Abstract

In this paper, we present a deterministic approach for tsunami hazard assessment for the city and harbour of Sines - Portugal one of the test-sites of project ASTARTE. Sines holds one of the most important deep-water ports which contains oil-bearing, petrochemical, liquid bulk, coal and container terminals. The port and its industrial infrastructures are facing the ocean southwest towards the main seismogenic sources. This work considers two different seismic zones: the Southwest Iberian Margin and the Gloria Fault. Within these two regions, we selected a total of six scenarios to assess the tsunami impact at the test site. The tsunami simulations are computed using NSWING a Non-linear Shallow Water Model With Nested Grids. In this study, the static effect of tides is analysed for three different tidal stages MLLW (mean lower low water), MSL (mean sea level) and MHHW (mean higher high water). For each scenario, tsunami hazard is described by maximum values of wave height, flow depth, drawback, maximum inundation area and runup. Synthetic waveforms are computed at virtual tide gauges at specific locations outside and inside the harbour. The final results describe the impact at Sines test site considering the single scenarios at mean sea level, the aggregate scenario and the influence of the tide on the aggregate scenario. The results confirm the composite source of Horseshoe and Marques Pombal fault as the worst case scenario with wave heights above 10 m which reaching the coast approximately 22 minutes after the rupture. It governs the aggregate scenario with about 60% and inundates an area of 3.5 km².

Keywords: Tsunami hazard assessment, numerical modelling, aggregate scenarios

1 **1 Introduction**

2 Tsunamis are low frequency but high impact hazards for coastal societies. The December 26th,
3 2004 Indian Ocean and the March 11th, 2011 Tohoku striking tsunami events raised awareness
4 due to the enormous loss of life and property. The Indian Ocean event in 2004 demonstrated
5 the need for operational early warning systems around the world. However, seven years later,
6 the 2011 Tohoku event showed the limitations of the scientific knowledge concerning tsunami
7 sources, coastal impacts, and mitigation measures. Since then, in the NEAM region (North East
8 Atlantic, Mediterranean and connected seas) many efforts have been addressed to understand
9 better the tsunamigenic sources and to improve the tsunami hazard assessment capabilities.
10 Within the NEAM region, the Gulf of Cadiz is among the most tsunami hazardous areas. The
11 historical reports include events dated back to 60 BC (Mendonça, 1758, Baptista and Miranda,
12 2009; Kaabouben et al., 2009), but the geological evidence indicates high energy events back
13 to 218 years BC (Luque et al., 2001).

14 The Portuguese coast is highly exposed to tsunami threat from local and regional active tectonic
15 sources. The main tsunamigenic area is the SWIM (South West Iberia Margin), with a number
16 of considerable SE dipping inverse faults (Fig. 2b) (Zitellini et al., 2009, Matias et al., 2013).
17 The most severe tsunami was the 1st November, 1755 caused by the Lisbon earthquake with an
18 estimated magnitude of 8.5 by Martins and Mendes Victor (1990). This magnitude was more
19 recently re-evaluated by Solares and Arroyo (2004) with an estimate of 8.5 ± 0.3 . The tsunami
20 hit the entire northern Atlantic basin with huge impact in Iberia and Morocco (Fig. 2) (Baptista
21 and Miranda 2009). In the 20th century, the 28th February 1969 earthquake with a magnitude
22 of 7.9 (Fukao, 1973) caused a small tsunami of 0.5 m amplitude in Lagos and Cascais (Fig. 1a)
23 (Baptista et al., 1992; Baptista and Miranda, 2009). The tsunami waves hit the coast circa 3
24 a.m. (UTC) in low tide conditions (Baptista et al., 1992) but no significant damage was
25 observed.

