## Abstract

Rainstorm damage caused by malfunctioning of urban drainage systems and water intrusion due to defects in the building envelope can be considerable. Little research on this topic focused on the collection of damage data, the understanding of damage mechanisms and the deepening of data analysis methods. In this paper, the relative contribution of different failure mechanisms to the occurrence of rainstorm damage are investigated, as well as the extent to which these mechanisms relate to weather variables. For a case study in Rotterdam, the Netherlands, a property level home insurance database of around 3100 water-related damage claims was analysed. Records include comprehensive transcripts of communication between insurer, insured and damage assessment experts, which allowed claims to be classified according to their actual damage cause. Results show that roof and wall leakage is the most frequent failure mechanism causing precipitation-related claims, followed by blocked roof gutters, melting snow and sewer flooding. Claims related to sewer flooding were less present in the data, but are associated with significantly larger claim sizes than claims in the majority class, i.e. roof and wall leakages. Rare events logistic regression analysis revealed that maximum rainfall intensity and rainfall volume are significant predictors for the occurrence probability of precipitation-related claims. Moreover, it was found that claims associated with rainfall intensities smaller than 7–8 mm in a 60 min window are mainly related to failures processes in the private domain, such as roof and wall leakages. For rainfall events that exceed the 7–8 mm h<sup>-1</sup> threshold, failure of systems in the public domain, such as sewer systems, start to contribute considerably to the overall occurrence probability of claims. The communication transcripts, however, lacked information to be conclusive about to extent to which sewer-related claims were caused by overloading of sewer systems or failure of system components.

# 1 Introduction

Heavy rainfall cause considerable damage to building structure and content all over the world. Research on this topic has mainly concentrated on the adverse consequences of river flooding (Douglas et al., 2010; Jongman et al., 2012). Little research focused on damage caused by malfunctioning of urban drainage systems and direct water intrusion due to defects in the building envelope. Severe rainstorms have demonstrated that the impact of local high-intensity rainfall to cities can be large. On July 2011, Copenhagen was hit by 150 mm of rainfall in three hours, which resulted in surcharging of sewer systems, flooded houses, shops, roads and railways. Danish insurers received more than 90 000 claims and paid out more than EUR 800 million (2011 value) in compensation (Garne et al., 2013). Another example is the heavy rainfall event of autumn 1998 in the Netherlands, which was associated with a return period of about 125 yr and caused around EUR 410 million (1998 value) to private buildings and agriculture (Jak and Kok, 2000). But also the cumulative damage of minor rainfall events can be considerable in the long run due to their high frequency of occurrence (Ten Veldhuis, 2011).

Many authors, from fields related to different kinds of weather-related risks (e.g. hailstorm, landslides, river flooding, coastal flooding), have recognized that damage data is lacking or biased and that this is limiting the development of reliable damage models (e.g. Pielke and Downton, 2000; Hohl et al., 2002; Elmer et al., 2010; Gall et al., 2009; André et al., 2013). The same is true for rainstorms; little research focused on the collection of rainstorm damage data, the understanding of mechanisms causing damage and the deepening of statistical methods to analyse damage data. Among exceptions are studies by Busch (2008), Smith and Lawson (2011), Einfalt et al. (2012), Cheng (2012), Zhou et al. (2013), Climate Service Center (2013), and Spekkers et al. (2013, 2014), who analysed damage data sources (i.e. from insurance industry, local media, rescue service reports) and their relationships to rainfall data. As a result, there is no strong foundation for the development and validation of prediction models for rainstorm

damage. Such models could help homeowners and water authorities to make better decisions on measures to prevent or reduce damage (e.g., retrofitting of buildings and early warning systems).

A potential source of damage data are insurance damage databases. They contain claims often collected over many years and from a large number of insured. A difficulty of insurance databases is that information on the mechanisms that cause damage and building-related, weather and socioeconomic variables are not or only limitedly available in claim data or cannot easily be retrieved from insurers' data archives (André et al., 2013; Spekkers et al., 2014).

This study aims to quantify the relative contribution of different failure mechanisms to the occurrence of building structure and content damage induced by rainstorms and to investigate to what extent the probability of occurrence of these processes is related to weather variables. For this purpose, a property level database of around 3100 water-related damage claims was analysed, for a case study in Rotterdam, the Netherlands. An interesting feature of this database is that it includes comprehensive transcripts of communication between insurer, insured and damage assessment experts, which allowed classification of claims based on the failure mechanisms causing damage. This information is, however, stored in an unstructured way that required substantial data classification efforts before data could be used for the analysis in present paper.

