## Abstract

Alexandria is the second biggest city in Egypt as regards population, is a key economic area in northern Africa and has a very important tourist activity. Historical catalogues indicate that it was severely affected by a number of tsunami events. In this work we assess the tsunami hazard by running numerical simulations of tsunami impact in Alexandria through the Worst-case Credible Tsunami Scenario Analysis (WCTSA). We identify three main seismic sources: the Western Hellenic Arc (WHA – reference event AD 365,  $M_w = 8.5$ ), the Eastern Hellenic Arc (EHA – reference event 1303,  $M_w = 8.0$ ) and the Cyprus Arc (CA – hypothetical scenario earthquake with  $M_w = 8.0$ ), inferred from the tectonic setting and from historical tsunami catalogues. All numerical simulations are carried out by means of the code UBO-TSUDF, developed and maintained by the Tsunami Research Team of the University of Bologna. Relevant tsunami metrics are computed for each scenario and then used to build aggregated fields such as the maximum flood depth and the maximum inundation area. We find that the case that produces the most relevant flooding in Alexandria is the EHA scenario, with wave heights up to 4 m. The aggregate fields are used for a building vulnerability assessment according to a methodology developed in the frame of the EU-FP6 project SCHEMA and further refined in this study, based on the adoption of a suitable building damage matrix and on water inundation depth. It is found that in the districts of El Dekhila and Al Amriyah, to the south-west of the port of Dekhila over 12 000 buildings could be affected and hundreds of them could incur in consequences ranging from important damage to total collapse. It is also found that in the same districts tsunami inundation covers an area of about 15 km<sup>2</sup> resulting in more than 150 000 residents being exposed.

# 1 Introduction

Alexandria is one of the oldest cities in the world, founded in 331 BC by Alexander the Great close to the Egyptian port of Rakotis that was already known in Homeric times, and remained the capital of Egypt for over 1000 years. Administratively, Alexandria governorate consists of one big town, i.e. Alexandria with about 4.1 million people, and two small cities, namely Borg El Arab City and New Borg El Arab, all together forming the Metropolitan Alexandria. The governorate of Alexandria counts a population of about 4.8 million. Today, Alexandria is one of the major cities in the Mediterranean sea, developing along a narrow strip of coast about 70 km long, separating the Mediterranean sea from the inner 75 km<sup>2</sup> Lake Mariout (with ancient name Mareotis). The city of Alexandria is considered the Egypt's second capital by virtue of its location and population size. During summer months, the city receives some 3 million visitors (it was a mere 309 000 in 2002), making it the most popular summer resort for Egyptians. The total area of Alexandria is 2680 km<sup>2</sup>, divided into six districts that from NE to SW are (see Fig. 1): Al-Montazah, Sharq (Eastern Alexandria), Al-Gomrok, which is the historic old town, Wassat (Central Alexandria), El-Dekhila-Agami (Western Alexandria) and Al-Amriyah, the first 5 sitting on the coast, and the last one being more in the interior.

Alexandria plays a key role in the national economy: the port of Alexandria is the Egypt's largest, with 57 % of the total port capacity in the country, and one of the major ports in the Mediterranean basin. In the paper (Fig. 1) we will denote the Ras El Tin harbour, that is mainly for yachting and fishing vessels, as the Eastern Port of Alexandria. Further, the harbour basin between Ras El Tin and Wassat will be considered as formed by two ports denoted as the port of Dekhila to the west and the Western Port of Alexandria to the east, which is the most important port facility of the region. Notice that the Eastern and Western Ports of Alexandria are separated by a "tombolo", i.e. by a narrow strip of land or isthmus connecting the mainland with the former island of Pharos. Close to the harbour area one can find also one of the most important industrial districts in Egypt, with several large, well-equipped industrial plants (e.g. Borg

El Arab, Merghem, Om Zegheow and El Gharbaneyyat) that give it a dominant position in the manufacturing sector. Other industrial sectors are very important: chemical and petrochemical, steel, iron and engineering industries, construction materials, wood products, food industries, etc.

From a physiographic point of view, the city of Alexandria lies on a series of narrow Late Pleistocene ridges running parallel to the coast separating the sea from the very shallow Lake Maryut, that is one of the many lagoons and marshes characterizing the vast area of the Nile delta. These brackish lakes are connected to the sea by a complex system of artificial waterways, two of which, the Alexandria and the Al-Max channels, drain the waters of the Lake Maryut into the Alexandria harbour basin also by means of pumping stations, between the port of Dekhila and the Western Port of Alexandria in the district of Wassat.

Alexandria was hit by a number of tsunamis in the course of the history (see Papadopoulos et al., 2007; Salamon et al., 2007), two of which have flooded the city with destructive effects, namely the 21 July AD 365 and the 8 August 1303 Crete tsunami events. The detailed reconstruction of these tsunamis is out of the scope of this paper. We will only recall their most relevant features in the following.

### 1.1 The AD 365 Tsunami

The AD 365 earthquake and tsunami were first described by coeval sources. Ammi-  
anus Marcellinus (see Guidoboni et al., 1994; Stiros, 2001), a Roman historian who  
lived in the fourth century (AD 325–391), writes in 378, that is 13 years after the event  
occurrence, that the earth was shaken by an earthquake and then a tsunami brought  
destruction to ships in the sea and to people on land. He speaks of a strong sea with-  
drawal and return, of several thousands of people drawn mainly because they were  
surprised unexpectedly by the returning water, of vessels landed on roofs, and of some  
other vessels carried on land more than two miles from the coastline. Indeed, Ammi-  
anus Marcellinus does not refer all the above occurrences to any specific geographical  
locations, apart from two exceptions: (1) he mentions Alexandria on speaking of ships

that were left on house roofs (“... Ingentes aliae naves, extrusae rabidis flatibus culminibus insedere tectorum, ut Alexandriæ contigit, ...” Other big vessels pushed out of the sea by the fury of winds ended onto the top of roofs, which occurred in Alexandria ...) and (2) he mentions Methoni, a town in Messenia, southern Peloponnese, Greece, on reporting of ships transported about two miles onshore (“... ad secundum lapidem fere procul a litore contortæ sunt aliquæ, ut Laconicam prope Mothonem oppidum nos transeundo conspeximus, diuturna carie fatiscentem ...” Some vessels were carried up to two miles away from the coast, as I saw one from Sparta dilapidated for a long decay while I was travelling near the town of Methoni). Therefore, his description, although quite realistic, cannot be used for a modern reconstruction. From later sources it seems that most of Alexandria escaped destruction and that damage was confined to the narrow causeway connecting the town to the island of Pharos, where the famous lighthouse, one of the seven wonders of the world, was built (Shaw, 2008; Stiros, 2010). It was called Eptastadion (Pararas-Carayannis, 2011) since its length was about 7 stadia (a stadium is an ancient Greek distance unit equal to 184.45 m) and the tombolo that formed on it divides today the East from the West Port of Alexandria in the district of Al-Gomrok (see the locality Ras el Tin in Fig. 1). Recent studies agree that the AD 365 shock was a large magnitude ( $M_w$  8.3–8.5) earthquake that occurred in the Hellenic subduction zone between southwestern Crete and the Peloponnese (e.g. Stiros, 2010). Uplifts up to 10 m of the coast in western Crete were recognised, identified and dated (Pirazzoli et al., 1992, 1996; Shaw et al., 2008) and, as for today, are the main clue to placing the source of this tsunami in the WHA. In this study an AD 365-like tsunami is one of the Worst-case Credible Scenarios we use to evaluate the tsunami vulnerability of Alexandria.