26 The second tsunamigenic zone to be considered is the Gloria Fault (Fig. 2c). The Gloria fault
27 is a segment of the Eurasia-Nubia plate boundary. It is a large strike slip fault, located between
28 24°W and 19°W , with scarce seismic activity but was nonetheless the location of several large
29 events during the 20th Century, in particular the 25th November 1941 earthquake, a submarine
30 strike-slip event of magnitude 8.3-8.4 (Gutenberg and Richter, 1949) and the 26th May 1975
31 with magnitude 7.9 (Lynnes and Ruff, 1975; Grimson and Chen, 1986).

1 In recent years, a considerable number of tsunami hazard assessment studies were published
2 for the North East Atlantic area. Most of these studies focus on the tsunami impact in the Gulf
3 of Cadiz using a scenario based approach namely: Lima et al. (2010), Omira et al. (2010), Omira
4 et al. (2011), Atillah et al. (2011), Baptista et al. (2011a), Renou et al. (2011), Omira et al.
5 (2013), Benchekroun et al. (2013) and Lemos et al. (2014). Recently, **Omira et al. (2015)**
6 published a probabilistic tsunami hazard assessment for the North East Atlantic.

7 In this study, we use a Deterministic Tsunami Hazard Assessment (DTHA) approach to
8 evaluate the tsunami impact in Sines. The study area contains the country's most important
9 deep water port which is connected to big industrial complexes by fragile infrastructure such as
10 pipelines and conveyor belts. In summer the city is a popular tourist destination.

11 The DTHA approach consists of studying the impact of specific tsunami events – tsunami
12 scenarios - in the study area. The impact is described in terms of maximum wave height
13 (MWH), maximum flow depth (MFD), maximum drawback (MDB), maximum inundation area
14 (MIA) and maximum inland penetration (MIP). We further built the aggregate scenario plotting
15 the MWH and MFD in each cell considering the contribution of the individual scenarios (Tinti
16 et al., 2011).

17 The final results are presented in integrated hazard maps for all the considered and the aggregate
18 scenario. Each integrated hazard map consists of MWH, MFD, MDB, MIA and MIP of the
19 corresponding scenario. The static effect of tides is analysed for three different tidal stages mean
20 lower low water (MLLW), mean sea level (MSL), and mean higher high water (MHHW).
21 Further we present the contribution of each scenario to the aggregate tsunami impact at MSL
22 condition.

23

24 **2 Study area and Digital elevation model**

25 **2.1 Study area**

26 Sines is a city located on the west littoral margin of the Iberian Peninsula about 150 km south
27 of Lisbon (Fig. 1a). The study area includes the city of Sines and parts of the surrounding
28 municipality covering a coastline of about 35 km. The city has approximately 15000 inhabitants
29 (Instituto Nacional de Estatística, 2011) and about 5000 floating population because of
30 economic and touristic purpose.

1 Sines plays a major role in terms of energy production and storage. There are 2 great production
2 centres of oil and gas industry (GALP refinery and Repsol YPF petrochemical industrial
3 complex) which are connected via pipelines to oil-bearing and petrochemical terminal of Sines
4 harbour (Câmara Municipal de Sines, 2007). The harbour is the country's most important deep
5 water port (with 28 m depth) situated south of the city centre and consists of 5 terminals: liquid
6 bulks, liquid natural gas, petrochemical, container and multipurpose; as well as fishing and
7 leisure ports (Porto de Sines, 2014). The liquid natural gas terminal (LNG) contains facilities
8 for loading and unloading processes of methane carriers, expedition facilities at LNG terminal
9 depot, three LNG storage tanks, LNG processing facilities and natural gas dispatch facilities for
10 the pipeline connecting the Sines LNG terminal to the Natural Gas Transport Network. At the
11 multipurpose terminal coal is stored in stockpiles and is transported by a conveyor belt to Sines
12 thermoelectric power plant. The power plant uses seawater for cooling of the generators which
13 is captured and returned at the intake and restitution points close to São Torpes beach (Fig. 1b).
14 The majority of the harbour facilities and big areas of the power plant are situated in possible
15 inundation area below the 25 m topographic contour. The liquefied natural gas storage deposits
16 is located right behind the port. In case of a destructive tsunami, facilities or leaking pipelines
17 raise the danger of explosion and may cause an environmental disaster.