The outline of the paper is as follows. In Sect. 2 insurance damage data and classification of claims are described, as well as, the statistical method used to model probability of claim occurrence as a function of weather variables. Results of data analyses and regressions are presented in Sect. 3, followed by discussion in Sect. 4. In Sect. 5, conclusions and recommendations are summarized.

## 2 Methods

### 2.1 Case study description

This study focuses on Rotterdam, which is, with a population of around 620 000, the second largest city of the Netherlands (Statistics Netherlands, 2014). Because the city is relatively flat (maximum ground level variations of 10–15 m), floods from heavy rainfall are typically characterized by flood depths up to a few decimetres and limited surface run-off. Rotterdam's sewers are mainly combined systems ( $\approx 1800$  km), some parts of the city have separate systems for wastewater and stormwater ( $\approx 500$  km) (Gemeente Rotterdam, 2011). The average density of sewer pipes in the city centre is  $15.6 \text{ km km}^{-2}$  and 13% of the area is surface water (i.e. city canals and ponds, not rivers) (Statistics Netherlands, 2013; Gemeente Rotterdam, 2014). The majority of the buildings in Rotterdam was constructed in the 20th century. Rotterdam's urban fabric is characterised by a combination of terraced houses and high-rise residential and commercial buildings (Kadaster, 2013).

### 2.2 Insurance data

Insurance damage data were provided by a Dutch insurance company that is part of the Achmea insurance group. Data are available at property level for the period of January 2007–October 2013 (data collected on: February 2014), containing around 3100 water-related claims. A claim relates to building structure or content damage or a combination of the two, depending on the available insurance policies at the risk address.

For each claim, the following information is available: risk address, type of insurance coverage, damage date, amount of compensation and detailed transcripts of communication between insurer, insured and damage assessment experts (e.g. calls, abstracts from reports). On average, the data set contains information of around 16 000 risk addresses, which is 6% of the total number of households in Rotterdam. These numbers

relate to data from one insurance company of the Achmea insurance group and do not reflect the market share in Rotterdam of the Achmea insurance group as a whole. Table 1 summarizes the key features of the home insurance policy related to the present database.

The general rule for a claim to be accepted is that damage should be unforeseen and have occurred suddenly. Damage due to river flooding is not covered. Damage due to pluvial flooding is covered, provided that damage is directly and solely related to localised heavy rainfall (Ministry of Transport, Public Works and Water Management, 2003).

### 2.3 Classification of claims

For the purpose of this study, claims were manually classified according to the actual cause of damage using the information in the communication transcripts. Transcripts contain telegram style summaries of calls and abstracts from reports and typically vary in length between a few lines to a few thousand words. When a claim is first reported at the insurer's call centre, the client is asked a few basic questions to verify if the client was indeed insured at the time of the damaging event and to make a quick assessment on the severity of the damage (e.g. "Is the risk address still habitable?"). Follow-up calls typically describe the actual cause of damage, an inventory of damaged goods and materials and the costs related to cleaning, drying, repairing or replacing goods and materials.

An easy-to-use web interface and SQL database was built based on the classification scheme listed in Table 2. Failure mechanisms described in Table 2 are also shown graphically in Fig. 1. Per claim only one cause class could be selected. Labels were given to each cause class to indicate whether the class relates to precipitation or not and whether the class relates to failures of systems in the public domain (i.e. responsibility of water authorities) or private domain (i.e. responsibility of homeowner, landlord or housing cooperative). Next to the classification scheme, a number of checkboxes was available to specify if (1) building or content was underinsured, (2) insured has

not responded to a request for a long time, (3) claiming process is still ongoing (typical processing time is a few months), (4) claim was rejected because of a lack of building maintenance and (5) damage was (partly) not insured.

Classification was done by three persons, by dividing the data set into three independent subsets containing 60, 36 and 4% of the claims. On average, classification took four minutes per claim. The entire text was read first while making preliminary classification choices. A second reading was used to verify and finalise selections. If the available information was unclear or multi-interpretable, claims were flagged for investigation by one of the other two persons. This happen to be the case for 7% of the claims.

