
16 October at 19:00 UTC and 17 October at 01:00 UTC), the cloud is shifted ahead  
of the observed polygon (see Fig. 7d and e). These differences in cloud arrival times  
can be explained if one considers that WRF-ARW over predicts wind velocities during  
this period (see Fig. 4c). Finally, it is worth noting that the little triangle observed in  
deposit region does not correspond to any resuspension phenomenon but reflects little  
eruptive events from CCVC remaining at that time.

## 6.2 Comparison with ground-based measurements

In this section we compare ground measurements of total suspended particulate matter  
concentration and PM<sub>10</sub> (denoted by  $C_{TSP}$  and  $C_{PM_{10}}$ , respectively) with the FALL3D  
values at the first model layer (10 m height). To this purpose, we decoded informa-  
tion of visibility, wind speed and direction, and present and past weather phenomena  
from the meteorological message SYNOP (surface synoptic observations) and METAR  
(Meteorological Aerodrome Report) issued by the stations of the Argentinean National  
Meteorological Service network and the National Direction of Meteorology of Uruguay  
(see Fig. 3 and Table 1). The SYNOP is a numerical code (called FM-12 by WMO) used  
for reporting weather observations made by manned and automated weather stations.  
We used the visibility observations to yield an estimation of the TSP (Total Suspended  
Particle) concentration using the following empirical relationship (Shao et al., 2003):

$$C_{TSP} = \begin{cases} 3802.29D^{-0.84} & D < 3.5 \text{ km} \\ \exp(-0.11D + 7.62) & D \geq 3.5 \text{ km} \end{cases} \quad (12)$$

where  $C_{\text{TSP}}$  is the TSP concentration (in  $\mu\text{g m}^{-3}$ ) and  $D$  is the visibility in km. Besides this data, we also considered measurements of respirable suspended particulate matter ( $\text{PM}_{10}$ ) from the EPA Air Quality Monitoring Stations Network (GCBA, 2013). This network consist of three stations located at the northeast (C1), downtown (C2), and southwest (C3) of CABA. The instruments installed at these stations are Thermo Model FH62 C14, which continuously measure the mass concentration of particulate utilizing a beta rays attenuation technique. The instruments meet US and International Particulate Monitoring Regulations and are US EPA certified to stick to the international air quality regulations. In the measurements, we subtracted a background value of  $32 \mu\text{g m}^{-3}$ , corresponding to the averaged anthropogenic contribution recorded in October 2010, in order to estimate to contribution owing to the presence of ash. Additionally, we tried also other sources of data like LIDAR from CEILAP at Villa Martelli, province of Buenos Aires, and raw and processed data from the AERONET network but, because of the presence of clouds, we did not have good-quality data during the considered period.

Figure 8 shows a comparison between simulated  $C_{\text{TSP}}$  using the three different schemes and observations at 15 different stations. As observed from the figure, best quantitative agreement is obtained for stations registering the cloud arrival on 16 October (e.g. M4, M6 or M7). In contrast, for far-field stations (e.g. M10 or M17) where the plume arrived on 17 October, the model predicts correctly the arrival time but underestimates the observed values by a factor of 3–5. Conversely, in the stations close to the emission points (e.g. M1 at Bariloche or M2 at Neuquén, not shown) all the emission schemes overestimate substantially.

In order to evaluate if the cloud arrival times were correctly predicted by the model, we defined a characteristic event time as the time when  $C_{\text{TSP}}$  reaches half of its maximum value. The comparison between simulated and observed characteristic event times shows good agreement, as observed in Fig. 9 for the WE scheme. Because the arrival time is mainly controlled by the meteorological model, characteristic event times given by the other two schemes were similar.