18 The study area limits are East to West from 8°47'00" to 8°55'00" and North to South from
19 37°58'00" to 37°55'00". In the northern part the landscape is designed by the influence of the
20 magmatic batholith of Sines with a steep and rocky seafront. On the south westernmost part of
21 the rocky outcrops begins the area of the port. The main jetty is facing south with a maximum
22 elevation of 15 m above MSL and a width of 10 m (Fig. 1b). The liquid bulks terminal and
23 petrochemical terminal are protected by the jetty against strong swell reaching the Portuguese
24 coast mainly from northwest. The smaller jetties protect the fishing and leisure ports, which
25 also protect the shell-shaped beach "Vasco da Gama" (Fig. 1b). Northwards is located the city
26 centre and the majority of domestic property on the top of the batholith with altitudes higher
27 than 25 m above sea level. Further east, the remaining terminals: multipurpose, container and
28 natural gas protected by a recently enhanced jetty of approximately 2.5 km length (Fig. 1b).
29 The container terminal is currently under construction due to expansion at the easternmost area
30 of the port exposing new economic value to tsunami threat. Further southeast at the coast are
31 situated the jetties to protect the intake and restitution points of the EDP thermoelectric power
32 plant. Right beyond the jetties southwards begins the popular highly visited beach of "São
33 Torpes" which is already a part of the natural park "Costa Vicentina" (Fig. 1b). The main port

1 areas and Vasco da Gama beach have their coastline facing southwards. The main tsunamigenic
2 sources are located south of the study area. Due to its openness and exposure to the sea, the
3 impact of tsunamis and other marine hazards like sea level rise are of great concern for the area.

4

5 **2.2 Digital elevation model**

6 In order to guarantee a good representation of the study area, we built a high-resolution Digital
7 Elevation Model (DEM). We combined three different datasets and set them to the same
8 reference system using GIS tools (Geographic Information System). We validated the final
9 dataset using real time kinetic GPS on field trips. The DEM is crucial for computation of
10 inundation on the dry land and near shore propagation.

11 Different types of datasets were used: a set of high resolution LIDAR dataset (Direção-Geral
12 do Território, 2011), a bathymetric model (Instituto Hidrográfico de Portugal, 2012), and a
13 nautical chart (Instituto Hidrográfico de Portugal, 2010). The LIDAR dataset of 2011 has a
14 resolution of 2 m. The data is available in PT-TM06/ETRS89 projection and referenced to the
15 altimetric datum of Cascais 2.08 m above hydrographic zero. The dataset of the bathymetric
16 model contains a grid based point information 100 m spacing based on hydrographic surveys.
17 In the overlapping areas of LIDAR dataset and the bathymetric model preference has been given
18 to the more recent and higher resolution LIDAR dataset. For further improvement, the nautical
19 chart of Sines (The nautical chart of Sines consists of 2 different charts one showing a more
20 detailed view of the port with a scale of 1:12500 and the general chart of the test site with a
21 scale of 1:30000) was scanned, geo-referenced, and digitized. Depth and altimetry data of the
22 bathymetric model and the nautical charts are referenced to the hydrographic zero. All data was
23 referenced to MSL which lays 2 m above hydrographic zero in Sines. In order to validate the
24 final datasets we used field surveyed data points with GPS-RTK (Global Position System Real
25 Time Kinetic). In order to fill gaps of the LIDAR data we used GPS-RTK to collect data to
26 implement a recently constructed extension of a jetty not yet present in the datasets. After
27 combination, validation and adaption of the existing datasets a grid representing the final study
28 area with 10 m resolution has been computed. The resulting DEM properly represents Sines
29 test site, especially the near shore areas, as LIDAR dataset is of very high resolution. The 10 m
30 grid represents small rocky outcrops of the batholith in between Vasco da Gama beach and the
31 leisure port. Other features like the connection to the main jetty in front of the multiuse-, liquid
32 natural gas- and container-terminal or the jetty at the leisure port suffer from the low resolution.