## 2.4 Weather variables

A set of weather variables was derived for each risk address and day to investigate explanations for claim occurrence (Table 3). Rainfall volume and maximum rainfall intensity were extracted from weather radar data, provided by the Royal Netherlands Meteorological Institute (KNMI), according to a method described in Spekkers et al. (2014). Maximum rainfall intensity was calculated using a 15, 30 and 60 min moving time window to study typical time scales of failure processes. Maximum temperature, daily-averaged wind speed, maximum hourly wind speed and wind gust were obtained from an automatic weather station operated by the KNMI, located in the north of the city, around 10 km from the city centre. The season of the year was included to account, for instance, for the occurrence of snow and hail and blockages of rain gutters due to autumn leaf fall.

## 2.5 Modelling the probability of claim occurrence

The modelling objective was to test the significance of weather variables in explaining the occurrence of precipitation-related claims. For each risk address and day the outcome ( $Y_i$ ) can be a reported claim (1) or not (0). The binary outcome can be linked

to a set of weather variables  $(x_1, \dots, x_n)$  using various types of models for binary data (McCullagh and Nelder, 1989). In this study a logistic regression model was used:

$$\log\left(\frac{\theta_i}{1-\theta_i}\right) = \beta_0 + \beta_1 x_{1i} + \dots + \beta_n x_{ni}, \quad (1)$$

where  $\theta_i$  is the probability of claim occurrence ( $Y_i = 1$ ) and  $\beta_0, \dots, \beta_n$  are regression coefficients. The regression coefficients were estimated using maximum likelihood estimation. The significance of the regression coefficients is tested using the Wald test. Logistic regression is known to generate biased estimates for rare events data, i.e. data series in which only a low percentage of events occur, resulting in an underestimation of the probability of rare events (King and Zeng, 2001). In present database, only 1031 precipitation-related claims were recorded in the period of 2007–October 2013, which is on average  $2.67 \times 10^{-5}$  claims per day per risk address. King and Zeng (2001) proposed a method, called rare events logistic regression, to deal with rare events data. This methods encompasses a case-control design where ten times more non-events (i.e. no claim from an insured) are selected than events (i.e. a claim from an insured). The method first estimates regression coefficient using an ordinary logistic regression model (Eq. 1), then correcting regression coefficients for finite sample and rare events bias. For this purpose, the *relomit* routine from the Zelig package (Imai et al., 2007) for R was used. Collinearity among explanatory variables was tested by calculating the Pearson's correlation coefficient between each pair of explanatory variables. None of the correlation coefficients yielded values  $> 0.7$ , which means that collinearity effects can be neglected (Dormann et al., 2013).

The likelihood ratio and a pseudo- $R^2$  statistic were used to evaluate goodness-of-fit of a model. The likelihood ratio compares the likelihood of a model with predictors to the likelihood of a model without predictors (i.e. intercept-only model), which tests if adding explanatory variables to a model significantly improves model fit. For logistic regression, there is no universally accepted measure that represents the proportion of variance explained by the predictors, such as  $R^2$  for ordinary least squares regression. Several pseudo- $R^2$  statistics exist; however, these statistics generally score much

lower than their equivalent in ordinary least square regression and are therefore found less informative. They can be used, nevertheless, to compare predictability of nested models. In this study McFadden's  $R^2$  is used (e.g. Long, 1997).

## 2.6 Discarded data

5 During the validation process of the insurance data, it was found that on three extremely stormy days (i.e. storm Kyrill on 18 January 2007 and storms on 27 July 2013 and 28 October 2013), despite occurrence of rainfall, no or hardly any precipitation-related claims were recorded. Upon further inquiry, the insurer has indicated that on  
10 extremely stormy days, precipitation-related claims are often inaccurately recorded as storm-related claims. These days are therefore excluded from the analysis.

## 3 Results

### 3.1 Relative occurrence frequencies and costs of claims

Analyses of the relative occurrence frequencies of damage causes show that leakage of roofs and walls is the most frequent failure mechanism generating water-related  
15 claims, followed by burst of household water supply pipes, blockage or leakage of household wastewater systems and leakage of household appliances (Fig. 2). Besides roof and wall leakages, other common precipitation-related failure mechanisms are blocked roof gutters, snow melting under roof tiles and sewer flooding.

In general, 34 % of the claims were related to precipitation and 43 % to non-precipitation causes. For the remaining 23 %, it was unknown if the claim was related to precipitation or not. These unknowns include claims caused by water discharges from  
20 neighbouring properties and groundwater flooding. In particular for groundwater flooding, insufficient information was available to distinguish between floods as a result of persistent rainfall or because of sudden wall failures not related to rainfall. For insurers,

Printer-friendly Version

Interactive Discussion

there is no strong need to collect information on the actual cause of groundwater flooding as they do not compensate for this type of flood (see also Table 1).