## 1.2 The 1303 Tsunami

The 8 August 1303 earthquake was destructive over a vast area of the eastern Mediterranean and also the ensuing tsunami caused a widespread damage in many countries including Egypt. According to several studies, that also consider Arab documentary

sources (e.g. Ambraseys et al., 1994; Guidoboni and Comastri, 1997, 2005; El Sayed et al., 2000) the most severe earthquake destruction was suffered by Candia (Heraklion today), Crete, but also Peloponnese towns were affected. Intense damage was reported in Cyprus, Palestine (city of Safad), and also in Egypt where Cairo and Alexandria resulted to be severely hit: in Alexandria the city walls and the lighthouse partially collapsed and many houses were ruined. The area of the reported damage was so large that some were induced to doubt that it was a unique event and to hypothesize that historical accounts put together effects of a series of earthquakes occurred in different seismic zones. There is a general consensus that the earthquake (or the bigger earthquake in case of a multiple source scenario) occurred in the EHA with  $M_w$  around 8.0 (Papadopoulos et al., 2014).

Effects of the tsunami are reported in several coeval sources with explicit reference to the towns of Candia (Heraklion), Crete, for Italian sources, and of Acre (Israel), Alexandria and Nile for Arab sources. In Alexandria, vessels broke moorings in the harbour and crashed against rocks, the tsunami reached the town walls and many shops and warehouses were flooded and destroyed (Ambraseys, 1962; Antonopoulos, 1980; Guidoboni and Comastri, 1997; El Sayed et al., 2000; Papadopoulos et al., 2007; Papadopoulos, 2011).

In this study, a 1303-like tsunami with source in the EHA is considered as one of the Worst-case Credible Tsunami Scenarios.

## 2 The Worst-case Credible Tsunami Scenario Analysis (WCTSA)

Tsunami scenarios are used as a tool to plan the immediate response of coastal communities to a tsunami attack by emergency managers in the context of tsunami early warning systems, as well as to carry out hazard, vulnerability and risk analyses in the frame of long-term mitigation policy planning. In this latter case, scenario-based techniques are often seen as a means that is alternative or complementary to probabilistic approaches. A typical product of a probabilistic tsunami hazard analysis (PTHA)

is the inundation area or the maximum sea surface elevation that are expected in a given place (stretch of coastline, port, beach, etc.) in a given return period, say 100 or 500 years. The method is essentially mimicked from the probabilistic analysis applied to earthquakes and was first suggested in early '80s by Lin and Tung (1982). The concept was independently developed and applied to evaluate the maximum expected wave at the coast in the Italian seas by Tinti (1991a, b) and in Morocco by El Alami and Tinti (1991), but it is only in more recent times that it was fully developed, discussed and extensively applied (see e.g. Geist and Parson, 2006; Burbidge et al., 2008; Lorito et al., 2008, 2015; Gonzalez et al. 2009; Sørensen et al., 2012; Leonard et al., 2014; Brizuela et al., 2014). The main drawback of this method is that it relies upon the occurrence probability distribution function of the tsunamigenic sources, that cannot always be estimated reliably, especially if submarine mass failures are involved. Therefore, it is often restricted to application where only tsunami of seismic origin are taken into account, with only rare exceptions (see Grilli et al., 2009).

The scenario-based approach stands on the idea that in many applications concerning tsunami mitigation what matters most is not the knowledge of the effects of a full spectrum of tsunami events with associated probability of occurrence, but only the knowledge of the features of the extreme events. Typically in a given coastal place one wants to assess the most extended inundation area due to tsunamis, the maximum tsunami height, etc. In principle, one could derive this information from a PTHA by considering longer and longer return times, but it is more practical to avoid all the probability assessment complications and consider only the largest sources and therefore the largest produced tsunamis. The main steps of the scenario-based hazard analysis can be summarized as follows: (1) identification and characterization of the sources (earthquakes, volcanos, landslides) capable of producing the largest tsunamis for a given target location, (2) simulation of the tsunamis and computation of the desired metrics in the target place, (3) computation of the local aggregate (envelope) scenario by combining all the individual scenarios. This method can be called the method of the Probable Maximum Tsunami (PMT) (see Grilli et al., 2011) or equivalently the method

of the Worst-case Credible Tsunami (WCT) (see Tonini et al., 2011). It is noted that the specifications “probable” and “credible” in these locutions means (i) that the scenarios considered are reasonably grounded on scientific acceptable assumptions (e.g. the maximum possible earthquake size of a given seismic zone) and (ii) that very im-  
probable scenarios are ruled out (e.g. the impact of a meteorite or asteroid in the sea just off the target place), which is a possible catastrophic case, but with an extremely low probability of occurrence.

The above steps lead to the computation of an envelope or aggregate scenario in a given place that forms the basis for the subsequent studies. In particular, in this paper we estimate the maximum area of inundation for the governorate of Alexandria and then we evaluate the exposure, vulnerability and damage of the buildings in the residential area and the number of the affected people.

### 3 The selected tsunamigenic sources

Seismotectonics focused on tsunami activity and potential in the eastern Mediterranean has been the subject of several recent works with regional and also local character (see Soloviev et al., 2000; Tinti et al., 2005; Fokaefs and Papadopoulos, 2007; Papadopoulos et al., 2007; Salamon et al., 2007; Lorito et al., 2008; Ebeling et al., 2012; Sørensen et al., 2012; Yolsal-Çevikbilen and Taymaz, 2012). Most of these works were mainly concentrated on tsunamis generated by earthquakes, but also tsunamis due to landslides are of some relevance in the region. Indeed, it is known (Fokaefs and Papadopoulos, 2007; Salamon et al., 2007; Papadopoulos et al., 2014) that tsunamis that occurred off Syria, Lebanon, Israel and Palestine, and that are associated with earthquakes in the Dead Sea Transform fault, have been attributed to submarine sediment failures triggered by seismic load rather than to the sea floor deformation caused by earthquakes (since faults are too far from the sea and with mechanism unfavorable to tsunamigenesis). Numerical simulations of tsunamis induced by these submarine mass failures (see the tsunami following a 1.25 km<sup>3</sup> volume collapse in the Akhziv submarine

Interactive Discussion

canyon, 30 km north of Haifa in Salamon et al., 2007) show that their effects may be disastrous near the source, but are minor in the far field. For this main reason, we restrict our attention only to scenarios of tsunamis caused by earthquakes in the present study. It is worth mentioning here also the work by Garziglia et al. (2007) who studied a huge, about 14 km<sup>3</sup>, mass-transport deposit, called S16, that was triggered during the Holocene sea-level rise circa 10 kyr BP in the western Nile margin in correspondence with exceptional river sediment supplies. Consequently, they simulated a tsunami with a source only some 50 kilometers north of Alexandria. The numerical simulations show that waves with height of 4 m can attack the coast (Garziglia et al., 2007). However, our evaluation is that probably the mass transport was too slow to generate a tsunami and that, even accepting that it was tsunamigenic, it is a scenario by far less probable to occur today than scenarios of tsunamis of seismic origin. Therefore, in the following we do not take it into account.