1

2 **3 Numerical Model and Nested Grids**

3 Numerical modelling of tsunamis is commonly divided into three stages: generation,
4 propagation, and inundation. We use an in-house developed and benchmarked numerical code
5 NSWING (Non-linear Shallow Water Model with Nested Grids) (Miranda et al., 2014) to
6 model the tsunami. The model supposes an instant seabed deformation that has been rendered
7 using the half-space elastic theory (Okada, 1985) embedded in Mirone suite (Luis, 2007). The
8 vertical sea bottom deformation is assumed to be equal to the free surface deformation and
9 transferred to the ocean surface.

10 The code solves linear and non-linear approximations of shallow water equations (SWEs) to
11 calculate tsunami propagation and inundation in a Cartesian or spherical reference system. In
12 the deep ocean nonlinear convective inertia forces are of secondary order as waves travel with
13 amplitudes much smaller than water depths. When the tsunami enters shallow coastal areas, the
14 non-linear convective inertia force and bottom friction become increasingly important. We
15 applied non-linear SWEs approximations in all instances, for deep-ocean, near-shore and on-
16 shore propagation.

17 NSWING employs a dynamically coupled system of nested grids and solves SWEs using an
18 explicit staggered finite leapfrog numerical scheme for linear terms and an upwind scheme for
19 nonlinear terms. **NSWING and the incorporation of the system coupled nested grids is mainly**
20 **based on the code COMCOT (Liu et al., 1998).** The code further applies a radiating boundary
21 condition, allowing wave motion pass from one domain to other, through boundaries with very
22 small reflections. A moving boundary algorithm (Liu et al., 1995), based on “wet” and “dry”
23 cells, is adopted to track shoreline movement while inundation.

24 Propagation and behaviour of tsunamis change because of varying bathymetry when entering
25 coastal areas. To model the impact in Sines we implement a dynamically coupled system of
26 nested grids. We interpolated the half minute North Atlantic grid (GEBCO, 2014) to 640m
27 resolution for the parent grid. Using four layers and applying a refinement factor of 4 we
28 achieved 10m final resolution in the DEM.

29 The amplitude of the tide in south-west Portugal is above 2m and must be taken into account in
30 Sines. (Baptista et al., 2011a) To study the tide effect, the tidal variation of the last three years
31 have been considered. We used the values of Mean High Water (MHW) and Mean Low Water
32 (MLW) from 2012 to 2014 and calculated the mean to obtain the MHHW and MLLW

1 respectively and referenced them to MSL. The MHHW is 1.22m above the MSL and the MLLW
2 0.88m underneath the MSL. These values have been subtracted and added respectively to the
3 established DEM. For each designed scenario we ran the model in MHHW, MSL and MLLW
4 conditions to study the static influence of the tide and is presented in the aggregate scenario
5 (Antunes, 2014).

6

7 **4 Tsunamigenic Scenarios**

8 To design the tsunami scenarios we use the main seismogenic source zones and the associated
9 Maximum Credible Earthquake (MCE) (Miranda et al., 2008; Omira et al., 2009). We used the
10 typical faults (TFs) presented in Omira et al. (2009) except the Portimao Bank Fault (PBF)
11 because it does not steer enough energy to the western Portuguese coast.

12 The seismogenic sources used here are SWIM and Gloria. For this study we considered four
13 TFs in the SWIM area and their MCE scenarios to reproduce initial condition for tsunami
14 propagation namely: the Cadiz Wedge Fault (CWF), the Goringe Bank Fault (GBF), the
15 Horseshoe Fault (HSF) and the Marques Pombal Fault (MPF) (Fig. 2b). Additionally we use a
16 seismogenic scenario consisting of a composite rupture of HSF and MPF (HSMPPF), proposed
17 by Ribeiro et al. (2006) for the source of the 1st November 1755 earthquake. This source is also
18 stated in Matias et al., (2013) with a maximum magnitude estimation of 8.75. This magnitude
19 value coincides with the upper limit of the magnitude estimate for the 1755 earthquake of
20 Solares and Arroyo (2004): 8.5 ± 0.3 . Once this source has been proposed we can not evaluate a
21 worst case scenario impact without considering it.