Although claims related to sewer flooding were less present in the data, they are associated with significantly larger claim sizes (EUR 1060–2800, based on the 95% confidence interval around the median in Fig. 3) than claims generated by roof and wall leakages (EUR 650–800), the majority class. Sewer floods are costly because of the required (chemical) cleaning of sewage spills and replacement of goods that cannot be cleaned properly. In contrast, costs related to roof and wall leakages, which usually do not involve large water volumes, are relatively low and limited to the repair of the leak and the painting of walls and ceiling.

Based on a qualitative analysis of outliers, it was found that exceptionally large claim sizes are related to cases where water leakage could not be stopped easily (e.g. burst of water supply pipe just outside property), flooding occurred while no one was at home or temporary housing was required.

### 3.2 Effects of rainfall intensity on claim occurrence probability

In Fig. 4 the empirical probability of precipitation-related claim occurrence per day per risk address, as a function of the rainfall intensity (black dots) is shown. A further distinction was made between the occurrence probability of claims caused by failure of systems in the private (grey dots) and the public domain (light grey dots), according to column 5 (“Domain”) of Table 2. The empirical probability is calculated as follows: within a bin, with a size of 5% of the range of  $x$  values, the number of successes (i.e. claims) are divided by the sample size (i.e. number of combinations of days and risk addresses that can generate claims). Empirical probabilities are evaluated at each  $x$  value that corresponds with a claim.

The top-left plot, based on a 60 min window, shows that the occurrence probability of precipitation-related claims increases with increasing rainfall intensity and that it increases considerably when rainfall intensity exceeds  $7\text{--}8\text{ mm h}^{-1}$ . For events with rainfall intensities smaller than  $7\text{--}8\text{ mm h}^{-1}$ , the occurrence probability of

precipitation-related claims is mainly determined by failure processes in the private domain, which are primarily roof and wall leakages. Thus, damage due to roof and wall leakage already occur at small rainfall intensities, which suggest that leaks may be latent before first observed during a rainfall event. For rainfall events that exceeds the 7–8 mm h<sup>-1</sup> threshold, failure processes in the public domain start to contribute substantially to the overall occurrence probability. Interestingly, this threshold is not in line with the design standards of sewers in the Netherlands. Dutch sewers are designed to cope with rainfall intensities of 21.6 mm h<sup>-1</sup> (Koot, 1977). Similar conclusions can be drawn from the other two plots related to a 30 min (top-right) and a 15 min window (bottom-left), with the difference that rainfall threshold shift to 9–10 and 12 mm h<sup>-1</sup> respectively. The locally-weighted regression lines reveal that relationships using the 30 and 15 min window have a less linear nature than the ones based on a 60 min window.

### 3.3 Logistic regression results

Logistic regression analyses were performed to test the significance of various combinations of explanatory variables in explaining the occurrence probability of precipitation-related claims. Separate analyses were made for the occurrence of claims caused by failures of systems in the public and private domain (according to column 5 in Table 2). From the three variants of maximum rainfall intensity, the one based on a 60 min window was used for modelling. Regression coefficients were estimated based on the data in the rainfall intensity range of 5 to 12 mm h<sup>-1</sup> (60 min window). Data associated with 12 mm h<sup>-1</sup> or larger are scarce and are, therefore, likely biased towards single rainfall events. In a first attempt to fit a logistic regression model to data in the range of 0–12 mm h<sup>-1</sup>, it was found that much weight was given to the data in the range of 0–5 mm h<sup>-1</sup>, resulting in a poor fit to data in the higher rainfall intensity range. Possibly, claims associated with rainfall intensities of 0–5 mm h<sup>-1</sup> are generated by a different process than the claims associated with rainfall intensities larger than 5 mm h<sup>-1</sup>. More on this can be read in Sect. 4.

Interactive Discussion

The goodness-of-fit measures of the various models, including a comparison of the likelihood ratio statistics between models are summarized in Table 4. The models that combine maximum rainfall intensity and rainfall volume result in better fits compared to the intercept-only models. Maximum temperature, wind parameters and season significantly improve the model fit for claims caused by failures of private systems, but not for claims caused by failures of public systems. Most of the explanatory power derives from maximum rainfall intensity and rainfall volume. Of all wind parameters, wind gust has best explanatory power.