Considering all the main tsunamigenic seismic zones of the Mediterranean, Sørensen et al. (2012) were able to show that the sources that are most influential for the area of Alexandria are essentially the EHA and the WHA. Following their suggestion, and on the basis of the tsunami history showing that the largest tsunamis known to have hit the town were due to the AD 365 earthquake in the WHA and to the 1303 earthquake in the EHA, we selected two scenarios with faults represented in Fig. 2 and with geometry and focal mechanism given in Table 1. The magnitudes of the scenario earthquakes are compatible with the ones taken by Sørensen et al. (2012). More in detail, the selected WHA source coincides with the fault introduced by Lorito et al. (2008), characterized by an  $M_w = 8.5$ . Instead, the geometry of the EHA source is borrowed from the paper by Yolsal-Çevikbilen and Taymaz (2012), but the position of the fault is chosen in order to maximize the tsunami propagation effect towards Alexandria.

In addition to the above cases, we explore also a third scenario, that is a tsunami of seismic origin from a fault in the Cyprus Arc (CA). The reason is that this zone is known to be tsunamigenic (Fokaefs and Papadopoulos, 2007) and to be susceptible to large magnitude earthquakes. We assume a  $M_w = 8.0$  earthquake, not far from

the assumption made by Salamon et al. (2007) who take  $M_w = 7.8$ , while Sørensen et al. (2012) and Papadopoulos et al. (2014) estimate a maximum magnitude for this area of  $M_w = 7.5$ . Further, the position and strike of the fault in the present study (see Fig. 2 and Table 1) is selected in such a way to maximize tsunami effects on the Egypt coasts, while a similar case treated by Salamon et al. (2007) was assumed in a different location along the arc, with a strike more suitable to direct most of the tsunami energy against Israel.

#### 4 Tsunami simulations

Tsunami simulations have been conducted by using the code UBO-TSUFUD that solves shallow-water non-linear equations with dynamic boundary conditions and a finite difference technique, where the unknowns are the sea surface elevation with respect to the still sea level and the two horizontal fluxes or discharges, i.e. the product of the sea surface elevation by the particle horizontal velocity components (Tinti and Tonini, 2013). The initial conditions for the tsunami scenarios are computed by means of the analytical Okada's formulas for the static deformation of an elastic half-space induced by a uniform co-seismic slip on a rectangular fault (Okada, 1992). The hypothesis is that the sea floor vertical displacement is transferred instantaneously and unchanged to the sea surface, which can be considered a quite acceptable assumption. The complementary hypothesis is that the initial horizontal velocity is identically zero. Both such conditions are usual for tsunami simulations, unless more precise knowledge of the rupture process (e.g. dynamic rupture pattern, heterogeneous slip distribution, etc.) is obtained from additional data. Pure transparency is imposed on the open boundaries allowing the tsunami waves to go across the grid limits with no spurious back-reflection, while on the coast an algorithm based on extrapolating the seaside wave profile landward determines if a cell is wet or dry and the shoreline position is computed dynamically (Tinti and Tonini, 2013).

Interactive Discussion

To ensure that the model computes adequately the tsunami interaction with the irregular coast in the target place (i.e. Alexandria) and at the same time to optimize computer resources, the strategy of nested grids is adopted by the code UBO-TSUDF with a full-coupling between the outer (coarser) and the inner (finer) grid. Usually, the finer grid is totally contained within the outer grid, and this is the case for the scenarios treated in this paper, but this is not a requirement of the code. Notice that in the area of overlapping, that is common to both grids, computations are carried out only in the finer grid. Technically, if we consider a multilevel nesting with level  $N + 1$  grids nested in the grid of level  $N$ , the computation domain of the level  $N$  grid is the one obtained as the difference between the area covered by the grid and the area that is the union of all grids at level  $N + 1$ . In total, the grid system in this work is formed by four grids, from level 1 to level 4, that are shown in Fig. 2. The external grid, at level 1, covers all the eastern Mediterranean sea with a 3 km resolution and is large enough to contain the faults of all tsunami scenarios as well as the respective tsunami initial conditions. Since the deformation produced by Okada's equations decays quite slowly with the distance from the fault (which results in an initial tsunami source virtually extending up to infinity), sea elevations in magnitude less than 5 cm have been put equal to zero, and a proper tapering window has been used to avoid discontinuities. The modified initial fields are given in Fig. 2. The second grid, grid 2, covers the south-eastern part of the Levantine sea with a 1 km resolution. Grid 3 (200 m resolution) and grid 4 (40 m resolution) cover a much smaller area and are centered respectively on the governorate of Alexandria and on Alexandria city, that is the study area in this paper.

The topo-bathymetric data sets used to build the grids are listed in Table 2. Grids 1 and 2 have been built by using basically GEBCO (30 arcsec) and SRTM ( $\sim 90$  m) databases. The local grids 3 and 4 have been integrated with bathymetry data in UTM coordinates from nautical charts (1 : 5000 and 1 : 10 000), and also from the work by El-Geziry et al. (2007) for the Western Port of Alexandria, while SRTM topography has been cross-checked with Google Earth data in selected control points. Specific attention has been posed to reconstructing the shoreline position and the shape of break-

waters and jetties in the ports of Alexandria and Dekhila by making use of Google Earth images. It is worth mentioning that bathymetry of the different grids have to be harmonized along and in the neighborhood of the common boundaries, especially in near-shore regions to avoid artificial depth discontinuities that might give rise to irregular wave behavior even resulting in numerical instabilities.

### 4.1 The WHA Tsunami

The WHA earthquake produces a tsunami that focuses most of its energy towards the Libyan coasts and SW-ward (see Fig. 3), whereas only a marginal part of the waves travel towards the eastern Mediterranean. Sea level maxima in the local grid 3 shown in Fig. 4 are above 2.5m along almost the entire Alexandria governorate coastline, with peaks above 4 m in correspondence with the Borg El Arab area, possibly related to local bathymetric features. We observe that we made reference to the grid number only for the sake of simplicity. To be more precise, when we show the fields in the region of computation covered by the grid of level  $N$ , we show at the same time also the fields calculated in all the nested grids at level larger than  $N$ . The fact that there is perfect continuity between fields across the grid boundaries as it appears from Figs. 3 and 4 is a demonstration of the good performance of the code UBO-TSUDF. The same comment applies to all other figures of the paper where tsunami fields are represented. Propagation fields depicted in Fig. 5 at intervals of 20 min for the first 140 min show the main front travelling quickly towards the south of the central Mediterranean basin. The last four panels of Fig. 5 show the propagation in the Levantine sea over grid 2. The tsunami advances with a leading negative wave attacking Cyprus in the north and Alexandria in the south about 80 min after the earthquake. Notice the strong bending of the southern part of the front to the east of Alexandria due to refraction, with the result that the tsunami front tends to align with the depth isolines and attacks the coast at a normal angle (see the bottom panels of Fig. 5). The tsunami produces a relevant flooding of the beaches to the west of Alexandria, of the port of Dekhila, of the Wassat area and of the harbour facilities of the Western Port of Alexandria (Fig. 6). The flooding

is less evident for the eastern port. In the areas where the inundation distance is larger, flow depth can exceed 2.0–2.5 m. Notice that the WHA scenario tsunami does not flood the tombolo between the Eastern and Western Ports of Alexandria, which was probably inundated by the AD 365 event. This is not, however, a serious drawback of the scenario, since probably the topography today is not the same as at the time of the historical tsunami. What is confirmed is that the tsunami is damaging, although not disastrous for Alexandria.