22 The major tsunami event in the SWIM is the one associated with the 1st November 1755
23 earthquake and the exact source remains unknown. Numerous studies and campaigns have been
24 carried out in order to solve the quest of the 1st November 1755 tsunamis source. Data (multi-
25 channel reflection seismic, refraction seismic, multibeam swath Bathymetry) has been gathered
26 to reveal more accurate information of the tectonic in the SWIM. This investigation in the
27 SWIM area revealed numerous geological evidences of the used TFs. Several authors proposed
28 distinct sources for this event.

29 Johnston (1996) suggested the GBF as a possible candidate source of the 1st November 1755
30 event through scale comparison of isoseismal maps with the 28th February 1969 event. Using
31 tsunami backward ray tracing methods Baptista et al., (1998) suggested a source location for
32 the 1755 tsunami closer to the Portuguese coast. Zitellini et al. (1999) found an active thrust

1 fault, the MPF through interpretation of multi-channel seismic data. Gutscher et al. (2002)
2 concluded that the identified active subduction, the CWF is a candidate source for 1755 event
3 and must be considered in natural hazard assessments. Further neotectonic structures and
4 deformed seafloor sediments at the HSF also show clusters with shallow seismicity (Gràcia et
5 al., 2003). Some authors suggest to consider multiple fault rupture scenarios to explain the high
6 magnitude observed in 1755 (Zitellini et al., 2001, Gràcia et al., 2003, Ribeiro et al., 2006,
7 Mendes-Victor et al., 2005). Nevertheless the exact source of the 1755 Lisbon event is still a
8 matter of discussion. These uncertainties related to 1755 source and the tectonic processes
9 acting in the SWIM confirm the need of systematic tsunami hazard assessment in surrounding
10 areas.

11 The Gloria zone is our far field source area. The Gloria fault is a transform fault running from
12 24° West to 19° West (Laughton and Witmarsh, 1974). Three strong magnitude earthquakes
13 occurred in the last 130 years: 22 December 1884 (Moreira, 1984), 25 November 1941 –
14 Magnitude 8.3 (Gutenberg and Richter, 1949, Moreira, 1984) and 25 May 1975 – magnitude
15 7.9 (Lynnes and Ruff, 1975 and Grimson and Chen, 1986). The 25 November 1941 and the 26
16 May 1975 produced small tsunamis recorded in the tide stations in the North East Atlantic basin
17 (Debrach, 1946, Moreira, 1984, Baptista et al., 1992, Baptista and Miranda, 2009). The 25
18 November 1941 epicenter location and the focal mechanism are presented in Baptista et al.
19 (2011b). We used these parameters to draw a 1941 like scenario for the Gloria source zone. The
20 TF parameters are presented in table 1 and the fault is presented in figure 2.

21

22 **5 Results**

23 We ran a total of eighteen simulations. For each typical fault we considered three tide
24 conditions: Mean Lower Low Water (MLLW), Mean Sea Level (MSL) and Mean Higher High
25 Water (MHHW). The results are presented in integrated maps of maximum wave height
26 (MWH), maximum flow depth (MFD), maximum drawback (MDB), maximum inundation area
27 (MIA) and maximum inland penetration (MIP) (Fig. 3a-e). For the scenarios at MSL, we
28 additionally present synthetic waveforms (Fig. 4 and 5) at chosen positions (Fig. 1b).

29 In figure 6 we present the aggregate scenario considering all calculated models. Figure 7 shows
30 the inundation and the drawback limits considering the aggregate scenarios at the three tide
31 conditions.