Table 5 lists the estimates of the regression coefficients for the two models that include all explanatory variables (using wind gust as wind parameter), further referred to as the private model and the public model. The categorical variable “season” was modelled as four separate binary variables, where one level was dropped to avoid multicollinearity. The summer season was found to positively correlate with the occurrence of claims related to failure of private systems. Moreover, regression analysis revealed that the regression coefficient of the maximum rainfall intensity is larger for the public model than for the private model, which means that rainfall intensity more strongly affects the claim occurrence by failures of public systems than private systems. The odds ratio ( $\exp(\beta)$ ) related to maximum rainfall intensity varies between 1.16–1.27 for the private model and 1.33–1.95 for the public model, which means a 16–27 % and a 33–95 % increase in odds for each  $\text{mm h}^{-1}$  change in rainfall intensity, for private and public model respectively.

**4 Discussion**

Based on the insurance data for the case study in Rotterdam, a distinct rainfall intensity threshold could be defined above which failures of public systems start to contribute considerably to the occurrence of damage claims (Fig. 4). Interestingly, this threshold of  $7\text{--}8 \text{ mm h}^{-1}$  (based on a 60 min window) is not in line with the design standards of sewers in the Netherlands. Dutch sewers are designed to cope with rainfall intensities

Interactive Discussion	

of  $21.6 \text{ mm h}^{-1}$  (Koot, 1977). This suggest that the threshold relates to some other damaging process than simply overloading of sewer systems, for example, blockages in sewer pipes or malfunctioning of non-return valves in sewer laterals. On closer inspection of the communication transcripts of claims labelled as “sewer flooding”, it was found that most cases relate to sewer backups from toilets or floor drains and to a lesser extent to run-off entering buildings at ground level. Still, communication transcripts were inconclusive about the extent to which these claims were related to overloaded sewer systems or failure of system components.

Results of this study have practical relevance for insurers. From present case study, it became evident that the majority of the water-related claims are caused by roof and wall leakages. Thus, damage prevention programs focussing on these causes may be helpful. Moreover, when it is raining heavily ( $> 7\text{--}8 \text{ mm}$  in a 60 min window) insurers can expect more claims related to sewer flooding that require special services for the cleaning of sewer spills.

In the higher range of rainfall intensities in Fig. 4, relationships between rainfall intensity and claim occurrence probability become less distinct, which can partly be explained by the limited amount of claim data associated with extreme rainfall events. The present insurance database covers almost seven years of claim data (2007–October 2013), where around 80% of the precipitation-related claims relate to rainfall events with return periods smaller than 2 yr. Around 10% of the claims can be attributed to two exceptional rainfall event with a return period of 14–18 yr. As a consequence, empirical probabilities in the higher range of rainfall intensities are unreliable and biased towards single rainfall events.

Claims associated with rainfall intensities of  $0\text{--}5 \text{ mm h}^{-1}$  in Fig. 4 (60 min window) are possibly generated by a different process than the claims related to rainfall intensities larger than  $5 \text{ mm h}^{-1}$ . The hypothesis could not be tested based on the present database. It maybe the case that more specific damage processes can be distinguished within the existing cause classes. For example, the class “roof leakages” may contain two processes; one related to the presence of latent leaks that are first

observed when it is raining and another one related to the exceedance of the “hydraulic capacity” of roofs.

There are a number of aspects with regard to uncertainty in insurance data. To begin with, the occurrence of claims that relate to causes that are not covered by insurers (e.g. groundwater flooding) are probably underestimated by the data, simply because people may be aware of the fact that damage is not covered and, thus, not make a claim. Moreover, the reported claim date may not always be the date on which the damage occurred, for example, because the exact damage data is unknown, which may be the case when people are on holidays. Furthermore, addresses of insured are based on static policyholder information, i.e. situation at a fixed point in time (reference date: 31 July 2013). Errors in addresses may occur if policyholder information has changed in time (e.g. policyholder moves to another address).

Failure of public systems (e.g. sewer system) will probably mostly affect buildings that occupy ground floor. In the present study, no distinction was made between terraced or detached houses and high-rise buildings (i.e. houses that occupy first floor or higher). As a consequence, claim occurrence probabilities related to failure of public systems is likely higher than the probabilities estimated in present study, which is based on all building types.