## 4.2 The EHA Tsunami

The EHA tsunami directs the bulk of its energy towards Alexandria (see Fig. 7). This is mainly due to the assumed strike of the fault, and is a well-known feature of essentially 2-D wave processes originating from long linear sources. The beam of sea level maxima is orthogonal to the fault and is strong along the entire path from the source to the Alexandria coasts where they amplify. The zoom on the area of Alexandria (see grid 3 represented in Fig. 8) shows that maxima may exceed 2 m offshore and that tsunami causes extended inundation all along the town coast from SW to NE. The propagating front is shown in the snapshots of Fig. 9. From panels at 20 and 40 min it is clear that the tsunami travels with a leading positive wave towards Alexandria. The panel at 1 h shows the strong interaction of the tsunami with the continental margin, causing the strong bending of the front and the remarkable shortening of the wavelength (with crests and troughs coming closer to each other). The snapshot at 1 h 20 min shows that the front is very strong not only in Alexandria, but even in the whole region to the east of the town, that indeed is covered only by the 1 km resolution grid 2. The inundation in the town of Alexandria is depicted in Fig. 10 (grid 4). It is seen that most of the coast is flooded and in some zones the tsunami penetrates a few kilometers deep in the interior beyond the coastal ridge. Flooding in the area of the old port of Alexandria (Ras El Tin) is noticeable, but not dramatic: the outer breakwaters of both Eastern and Western Ports of Alexandria are overtopped and the harbour facilities together with the

Interactive Discussion

Looking at tide gauge 2, one observes that the ranking of the scenarios as regards the size and the arrival time is unchanged. Waves are remarkably amplified by a factor of 2 or more. Tide gauge 4 is the last virtual sensor facing the open sea: here EHA and WHA exhibit comparable maximum amplitudes, although at different arrival times.

5 Moreover, EHA signal amplitude is reduced with respect to tide gauge 2, while comparable values are observed for WHA in the two virtual sensors, a similar observation holding also for CA. The time histories of tide gauge 3 show the protecting effect of the harbour jetties and the interaction of the harbour with incoming waves of different wavelengths. The size of the EHA signal is smaller than for coastal tide gauges 2 and  
10 4. The signal, however, seems to be dominated by normal modes of the harbour basins more than by the source signature: the oscillations persist with little decay for a longer time and seem to be “more periodic” with period of about 30–35 min for all scenarios. These harbour basins normal modes are even more evident in the time-history relative to WHA: the amplitude is comparable to those observed in tide gauges 2 and 4, and  
15 remains almost unchanged for more than four hours.

A further consideration is that the arrival times of tsunamis at the coastal tide gauges are in the order of 70–80 min and, in case of early warning, would allow exposed people to react and to evacuate, provided that evacuation plans are implemented.

## 5 The aggregate scenario

20 Building the aggregate scenario is the last step of the scenario-based tsunami hazard analysis. After selecting the appropriate tsunami metrics or parameters, one produces the aggregate fields by taking the envelope of the individual scenarios, which more precisely means by selecting the extreme of the values of the individual scenarios for each point of the field. In this study a fundamental parameter is the depth of the  
25 water column in the inundated area that has been shown in Figs. 6, 10 and 14 for the respective WHA, EHA and CA cases. The corresponding envelope is shown in Fig. 16, which gives also the maximum inundation line superimposed on a Google

Earth image, marking the boundary between the area that is not inundated by any one of the scenario tsunamis and areas that are inundated by at least one tsunami. It has to be remarked that in practice the envelope is very similar to the EHA scenario, with the exception of the Dekhila port area, where WHA gives the predominant contribution.

The identification of a single scenario with the aggregate one is not surprising, though it is not the rule, but usually one finds a dominant scenario contributing to the aggregate much more than all the others (see Tonini et al. (2011) for the town of Catania; see also Table 3 in Sørensen et al. (2012), where the deaggregated weight of the single scenarios is estimated for various towns in the Mediterranean).

Of interest is also the field of the maximum value of the speed of the material fluid particles, whose aggregate is depicted in Fig. 17. Notice that in this example the portrayed field is restricted to the still sea region and does not extend into the flooded area on land. Expectedly, the velocity is small offshore where the water is deeper, and increases in the shallow water region near the shore. The zones of the highest speed values, exceeding  $3 \text{ m s}^{-1}$ , include the tip of the breakwaters and the narrow mouths of the harbours, especially in the Eastern and Western Ports of Alexandria.

## 6 Exposure and vulnerability

Exposure and vulnerability to tsunamis are concepts often used, but rarely well defined in tsunami studies, in spite of the abundant literature on tsunami hazard, vulnerability, risk and resilience that has been particularly flourishing after the megatsunamis of December 2004 in the Indian Ocean and of March 2011 in Japan. Indeed, in spite of attempts to systematize the conceptual framework, often researchers use the same terms for different concepts or different words for the same concept (see the discussion on different approaches made by Birkmann and Fernando, 2008; see also Camarasa Belmonte et al., 2011). It is not in the scope of this paper to provide a critical review of the subject, but for the sake of clarity it is relevant to highlight the main concepts we use in our application. In this paper, the vulnerability of an element (or asset) to tsunami

Interactive Discussion

is related to its capacity or ability to resist to the tsunami impact and depends on the properties of the element. Usually one considers two broad categories of elements (the physical inanimate objects, like buildings, cars, vessels, boulders, and the animate beings, like animals and persons), that can be taken individually or in groups (e.g. complex of buildings, marinas with boats and yachts, coastal forests, cultivated lands, passengers of ferries, tourists at the beaches, . . . ), and that can be also assembled at a higher level of complexity (examples of vulnerable elements that can be placed at the top of complexity hierarchy are ecosystems, social communities like villages and towns, . . . ). The more complex is the element under study, the more difficult is to measure its capacity of resisting to the attack of a tsunami and, consequently, the harder is to provide properties and criteria to measure its vulnerability. And it is exactly in the attempt of coping with a wide range of complexities that often researchers mix concepts and place undefined boundaries between hazard, exposure, vulnerability, risk, resilience, etc.

In this paper, we will confine our attention only to the vulnerability of buildings, and we will leave the assessment of vulnerability of more complex elements to further analyses. As for the tsunami exposure, we simply consider that an element is exposed to a tsunami if it is found in an area that can be reached by the tsunami. Therefore, elements that are in the sea, like vessels and offshore structures are exposed, while elements that are on land, like edifices or persons are exposed if their positions fall within the inundation area, and not exposed if they happen to be outside the inundation area. This simple definition identifies the exposure with the geographical position of the elements, that of course can be static (for a building), or variable in time (for persons who might be on a beach susceptible of flooding in the day, and in a house far away from the sea in the night). Since the extension of the flooded area depends on the analyzed tsunami scenario, as was shown in the previous sections where the WHA, the EHA and the CA tsunamis were investigated, accordingly also the number of elements exposed varies from case to case.