1 **5.1 MSL Results**

2 The analysis of figures 3 - 5 shows that all SWIM scenarios produce heavier inundation and
3 drawback in comparison to the Gloria fault scenario. The Gloria scenario produces MWH
4 values of approximately 1m while the SWIM scenarios produce MWH above 10 m. Figures 3
5 - 5 present results of the individual scenarios and their absolute values are summarized in table
6 2. The HSMPF scenario, corresponding to the worst case scenario, produces 18.6 m of MWH
7 and 3.47 km² of inundated area. Detailed analysis of figure 3d shows flow depths greater than
8 0.5 m in 90% of the inundation area. The GBF and HSF scenarios, with MWH above 15 m,
9 also produce inundation above 3 km² (cf. table 2 and Fig. 3b and Fig. 3c). The remaining SWIM
10 scenarios (CWF and MPF) still produce MWH above 10 m and leave more than 2 km²
11 inundated.

12 Among the SWIM scenarios, the MPF produces the weakest impact in Sines but still with MWH
13 above 10 m (cf. Fig. 3e). Maximum runoff up to 19.3 m occurs during the HSF scenario at the
14 south of the test site (cf. table 2). All SWIM scenarios produce sufficient drawback (see blue
15 lines in figure 3a-e) to leave the intake and restitution points of the thermoelectric power plant
16 dry. MDB occurs during the composite tsunami model HSMPF. The Gloria scenario produces
17 1.2 m MWH in certain areas and inundates low lying areas such as beaches. The flooded area
18 of the Gloria scenario is less than 0.2 km² and the area at the intake and restitution points does
19 not stay dry (Fig. 5a and table 2).

20 The analysis of the synthetic waveforms at the virtual stations shows similar periods and
21 tsunami travel time (Fig. 4) for all SWIM scenarios. First arrival occurs in all records at point
22 P3 (blue curves in figure 4 and figure 5b). Clearly distinguishable are the records for the Gloria
23 scenario presented in figure 5b which shows an arrival time of about 85 minutes after initial sea
24 surface displacement. The maximum amplitude is about 0.4 m with a period of approximately
25 10 minutes (Fig. 5b). The record in tide gauge point P2, at 5.6 m depth right in front of the
26 intake and restitution points, confirms that no considerable drawback is happening throughout
27 the event (Fig. 5b). The records of the SWIM scenarios GBF, HSF, HSMPF, MPF show periods
28 of 15 to 20 minutes and for the CWF approximately 25 minutes. Maximum amplitudes are
29 obtained at the tide gauge P2 for the tsunamis produced by CWF at the 3rd wave, HSF and
30 HSMPF at the 1st and 3rd wave, respectively. At point P2 waveforms indicate that the cell stays
31 at least once dry for all SWIM scenarios (Fig. 4). Attenuation is visible for all scenarios after 6
32 hours runtime except for the Gloria scenario where attenuation occurs after 15 hours.

1 **5.2 The aggregate scenario and the influence of the tide**

2 The aggregate scenario map depicts the extreme hazard values field point by taking the
3 envelope of all individual scenarios. We present aggregate scenarios of MWH, MFD, MDB,
4 MIA and MIP for the different tide conditions (Fig. 6).

5 The aggregate scenario map (Fig. 6), considering all stages of the tide, shows 4.8 km² MDB
6 area and 4.1 km² maximum inundated area. Maximum runup values over 20 m occur close to
7 the cliffs at Vasco da Gama beach and are reached in MHHW condition. In other areas, such as
8 behind the liquid bulks and petrochemical terminal and at the railway connection to the port,
9 maximum runup values exceed 15 m. MWHs above 10 m have been modelled along the entire
10 coastline (Fig. 6). In high tide condition the inundation area is over 4 km² and 3.5 km² in low
11 tide condition considering the aggregate scenario. Inundation area is 5% bigger at MSL and
12 14% at MHHW compared to MLLW (Fig. 7). MDB area is 16% greater at MLLW and 11%
13 greater at MSL than in MHHW conditions (Fig. 7). The flooded area at Vasco da Gama beach
14 is not significantly bigger at MHHW as the area behind the beach is confined by the steep
15 topography. Moreover figure 6 shows that the mean MFD values are about 1.5 m higher at
16 MHHW than at MLLW in the area of the beach. Other areas behind the multipurpose and
17 container terminal or at São Torpes beach show clearly greater inundation areas in high tide
18 condition (Fig. 7). The limits of MDB and MIP for the aggregate scenario concerning MLLW,
19 MSL and MHHW are mapped in figure 7.