Interactive Discussion

Figure 10 compares modelled and observed maxima of  $C_{TSP}$  (associated with the plume arrival at each station). Although some scattering exists, differences are in general within a factor of 2 (dashed line in Fig. 10). In order to quantify the performance of the different schemes, we define the residual of the  $i$ th observation as the difference between modelled and observed values of  $C_{TSP}$ , i.e.  $e_i = C_{mi} - C_{oi}$ . The mean ( $\langle e_i \rangle$ ) and root-mean-square ( $\sqrt{\langle e_i^2 \rangle}$ ) of residuals are reported in Table 2 (note that  $\langle e_i \rangle \neq 0$  is an indicator of model bias and  $\langle e_i^2 \rangle$  quantifies the error). As shown in Fig. 10,  $C_{TSP}$  at points where the plume arrived on 17 October (triangles) are clearly underestimated by the model, contributing with negative residuals. From values in Table 2 we conclude that, for this particular episode, the WE and MB schemes give similar results, with WE showing the lower bias and error. In contrast, the SH scheme tends to overestimate  $C_{TSP}$  (higher mean residuals) and shows larger differences with observations. Additionally, and regarding  $PM_{10}$  concentration, we observed that MB and SH widely underestimate measurements in CABA (stations C1, C2, and C3) whereas WE gives the right order of magnitude. These low values can be attributed to several factors but, in our opinion, are explained by an incorrect prediction of the threshold friction velocity, which in the MB and SH schemes depends on soil moisture provided by WRF-ARW. In fact, we checked that using the MB scheme without soil moisture correction gives much better results for  $PM_{10}$  concentration in CABA (see Fig. 11).

## 7 Conclusions

We have implemented and tested three different dust emission schemes in the FALL3D-7.0 tephra dispersal model in order to simulate the 14–18 October 2011 ash resuspension events in Central Patagonia. The modeling strategy combines a preliminary simulation to characterize the fallout deposit followed by the simulations of resuspension using FALL3D driven off-line by WRF-ARW. Even if not specifically developed for volcanic ash, all the emission schemes give very promising results when compar-

ing the simulated clouds with satellite images and the predicted concentrations of PM<sub>10</sub> and TSP at ground with measurements at different stations.

The three schemes present a similar qualitative behavior, but differ in the amount of emitted ash. Total resuspended mass is  $8.4 \times 10^{10}$  kg for SH;  $7.7 \times 10^{10}$  kg for MB and  $3.3 \times 10^{10}$  kg for WE. For comparison, Collini et al. (2013) estimated a total amount of erupted ash mass of  $1\text{--}5 \times 10^{12}$  kg during the period 4–19 June 2011. This amount of mass can give an idea of the hazards and disturbances caused by resuspended ash transported during the period considered in this study.

Remarkably, we find better agreement with observations using the simplest emission scheme (WE), although MB and SH showed also a good agreement. This result highlights the role of the sensitivity of more complex emission schemes to input parameters. In fact, relevant magnitudes for the source strength in the MB and SH schemes, such as granulometry or soil moisture, were obtained from modeling and are subject to large uncertainties. On the other hand, the simplest WE scheme seems more attractive from an operational point of view given its versatility. For example, an operator could easily set  $u_{*ts}$  according to a specific situation in order to match partial observations with model results. Our next research steps are to explore how to better constrain inputs for more sophisticated schemes and to investigate how to improve model accuracy in the near-field areas.

**Table 1.** Stations list referred in the text. Meteorological stations (from M1 to M17) provide visibility and wind velocity measurements. Air quality stations (from C1 to C3) provide direct measurements of PM<sub>10</sub> concentration at CABA. All stations belong to Argentina, except M16 that is located in Uruguay.