In the frame of the above definitions, the goals of our work are to assess the vulnerability of buildings that are found inside the inundation area of the aggregate scenario (shown in Fig. 16) and to estimate the number of persons that are exposed to tsunamis.

## 7 Buildings vulnerability assessment

Tsunami vulnerability is still a new science and has basically derived its chief analysis tools from earthquake and flood vulnerability sciences that have a much longer tradition. The main idea is that the vulnerability of an asset is described by means of damage functions. A damage function puts in relation one or more hydrological parameters of the tsunami with the damage level of the asset and can be inferred from empirical data (i.e. post-event field surveys or laboratory experiments), from numerical simulations (e.g. theoretical studies of the structural effects of tsunami waves and currents), and by means of heuristic analyses, or through a combination of these methods. Though it is known that tsunami loading on buildings is exerted via a number of various hydraulic forces (hydrostatic, surge, impact, buoyancy, etc.) that act in combination, in most studies the tsunami parameters taken into account are the height of the water column and less often the horizontal velocity of the flow and the momentum flux (that is the product of the column water height by the squared velocity). Unfortunately, the speed of the tsunami stream is quite difficult to determine for real tsunamis in the flooding areas and was measured only in exceptional cases (see Fritz et al., 2012). Instead, the height of the tsunami and tsunami run-up are standard observables of the tsunami post-event surveys. There is no surprise, therefore, that most of the damage functions in the literature are based on the height of the water column, also known as the flow depth (see Ruangrassamee et al., 2006; Koshimura et al., 2009a, b; Suppasri et al., 2013).

In this paper we make use of damage functions that are specific for different categories of buildings based on the work by Leone et al. (2011) on the Indian Ocean tsunami, who identified classes and subclasses of buildings mainly on the ground

of their structural materials and characteristics. These classes were revisited and adapted to the Euro-Mediterranean building stocks in the European project SCHEMA, where also the original damage functions were reappraised and modified (Valencia et al., 2011; Gardi et al., 2011). The five main buildings classes from A to E considered in this paper are briefly summarized in Table 3 in a version where all references to the buildings position is removed, since, according to our definition given above, the geographical position of any asset pertains to the asset exposure rather than to the asset vulnerability. For each buildings class Valencia et al. (2011) defined six levels of damage from D0 (no damage) to D5 (total collapse), and, as a first stage, determined the corresponding fragility curves, providing the probability that a building of that class might incur in a damage  $D_j$  ( $j = 0, 1, \dots, 5$ ) as a function of the maximum flow depth. In the second stage, from the fragility curves, they determined the damage functions, providing the maximum damage  $D_j$  expected for a building of a given class as a function of the maximum flow depth. A synoptic view of these curves is summarized in the damage matrix of Table 4 where each column represents the discrete version of a damage curve for a specific buildings class. Note that the damage matrix used in this study and presented in Table 4 is a modified version of the original table by Valencia et al. (2011). In that formulation, a single damage level (“light damage”) was attributed to any building affected by a flow depth in the interval 0–1.8 m. The field observations carried out for recent events like the 2011 Tohoku tsunami evidenced that this assumption is not appropriate, as described and discussed for instance by Suppasri et al. (2013). In that work, tsunami damage analyses performed on about 250 000 buildings after the Tohoku event showed that for an inundation depth of 1 to 1.5 m, more than 10 % collapsed and about 55 % suffered major damages. To account for this variability, we modify classes A, B and C in Table 4: in particular, with respect to Valencia et al. (2011) class A is completely redefined, class B is modified for levels D0–D4 and class C for levels D0–D1. The modifications we propose derive from the fragility curves reported in Reese et al. (2007) on the basis of the damage observed after the 17 July 2006 Java tsunami.

The matrix provides a tool that is very simple and easy to implement: if one knows the maximum flow depth attacking a building of a specific class, the matrix renders the maximum expected incurring damage (see e.g. the applications by Atillah et al. (2011); Ribeiro et al. (2011) in the frame of the project SCHEMA).

## 8 Buildings damage analysis

The aggregate inundation area is portrayed in Fig. 16 on a Google Earth image embracing all the coast of Alexandria from Al-Amriyah and El-Agami to Al-Montazah. It shows that in all the coastline to the north-east of the old town, extending from Al-Gomrok to Al-Montazah (see toponyms in Fig. 1) where most of the modern residential Alexandria has been built, the inundation is limited only to beaches, since the coastal ridge is high enough to oppose to the tsunami waves. On the contrary, the inundation in the zone from the Eastern Port to Al-Amriyah and El-Agami is more severe and in some areas penetrates deep in the interior. All the three harbours here (the Eastern and Western Ports and the Dekhila Port) are inundated, which may be better appreciated in the zoom of Fig. 18. In the Eastern and Western Ports, inundation affects the breakwaters and the former island of Pharos, that is the docking area for cruise ships, as well as the area of Ras El Tin Palace and the Ras El Tin beach. In the Dekhila Port, where the main activity is loading/unloading of cargos, the sea water goes about 2–3 km far from the sea line, flooding the container terminal and deposits, silos, tanks. . . The area suffering the major inundation is found in Wassat, around Al Max, where there is no protection from the outer breakwater and where two flooding tongues penetrate 4 km deep (see Fig. 18) following topographical lows corresponding to the drainage channels of the Lake Maryut. Here the flooded area is occupied by big industrial plants and installations (e.g. the Solvay Alexandria Sodium Carbonate company that is the main producer of soda ash for the domestic Egyptian market; the Titan Cement company, a multinational company based in Greece that incorporated the most important Egyptian cement producers in 2008; the Alexandria Petroleum Company refinery), whereas

Interactive Discussion

the Al Max residential quarters are located at a level high enough to be almost untouched.

To the south-west of Dekhila the inundation is very strong and involves further installations of the Alexandria Petroleum Company refinery to the west, and a vast residential area in Abu Talat and in El-Agami (Fig. 16). Since in this paper our main interest is in the assessment of damage to buildings, we concentrate our analysis on this area. Indeed, the damage matrix of Table 4 is inadequate for industrial installations and infrastructures, that should be rather analyzed by means of specific studies, since in this case not only the direct effects are of importance, but the induced cascade effects might be even more relevant and worth of a thorough investigation (see the disaster following the meltdown of three reactors of the Fukushima Daiichi nuclear power plant induced by the Japan 2011 tsunami; see also Cruz et al., 2011). Therefore, we leave this subject for further studies.

The buildings damage analysis in the area to the south-west of the Dekhila port is essentially based on images of the Google Earth database, including satellite imagery and ground pictures. Since the beginning of vulnerability assessment science, remote sensing with global coverage has been seen as a powerful and practical tool to conduct vulnerability studies over vast coastal areas. It is worth stressing that from the experience gained in very many applications it has been shown that, though in principle ground surveying is necessary to validate remote sensing based analyses, often it results only in slight corrections, and a few control points may suffice for a good validation (see Tonini et al. (2011); Pagnoni et al. (2014) for buildings vulnerability studies on eastern Sicily towns).