## 5 Conclusions and recommendations

The main goal of the current study was to investigate the relative contributions of different failure mechanisms to the occurrence of rainstorm damage to building structure and content, as well as the extent to which the probability of occurrence of these failure mechanisms relate to weather variables. For this purpose, a property level home insurance database of around 3100 water-related damage claims was analysed, for a case study in Rotterdam, the Netherlands.

The results of this investigation show that leakage of roofs and walls is the most frequent failure mechanism causing precipitation-related claims, followed by blocked

roof gutters, snow melting under roof tiles and sewer flooding. Although claims related to sewer flooding were less present in the data, they are associated with significantly larger claim sizes (EUR 1060–2800, 95 % confidence interval around the median) than claims generated by roof and wall leakages (EUR 650–800), the majority class. Rare events logistic regression analysis revealed that maximum rainfall intensity and rainfall volume are significant predictors for the occurrence probability of precipitation-related claims. Moreover, it was found that claims associated with rainfall intensities smaller than 7–8 mm in a 60 min window are mainly caused by failures of systems in the private domain, such as roof leakages and blocked roof gutters. For rainfall events that exceeds the 7–8 mm h<sup>-1</sup> threshold, failure of systems in the public domain, such as sewer systems, start to contribute considerably to the overall occurrence probability of claims. The communication transcripts, however, lacked information to be conclusive about to extent to which sewer-related claims were caused by overloading of sewer systems or failure of system components.

An important limitation of this study is that the number of claims associated with extreme rainfall events was relatively small. Given the fact that manual classification took considerable amount of work, it is recommended to explore methods to automate and standardize classification of claim data, with the aim to process more data in future analyses.

*Acknowledgements.* This research was supported by the KIC-Climate project OASIS. The authors would like to thank the Achmea insurance group and Royal Netherlands Meteorological Institute for their support and making available the data. Martijn Koole and Emiel Versteegen, MSc students at the TU Delft, are acknowledged for their help with the classification of claim data. Martijn Koole also helped with creating Fig. 1. Johan Post provided helpful comments to a draft version of the manuscript.

## On the occurrence of rainstorm damage

M. H. Spekkers et al.

**Table 2.** Classification scheme of water-related failure mechanisms applicable to residential buildings. The column “Domain” indicates whether damage prevention mainly concerns homeowners (private) or water authorities (public).

Id	Short name	Description	Precipitation-related?	Domain	Remark
1	Roof and wall leakages	Rainwater intrusion through roofs, facades, walls, wall-window interfaces and closed doors, which includes rainwater intrusion as a result of overloaded rain gutters	Yes	Private	
2	Rainwater through open window	Rainwater intrusion through open windows, open doors	Yes	Private	
3	Hail impacting roofs	Hail impacting roofs or windows	Yes	Private	
4	Precipitation-related in private domain	Precipitation-related in private domain, but other or unknown actual cause	Yes	Private	Residual group
5	Melting snow	Intrusion of melting snow and ice, in particular snow blowing up under roof tiles	Yes	Private	
6	Blocked roof gutters	Overflowing of roof gutters due to blockages in gutter or downpipe (e.g. by leaves or ice)	Yes	Private	
7	Sewer flooding	Flood water entering buildings through doors or openings as a result of overloaded public sewer systems, including sewer backups	Yes	Public	
8	Depression filling	Flood water entering buildings through doors or openings as a result of depression filling, i.e. rainwater filling up depressions if no drainage facilities are available	Yes	Public	
9	Blocked sewer inlets	Flood water entering buildings through doors or openings as a result of blocked sewer inlets	Yes	Public	
10	Flooding from local watercourses	Flood water entering buildings through doors or openings as a result of flooding from local watercourses (e.g. city canal, pond)	Yes	Public	
11	River flooding	Flood water entering buildings through doors or openings as a result of flooding from river systems	Yes	Public	
12	Precipitation-related in public domain	Precipitation-related in public domain, but other or unknown actual cause	Yes	Public	Residual group
13	Precipitation-related	Precipitation-related, but other or unknown actual cause	Yes	Unknown	Residual group
14	Leakages of household appliances	Leakages of household appliances (e.g. washing machines, dishwashers, aquaria, waterbeds)	No	Private	
15	Bursts of household water supply pipes	Bursts of household water supply pipes, including attached facilities	No	Private	
16	Leakages of central heating systems	Leakages of central heating systems, which includes boilers, radiators and pipes	No	Private	
17	Blocked or leaking household wastewater systems	Flooding of wastewater due to blockage in or leakage of wastewater system located inside the building	No	Private	
18	Non-precipitation-related in private domain	Non-precipitation-related in private domain, but other or unknown actual cause	No	Private	Residual group
19	Bursts of public water supply pipes	Bursts of water supply pipes owned by water supply company	No	Public	
20	External water discharges	External water discharges (e.g. extracted groundwater from a construction site, fire extinguishing water)	No	Public	
21	Blocked public wastewater system	Flooding of wastewater due to blockage in sewer lateral or sewer main, not related to rainfall events	No	Public	
22	Non-precipitation-related in public domain	Non-precipitation-related in public domain, but other or unknown actual cause	No	Public	Residual group
23	Non-precipitation-related	Non-precipitation-related, but other or unknown actual cause	No	Unknown	Residual group
24	Water discharge from neighbours	Water discharge from neighbours, but other or unknown actual cause	Unknown	Private	Residual group
25	Groundwater flooding	Groundwater flooding due to persistent rainfall or sudden wall failure	Unknown	Unknown	
26	Water-related	Water-related, but other or unknown actual cause	Unknown	Unknown	Residual group