Station ID	Station Name	Location	Latitude (°)	Longitude (°)	Altitude (m)	Distance to CCVC (km)
M1	Bariloche	Río Negro	−41.15	−71.17	845	108
M2	Neuquén	Neuquen	−38.95	−68.13	270	386
M3	Santa Rosa	La Pampa	−36.57	−64.27	190	815
M4	Laboulaye	Córdoba	−34.13	−63.37	136	1053
M5	Río Cuarto	Córdoba	−33.12	−64.23	420	1084
M6	Venado Tuerto	Santa Fe	−33.67	−61.97	112	1182
M7	Junín	Buenos Aires	−34.55	−60.92	82	1192
M8	Pilar	Córdoba	−31.67	−63.88	338	1233
M9	Marcos Juárez	Córdoba	−32.70	−62.15	110	1246
M10	Córdoba	Córdoba	−31.32	−64.22	484	1248
M11	Rosario	Santa Fe	−32.92	−60.78	25	1319
M12	Ezeiza	Buenos Aires	−34.82	−58.53	20	1355
C1	Centenario	CABA	−34.61	−58.43	27	1376
M13	Aeroparque	CABA	−34.57	−58.42	6	1379
C2	Córdoba	CABA	−34.60	−58.39	35	1379
C3	La Boca	CABA	−34.63	−58.37	11	1380
M14	Punta Indio	Buenos Aires	−35.37	−57.28	16	1423
M15	Paraná	Entre Ríos	−31.78	−60.48	74	1428
M16	Carrasco	Montevideo	−34.83	−56.01	32	1551
M17	Concordia	Entre Ríos	−31.30	−58.02	35	1633

## Modeling volcanic ash resuspension

A. Folch et al.

**Table 2.** Characteristic quantities for each emission scheme. The correction factor  $\phi$  is adjusted to match the maximum measured concentration of  $C_{\text{TSP}} = 3.91 \text{ mg m}^{-3}$  in the M13 station. The total emitted mass, mean ( $\langle e_i \rangle$ ) and root-mean-square ( $\sqrt{\langle e_i^2 \rangle}$ ) of residuals at all stations (see Sect. 6.2) are also reported. These can be considered a measure of model to data bias and error respectively. Residuals are given in  $\text{mg m}^{-3}$ .

Scheme	WE	MB	SH
$\phi$	0.10	0.10	17
Total emission ( $\times 10^{10} \text{ kg}$ )	3.3	7.7	8.5
PM <sub>100</sub> emission ( $\times 10^{10} \text{ kg}$ )	2.4	3.7	8.5
PM <sub>20</sub> emission ( $\times 10^{10} \text{ kg}$ )	1.4	0.26	0.012
PM <sub>10</sub> emission ( $\times 10^{10} \text{ kg}$ )	0.95	$\sim 10^{-4}$	$\sim 10^{-5}$
$\langle e_i \rangle$	-0.14	0.20	1.87
$\sqrt{\langle e_i^2 \rangle}$	2.08	2.82	5.72

## Modeling volcanic ash resuspension

A. Folch et al.

**Fig. 1.** Dependency of the threshold friction velocity  $u_{*t}$  on particle size (in  $\mu\text{m}$ ) according to Shao and Lu (2000) (red line, Eq. 3) and Marticorena and Bergametti (1995) (blue line, Eq. 2). Solid lines are without moisture correction ( $w = 0$ ). Dotted lines show the effect of moisture using Eq. (4) with  $w = 25\%$  and  $w' = 10\%$ . For comparison, the solid black line shows the constant threshold friction velocity  $u_{*ts} = 0.25 \text{ m s}^{-1}$  used in WE scheme and the dotted black line its correction when a moisture of  $w = 25\%$  is considered.

**Fig. 3.** Simulated deposit load (in  $\text{kg}/\text{m}^3$ ) used as the initial condition in the simulations of resuspension. The location of the CCVC is indicated by a triangle. Circles show the location of the ground stations of the Argentinean National Meteorological Service and EPA Air Quality Monitoring Stations Network used to validate the model results.

## Modeling volcanic ash resuspension

A. Folch et al.

**Fig. 4.** Comparison between WRF-ARW wind surface velocity (blue lines) and measurements (red lines) at 3 different meteorological stations (see Fig. 3 and Table 1): M1 (Bariloche), M2 (Neuquén) and M13 (Buenos Aires Aeroparque). Measurements were averaged every 3 h to match the WRF-ARW time output resolution.