In this paper the buildings damage analysis has been performed according to the following 5 step procedure. First, the area of inundation resulting from the envelope scenario with 40 m resolution is put in a Google Earth file format. This allows one to import the inundation area in the Google Earth satellite images, as displayed in Figs. 16 and 18 already referred to above. Here it is worth stressing that the need to superimpose the computed inundation area to georeferenced Google Earth images derives from the

Interactive Discussion

fact that the potential tsunami damage is estimated by cross-checking data of tsunami inundation (available in maps produced by the tsunami simulation code UBO-TSUFUD) with data on the buildings (inferred from the Google Earth satellite images). It is further worth underlining that such images are quite recent in the Alexandria region, since they were mostly acquired in years 2014 and 2015.

Step 2 consists in the land use characterization of the flooded area with the purpose of identifying the zones with buildings where to focus vulnerability and damage analysis. This enabled us to restrict the analysis to the zone to the south-west of the Dekhila port illustrated in green in Fig. 19 and to discard other sectors of the aggregate flooded area because either they are industrial zones (APC refinery) or container terminals (Dekhila port) (see the red zones of Fig. 19) or they are basically with no buildings (e.g. beaches, swamps...).

Step 3 is the creation of a discretization grid suitable for both flow depth analysis and buildings vulnerability analysis. When no automatic digital tool for image processing is available and when the extension of the inundation area is large, painstaking visual inspection can be a very heavy and time-consuming process, with costs increasing with the grid resolution. In our study we have considered as a useful compromise a 80 m resolution tessellation, by which we have covered the part of the inundation area resulting from the selection of step 2. Figure 20 portrays the flow depth (water column height) of the envelope scenario for the 80 m grid, that is easily built from the 40 m grid of the tsunami numerical model by proper node selection, since by purpose the size of the tessellation grid cell is a multiple of the simulation grid. This is an advantage but is not a strict requirement, since all normal interpolation methods are straightforward and adequate to compute coarser fields from higher resolution maps. From the flow depth map (Fig. 20) one can observe that the highest values are in the range of 3–4 m and that are mostly found close to the shoreline. Expectedly the flow depth decreases moving landward, but there are two remarkable high zones with values between 2–3 m (red in the figure) that can be explained as the effect of local topographic lows.

[Interactive Discussion](#)

In step 4, by making use of the adopted tessellation, we identify all the buildings that are located within the selected portion of the inundation area and assign each of them to one of the five buildings classes from A to E given in Table 3. The analysis is performed for each cell of the tessellation. We have counted a total of 2433 inundated cells, covering an area of about 15.571 km<sup>2</sup>. At this stage, a more accurate inspection showed that as many as 479 cells (around 20 % of the total) have no buildings: most of these are located on the coast and cover the area between the coastline and the first line of buildings (see Fig. 21 displaying the map of the building density per cell). It is worth observing that in attributing the building to a given cell, buildings on the cell boundary are counted in the cell if their footprint is inside the cell in a proportion larger than 50 %, which entails some degree of overestimation, with a bias that is larger in percentage, the smaller the cell size is. On the other hand, when deducing the flow depth in each cell (which is done in step 3), the bias decreases along with the cell size. This explains that a further requirement of the step 3 tessellation (in our case 80 m) has to be a compromise between the counting of buildings (with estimate improving with the size of the cells) and the assumption that the value of the inundation depth is constant within a cell (with approximation worsening with the cell size). The total number of constructions within the flooded zone has been found to exceed 12 000. Most of them are brick houses with some reinforced structural elements (class D), or mere brick houses (class C) or more solid buildings with reinforced concrete (class E), and only a few are weak brick houses (class B) or light constructions (class A). The distribution of buildings into the adopted SCHEMA classes is shown in Table 5. The number of buildings per cell, that can also be seen as a building density, is shown through the histogram of Fig. 22 and the map of Fig. 21. To help readability, all classes of Fig. 22 have width 2 and are denoted on the horizontal axis with an even number. This means that a generic class denoted by 2n contains all tessellation cells counting either 2n - 1 or 2n buildings. The first class is an exception: it has width 1 since it contains only cells with 0 buildings. Of the 2433 (80 m × 80 m) cells, as many as 479 result to be with no constructions, as already noted before. Considering only the occupied cells, one

observes that the highest columns of the histograms are the classes ranging from 3 to 8 buildings. Further, the average density results to be 5.1 bpc (here bpc stands for buildings per cell) and, if one restricts only to the occupied cells, it increases to about 6.3 bpc. The building density map (Fig. 21) shows that no-building cells are found (i) along the shoreline, (ii) in alignments normal to the shore, corresponding to stream banks, and (iii) in areas close to the industrial (on the left) and port (on the right) installations.

The fifth step of our procedure is the evaluation of the damage that might incur to each building by applying the modified damage matrix shown in Table 4. The result of the analysis is summarized in Table 6. The first four columns give respectively the flow depth discretized in steps consistent with the damage matrix, the corresponding number of cells, the area they cover, and the overall number of buildings they contain. From the table, one sees that the number of cells, and therefore the corresponding area, decreases strongly as the flow depth increases. The area where the sea level is found to be less than 1 m results to be as much as 59 % of the total, while only 5.8 % is inundated by more than 2.5 m of sea water. Consequently, also the number of affected buildings (column 4 of the table) is an inverse function of the flow depth. It is worth noting that the building density in the least inundated cells turns out to be 5.56 bpc which is somewhat larger than the average (5.1 bpc). Notice further that this density tends to decrease as the flow depth increases: it is 4.0 bpc for the central flow-depth class (1.5–2 m) well below the average, and goes down to the extreme value of 0.95 bpc for the most inundated cells. This shows that the areas subject to the highest tsunami inundation (usually found close to the shoreline or the river banks) have been traditionally considered by local people not adequate for population settlements. Determining if this has occurred as the result of specific tsunami hazard awareness or of more generic flooding hazard awareness or of other reasons related to construction technique (inadequacy of soil for foundation) is out of the scope of the present analysis. However it is a noteworthy feature since it has a positive consequence on reducing the potential tsunami damage.

[Interactive Discussion](#)

The other columns of Table 6 display the frequency distribution of the damage level from D0 to D5. Notice that since by choice all the considered buildings are found inside the inundation area, none of them falls in the D0 damage category, that applies only to buildings not affected by any tsunami wave. The sub-table including the columns from D1 to D5 can be commented by considering rows, i.e. the flow depth, or by considering columns, i.e. the damage level. In the first case, one may notice that when the flow depth is small (less than 1.0 m) all buildings incur only damage D1, with the exception of less than 0.2 % of constructions incurring in damage of type D2. With higher values of flow depth, the distribution of buildings tend to be less peaked, involving also other levels of damage, and at the highest flow depth values, i.e. between 3.5–4 m, some buildings are found to incur in the maximum level of damage, D5. The final result of this analysis is that 11 732 buildings are expected to have a damage not exceeding D1 (light), as many as 479 a damage not exceeding D2 (important), 143 a heavy damage (D3) and only 39 and 5 buildings can be affected respectively by partial collapse (D4) and total collapse (D5).