20

21 **6 Discussion and Conclusions**

22 We ran a total of 18 scenarios to study the tsunami impact at Sines. Our results show that all
23 SWIM scenarios cause severe inundation and drawback. To complement the integrated hazard
24 maps of MWH, MFD, MDB, MIA and MIP we recorded synthetic waveforms at chosen points
25 (see figure 1). The signals of the waveforms are diverse. This fact may be explained due to
26 differences in the TF parameters. Waveforms from HSF, MPF, GBF and HSMPF are
27 comparable in terms of period and arrival time (Fig. 4a-e). These TFs are dextral reverse with
28 SW-NE trending and the hanging block in the SE. They are all located in the SWIM area. They
29 are distinguishable through their dimensions and slip. Other parameters like strike, dip and rake
30 are similar. Among the single fault scenarios the GBF is the biggest single fault producing 17.1
31 m MWH in the study area (see table 2). The HSF, although smaller, produces a similar
32 inundation and wave height pattern as the slip is 5 m higher compared to the GBF (see table 1).

1 The MPF is smaller in terms of dimensions and has a slip of 8 m and therefore produces the
2 weakest tsunami in the SWIM (Table 1 and Fig. 3e). Nevertheless, MWHs are above 10 m and
3 MPF is the nearest fault to the test site that produces short tsunami travel time (22 minutes in
4 figure 4e). The composite scenario HSMPF is the worst case scenario and combines the effects
5 of both faults: First wave arrives 22 min after the earthquake and tsunami triggered by HSMPF
6 causes worst inundation and drawback in Sines. The CWF is a subduction slab and has different
7 fault parameters compared to the other TFs in the SWIM. The shallow east dipping slab has
8 dimensions of 170x200 km and a slip of 20 m (see table 1). The analysis of the waveforms
9 shows that wave periods generated by the CWF are larger than the others from the TFs in the
10 SWIM. This fact may be explained by the larger displaced area by this scenario. Cape St.
11 Vincent (Fig. 2b) in the southwest of Portugal might act as an obstacle to the tsunami leading
12 to reduce the impact. The CWF has higher impact in the southern part of the study area but with
13 decreasing inundation and amplitudes towards the north. Nevertheless, wave amplitudes of 5 m
14 cause considerable inundation in the northern part of the port. The waves produced by CWF
15 reach Sines 38 minutes after the earthquake (Table 2). The Gloria fault located at 37°N between
16 14°W and 24°W produces the smallest inundation in the study area. It is a transform fault
17 triggering slight vertical movement because of 160° rake with a slip of 11 m (Table 2). The
18 scenario produces amplitudes between 0.3 - 0.4 m with approximately 10 minute period (Fig.
19 5b). The earthquake in 1941 generated similar waveforms showing weak attenuation with
20 amplitudes around 0.4 m in Cascais (Baptista et al., 1992; Baptista and Miranda, 2009). Site
21 effects, observed in some few coastal locations (Fig. 5a), caused MWH over 1 m with some
22 smaller inundation in unhabituated area between the container terminal and the intake and
23 restitution points of the EDP power plant. Because of the larger distance to the Portuguese coast
24 the tsunami travel time is approximately 85 minutes (Table 2).

25 We also calculated flow velocities for the composite scenario HSMPF at MSL for different
26 stages of tsunami propagation. The median values are about 10 m/s in the inundation area at all
27 terminals in the port. Some extremes of about 20 m/s or higher occur close to the jetties and in
28 the inundation area when the flow depth values are small depending on the considered
29 propagation instant. In general we find that flow velocities increase with lower flow depth
30 values in the inundation area.