## Modeling volcanic ash resuspension

A. Folch et al.

**Fig. 5. (a)** WRF-ARW friction velocity (blue, left axis) and soil moisture (red, right axis) spatially-averaged over the deposit along the period 14–18 October 2011. The discontinuous red line at  $u_* = 0.4 \text{ m s}^{-1}$  is shown for reference. **(b)** Ash emission rate (integrated over the deposit) for the three different emission schemes considering the soil moisture correction on the threshold friction velocity: WE (assuming  $u_{*ts} = 0.25 \text{ m s}^{-1}$ ), MB and SH. Note how two resuspension events, a minor on 14 October at 18:00 UTC and a major 24 h later, are clearly predicted by all the emission schemes.

Interactive Discussion

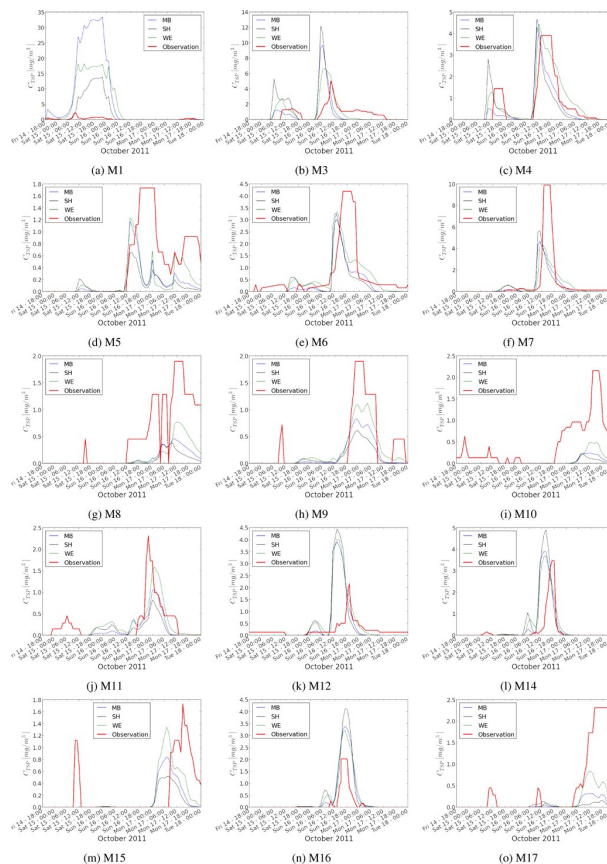

**Fig. 7.** Comparison between remote sensing observations and simulation results. The first column shows the MODIS images processed with the BTD algorithm. The second and third columns show FALL3D-7.0 results for the total cloud mass per unit area (vertical integration of concentration) using the MB and SH emission schemes respectively. On these pictures, the polygons of the VAG issued by the Buenos Aires VAAC are superimposed for reference. The VAG times in UTC are: **(a)** 14 October, 19:28, **(b)** 15 October, 19:28, **(c)** 16 October, 01:28, **(d)** 16 October, 19:28 and **(e)** 17 October, 01:15. Note how the presence of a band of middle and high altitude clouds impedes the complete visualization of the cloud by the satellite.

## Modeling volcanic ash resuspension

A. Folch et al.

**Fig. 8.** Comparison between  $C_{TSP}$  (in  $\text{mg m}^{-3}$ ) computed using the three different emission schemes and measurements at 15 different stations. At stations M3 and M4, the two concentration peaks caused by the two resuspension events are clearly visible. In other cases, only the second event can be identified. Other small maxima correspond to different atmospheric phenomena like mist (e.g. the peak recorded on 15 October at station M11, located in Rosario).

**Fig. 9.** Comparison between modelled and observed cloud arrival times at the considered stations. Note that model arrival times tend to be slightly ahead of observed during 17 October, presumably because WRF-ARW overestimates wind velocities. Results are shown only for the WE case, but similar results are observed for the MB and SH schemes.

## Modeling volcanic ash resuspension

A. Folch et al.

**Fig. 10.** Modelled versus observed maxima of  $C_{TSP}$  at the different stations and for the 3 emission schemes. Note that during 17 October (red triangles), the model underestimates regardless the emission scheme. However, observations and model estimations of maxima are, in general, within a factor of 2 (dashed line).