On the occurrence of  
rainstorm damage

M. H. Spekkers et al.

**Table 3.** Definitions of explanatory variables and variable value ranges.

Variable name	Definition	Min – Median – Max
Rainfall volume (vol)	Volume of rainfall event at the radar pixel intersecting the building's centroid (mm)	0 – 4.9 <sup>1</sup> – 86.2
Maximum rainfall intensity (max <sub>15</sub> )	Maximum intensity of rainfall event at the radar pixel intersecting the building's centroid, using a 15 min moving time window (mm h <sup>-1</sup> )	0 – 3.8 <sup>1</sup> – 102.3
Maximum rainfall intensity (max <sub>30</sub> )	Maximum intensity of rainfall event at the radar pixel intersecting the building's centroid, using a 30 min moving time window (mm h <sup>-1</sup> )	0 – 2.8 <sup>1</sup> – 62.3
Maximum rainfall intensity (max <sub>60</sub> )	Maximum intensity of rainfall event at the radar pixel intersecting the building's centroid, using a 60 min moving time window (mm h <sup>-1</sup> )	0 – 2.0 <sup>1</sup> – 34.2
Maximum temperature (temp)	Maximum temperature measured at the KNMI Rotterdam weather station (°)	-6 – 14.8 – 35
Daily-averaged wind speed (wind <sub>d</sub> )	Daily-averaged wind speed measured at the KNMI Rotterdam weather station (mm s <sup>-1</sup> )	0.7 – 4 – 14.3
Maximum hourly wind speed (wind <sub>h</sub> )	Maximum hourly-averaged wind speed measured at the KNMI Rotterdam weather station (mm s <sup>-1</sup> )	2 – 6 – 16
Wind gust (wind <sub>g</sub> )	Wind gust measured at the KNMI Rotterdam weather station (mm s <sup>-1</sup> )	3 – 11 – 28
Season (seas)	Season of the year: winter = Dec–Feb, spring = Mar–May, summer = Jun–Aug, autumn <sup>2</sup> = Sep–Nov	NA

<sup>1</sup> Median based on non-zero values only, <sup>2</sup> The level "autumn" was dropped to avoid multicollinearity.

## On the occurrence of rainstorm damage

M. H. Spekkers et al.

**Figure 3.** Distribution of claim sizes associated with various failure mechanisms. Claim size is the sum of property and content damage. Only risk addresses are included for which both property and content insurance were available. Results are only shown for failure mechanisms with at least 20 claim records. The grey rectangles display the 95 % confidence interval around the median. If the grey rectangles of two boxplots do not overlap, there is a strong indication that the median are statistically different.

On the occurrence of  
rainstorm damage

M. H. Spekkers et al.

**Figure 4.** The empirical probability of claim occurrence per day per risk address as a function of rainfall intensity, using a 60 min (top left panel), 30 min (top right panel) and 15 min moving time window (bottom left panel). Results are related to precipitation-related claims (black dots), broken down to those classified as “private” (grey dots) and “public” (light grey dots). The range of  $x$  values is from  $0 \text{ mm h}^{-1}$  to the rainfall intensity associated with a return period of 5 yr. Locally-weighted regression lines are based on penalized B-splines.