The buildings damage estimates summarized in Table 6 are the result of the 5-step procedure illustrated above where at some point we have introduced a convenient 80 m resolution tessellation in place of the 40 m grid resulting from the tsunami simulations. In doing so we have assumed that the flow depth of the envelope scenario is constant in each cell of the tessellation and have taken this constant value, say  $d$ , to assess the damage to all constructions inside the cell, with account for their respective vulnerability class. It is trivial to see that the tessellation cell spans an area covered by 4 tsunami grid cells, in general with different flow depth values. If we denote respectively the highest and smallest of such values with  $d_{\max}$  and  $d_{\min}$ , and repeat the damage assessment by making use of these values, we will obtain respectively higher and lower damage levels for the buildings in the cell. Table 7 gives the total number of buildings in each damage class resulting from applying the analysis in all cells of the inundation area. Comparing Table 7 with the last row of Table 6, one sees that figures computed with the flow  $d$  are bracketed by the ones obtained by using  $d_{\max}$  and  $d_{\min}$ , which provides an

[Interactive Discussion](#)

estimate of the uncertainties deriving from the coarser discretization of the tessellation grid. In our case, the general pictures of the damage analyses of Tables 6 and 7 do not differ substantially, and therefore the 80 m resolution can be considered acceptable in this respect.

The vulnerability analysis illustrated here is the result of the careful identification of the building types that are located in each single cell of the tessellation, which is a manual procedure taking long if one extends the analysis to the full set of the tessellation cells, as was done before. One could wonder how the final results are affected if one takes into consideration only a suitable selected cells sample. To this purpose we have selected a number of random samples, each of 243 cells, thus corresponding to the 10 % of the total tessellation set. The results are shown and discussed in the Appendix.

## 9 Population exposure analysis

The population exposure is computed from census data of Alexandria. Since we are considering a residential area, we assume that there is no seasonal variability, which is usually related to touristic fluxes. Further, we neglect also the daily variability assuming that all residents are at home, which is consistent with the worst-case scenario approach adopted in this study.

Census in Egypt is conducted regularly every 10 years since 1976 and there are data for the years 1937, 1947 and 1960. The last survey was carried out in 2006 by the Central Agency for Public Mobilization and Statistics (CAPMAS). The census data provided by CAPMAS regard mainly constructions and population. As to the former, one can trace the huge expansion of the building patrimony for the whole Egypt as well as for the individual governorates. The increase of the number of buildings for the governorate of Alexandria is shown in the histogram plotted in Fig. 23 for the interval 1944–2015 where the data of the national surveys are interpolated and extrapolated for those years not covered by the surveys. One can observe a more than 10 times

Interactive Discussion

increase in the last 55 years with building stock passing from 31.3 thousand to about 390 thousand in 2015.

The population of Egypt has a general growing trend with an increase of more than 22 % in the years from 1996 and 2006, which is rather homogeneous throughout the country. In the same decade, the governorate of Alexandria population grew by 20 % passing from 4 million to 4.8 million people while in the last 55 years the population grew by a factor slightly less than 3.3 (see the histogram of Fig. 24). By combining census data on buildings and population, one can draw the curve of the people density per buildings as a function of time, which is also provided in Fig. 24. One can see that this density went remarkably and steadily down from 69.5 to about 11.6 ppb (persons per building) in the second half of 900, and that it started to increase slowly after 2000, reaching the value of 12.4 ppb in 2015. This people density is the basic figure that allows us to estimate the persons resident within the aggregate inundation area shown in Fig. 20. The last column of Table 6 gives the number of exposed persons that are resident in areas with different estimated level of flow depth, where the figures are obtained simply by multiplying the corresponding number of buildings listed in column 4 by the average density factor of 12.4. The total number of exposed people results to be 153 916, which is quite large in absolute value, though it is only 3.2 % of the total population of the governorate. We stress that the population density we have used is the average value for the governorate of Alexandria evaluated for the year 2015 and that using values specific for the districts where the inundation area extends could provide more accurate, but expectedly not so different, estimates.

## 10 Comparison with other studies

The tsunami vulnerability of Alexandria has been the subject of only one previous paper, to the knowledge of the authors. On making use of remote sensing and field data, Eckert et al. (2012) estimated the building vulnerability of Alexandria by applying a vulnerability model that is based on flow depth values, but also on several other attributes

Interactive Discussion

of the buildings. Since three basic factors of Eckert et al. (2012) study (i.e. usage of remote sensing data, usage of field data, damage functions taking into account flow depth values) are common with the present paper analysis, one could expect similarities in the result, which is unfortunately not true. The two studies happen to be incomparable and totally inconsistent in the conclusions, since the hazard analysis, that is a prerequisite for the vulnerability analysis is quite different. Adopting a bathtub-like approach and skipping numerical modelling, Eckert et al. investigated two tsunami scenarios where the sea level rises by 5 m and by 9 m uniformly all along the coast of Alexandria due to a tsunami attack. Since under this hypothesis the inundation area covers the entire coast of the governorate of Alexandria, for practical reasons they restricted the analysis to the districts of Al-Gomrok and Al-Montazah (see Fig. 1 for toponyms). However, according to our study based on worst-case credible scenarios, the buildings in these two districts result to be almost untouched by the tsunami, since the inundated area turns out to be more to the south-west, and even here run-up values do not reach 10 m height.

# 11 Conclusions

In this paper we have investigated the tsunami hazard of Alexandria by using the WCTSA technique. We have considered three scenarios (WHA, EHA and CA) where tsunamis are generated by big earthquakes in the subduction arcs marking the boundary between the Africa and the Eurasia plates. All these are remote sources, which means that seismic shaking is expected to be moderate in Alexandria and that tsunami is the major threat.

The inundation resulting from enveloping the inundation maps of the individual cases happen to be very similar to (although not coincident) the EHA scenario, that is therefore the predominant one; the WHA scenario adds a relevant contribution especially in the El Dekhila area. Flooding affects mostly the Alexandria coast to the west of the old town where a number of tongues (two in the area between Al-Gomrok and El

Dekhila and two more to the south west of El Dekhila) penetrates some kilometres on land beyond the coastal ridge, primarily exploiting the drainage channels of the Lake Maryut. We have applied a buildings vulnerability model elaborated in the European project SCHEMA to estimate the damage to buildings in the affected residential areas of El Dekhila and Al-Amriyah. Our finding is that 12 398 constructions can be damaged (most of which only slightly) by the tsunami and that about 154 000 residents are exposed, which corresponds to the 3.2 % of the total population of the governorate of Alexandria.