31 Considering the HSMPF scenario in MSL conditions the pipelines at the liquid bulk and
32 petrochemical terminal are entirely inundated with up to 5 m flow depth values. These
33 structures are subject to flow velocities of about 10 m/s at first wave impact. At the 17 m

1 topographic contour, the pipelines behind the liquid bulk and petrochemical terminal are not
2 affected by the tsunami (Fig 3d). We find similar flow velocity values at the multipurpose
3 terminal where the pipelines of the liquefied natural gas storage tanks pass. Here the maximum
4 flow velocity values there are slightly above 10 m/s at wave impact, and MFD are between 5 –
5 10 m. The conveyor belt and the stockpiles at the multipurpose are nearly entirely inundated up
6 to 5 m and show flow velocities of 10 m/s at first wave impact. The pipelines at the liquid bulk,
7 petrochemical and multipurpose terminal are inundated by all scenarios in the SWIM. These
8 quantitative DTHA results indicate a high risk of potential damage in case of tsunami impact.
9 However, in the building vulnerability is beyond the scope of this study.

10 The tide has important influence on tsunami impact in Sines. The tidal regime is semi-diurnal
11 with an amplitude of about 2 m. As expected the aggregate scenario at MHHW condition caused
12 larger inundation areas and higher MFD values. On the other hand the aggregate scenario at
13 MLLW produced larger drawback areas. A tsunami impact at low tide does not exclude the risk
14 of heavy inundation and increases MDB by 16% compared to MHHW (Fig. 7).

15 Our results are compatible with the PTHA results for the Northeast Atlantic. **Omira et al. (2015)**
16 show that wave heights exceeding 5 m have a probability of 45% of occurrence in 500 years at
17 Sines. Only the scenarios of the SWIM area have the capacity to produce such high tsunami
18 impact along the Portuguese west shore. **Moreover our results are comparable with the unique**
19 **historical report showing that the tsunami did not reach the city (Falcão, 1987).**

20 We computed a map showing the contribution of the individual scenarios to the aggregated
21 scenario at MSL (Fig. 8). Four scenarios contribute to the aggregate scenario, namely CWF,
22 GBF, HSF and HSMPF. The main actor in the aggregated model is the HSMPF scenario that
23 contributes with more than 60% independent of the tidal amplitude (Table 3). The scenarios
24 CWF, GBF, HSF contribute about 12±4% to the aggregate model. The MPF and Gloria do not
25 contribute to the aggregate scenario (Table 3 and Fig. 8).

26 Concluding we find that all SWIM scenarios (CWF, GBF, HSF, MPF and HSMPF) demonstrate
27 high impact in Sines test site. Still the weakest source, the MPF, causes considerable inundation
28 and MWH above 10 m. The proximity of the faults within the SWIM results in short tsunami
29 travel times. For the models MPF and HSMPF we calculated 22 minutes propagation time from
30 the source to Sines test site. This closeness to possible tsunami sources raises the need of an
31 efficient early warning system and meticulously planned evacuation for the port and other

1 coastal areas. Also, coastal societies need to be educated and prepared for possible tsunami
2 impact.

3 The Gloria fault differs from the other scenarios and produces MWH of approximately 1 m in
4 certain areas, one order of magnitude less than the scenarios in the SWIM.

5 The aggregate scenario allows to consider a set of faults to produce a synthesis of different
6 scenarios. We further state the importance of this tool as important indicator for evacuation and
7 city planners. We showed with the contribution map that different sources play varying
8 importance in our study area. Although the worst case scenario may contribute more to the
9 aggregate scenario than other considered faults, still other faults may have more significant
10 impact on other parts of the test-site. The aggregate scenario is a valuable tool for quantitative
11 presentation of tsunami impact from multiple sources. Especially in areas exposed to threat
12 from near-field sources, the aggregate scenario maps help establishing accurate evacuation
13 plans and thus allowing efficient and faster reaction to tsunami warning.