The present study can be considered preliminary and will be refined in future work. One key point is the hazard analysis that should investigate all the possible credible large tsunami sources. In our discussion on tsunami hazard for Alexandria we have mentioned a Holocene huge mass flow whose tsunamigenic potential was investigated by Garziglia et al. (2007). Though we decided to discard this as a credible source for a tsunami, it would be interesting to explore whether small scale submarine sediment movements are able to generate tsunami affecting Alexandria more severely than the earthquake-induced tsunamis, and hence to contribute to the aggregate scenario. Further, uniform-slip earthquake sources have been assumed here, while it is well known that for all large earthquakes the on-fault co-seismic slip occurs in patches with the slip magnitude much higher than the average value. Third, as regards vulnerability analysis, we remark that the damage to buildings might be only a fraction of the total economic loss especially when the hit area is full of large industrial plants with high pollution potential like the ones in the analyzed districts of Alexandria. In addition, these industries act as attraction points for workers, which increases the number of persons exposed to tsunami especially during day light. This is also true for the port structures that are key port terminals for the whole Egypt country. Deepening these topics is at the frontier of the today's tsunami vulnerability analysis and will be subject of future research.

# Appendix A

Counting the buildings in all the cells of the area resulting from the envelope of tsunami inundation maps can be a very long procedure, taking time resources increasing with the extension of the area, which can cover tens or hundreds of km<sup>2</sup>. In the case of Alexandria studied here, the inundation area covers more than 15 km<sup>2</sup> and involves 2433, 80 m × 80 m, cells and 12 398 constructions. In order to reduce the time for the analysis, one might consider to apply the vulnerability analysis to a subset of such cells, under the assumption that results are representative of the entire set. We have investigated this possibility by taking as many as 10 samples of the 2433 cells, each consisting of 243 cells (about 10 % of the total). Each sample resulted from a random selection (corresponding from sampling a uniform distribution of integers running from 1 to 2433), tempered however by the criterion that the selected cells should be distributed almost uniformly over the entire inundation area. This latter requirement was checked by visual inspection and was used to avoid concentration of cells in specific geographic zones with properties far from the ensemble properties (e.g. with very low or very high buildings density, or with very low or very high flow depth, etc.).

To each of the 10 samples we have applied the procedure described in the paper section on vulnerability analysis, and then estimated the values for the entire set. In particular, we have counted the number of buildings for each building type from A to E and the total number of buildings of the sample. It is easy to see that if  $N_S$  is one of these numbers, the statistical standard deviation associated to it is  $\sigma_S = \sqrt{N_S}$ , and the estimates of the corresponding number for the entire set are  $\alpha N_S$  and  $\alpha \sigma_S$  where  $\alpha$  is the ratio between the total number of cells and the number of cells in the sample. In our case  $\alpha = 10$ . The results are shown in Fig. A1 where for each building types the estimates are provided together with the error bars. They are compared with the corresponding values we obtained by using the full set of data shown in Table 6. It can be observed that for most samples the real values (solid black lines) are within the  $1\sigma$

error bar (exception are samples 2, 5 and 6) and that for all samples they fall within the  $1.5\sigma$  error bar.

If we extend the analysis from the above building classification to the damage evaluation, we obtain a similar plot (see Fig. A2). The number of buildings with a given level of damage obtained by the samples usually falls within  $1\sigma$  error bar, and always within the  $1.5\sigma$  error bar. This proves that making estimates on samples can be a viable tool to obtain satisfactory results and to save analysis time, though, however, the cost to pay is to introduce same statistical error.

*Acknowledgements.* The research conducted in this paper is the follow-up of a research initiated during the European FP6 project TRANSFER (Contract no. 037058) and continued in the frame of the FP6 project SCHEMA (Contract no. SST5-CT-2006-030963). It is also partially financed by the on-going FP7 project ASTARTE – “Assessment, Strategy And Risk Reduction for Tsunamis in Europe” (FP7-ENV2013 6.4-3, Grant 603839).

**Table 3.** Buildings classes after the project SCHEMA (Valencia et al., 2011). Any reference to building exposure is removed.

Class		Building attributes	Storeys
I. Light constructions	A1	Very light isolated constructions. Wooden, timber, clay materials	0 to 1 level, rarely 2
	A2	Very light constructions without any design (like in a shantytown). A set of huts very rudimentary, built using wood, clay, timber, slabs of zinc	1 level only
	A3	Light constructions very concentrated (like in old towns). Wooden, timber and clay materials	1 level only
II. Masonry constructions and not reinforced concrete	B	Brick not reinforced. Cement, mortar walls, fieldstone, masonry	1 or 2 level
	C	Individual buildings, villas. Brick with reinforced column and masonry filling	1 or 2 level
	D	Large villas or collective buildings, residential or commercial buildings. Not reinforced concrete	1 to 3 level
III. Reinforced concrete constructions	E1	Residential or collective structures or offices, car parks, schools. Reinforced concrete, steel frame	0 to 3 levels
	E2	Residential or collective structures or offices, car parks, schools, towers. Reinforced concrete, steel frame	> 3 levels

# Scenario-based assessment of buildings damage and population exposure

G. Pagnoni et al.

**Table 4.** Building damage matrix after the project SCHEMA (Valencia et al., 2011) modified in buildings classes A and B following the fragility curves proposed by Reese (Reese et al., 2007). The first column reports the description of the damage level. The columns from A to E give the flow depth intervals in meters. Notice that damage D0 is attributed only to buildings reached by no tsunami waves.

Damage level		Class A	Class B	Class C	Class D	Class E
No damage	D0	0	0	0	0	0
Light damage	D1	0–0.5	0–1	0–2	0–2.8	0–3
Important damage	D2	0.5–1	1–2	2–4	2.8–4.5	3–6
Heavy damage	D3	1–2	2–4	4–6	4.5–6.5	6–9.5
Partial collapse	D4	2–3	4–5	6–8	6.5–9	9.5–12.5
Total collapse	D5	> 3	> 5	> 8	> 9	> 12.5

# Scenario-based assessment of buildings damage and population exposure

G. Pagnoni et al.

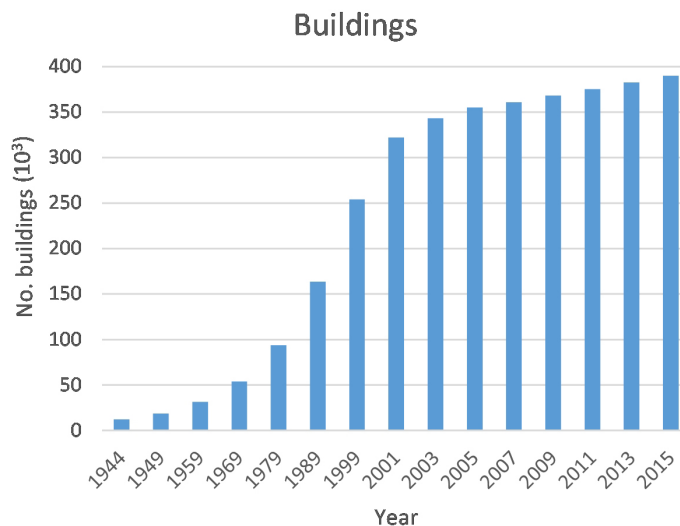

**Figure 22.** Distribution of buildings per cell in the inundated area selected in step 2 (see text). Each class is denoted by an even number. All classes, but the first on the left, have width 2. This means that the column denoted with 2 contains all cells having either 1 or 2 buildings, the next denoted with 4 contains cells with 3 or 4 constructions, etc. Instead the first column contains only cells with no buildings. Figures in the columns are the number of cells.
