9 ABSTRACT

- 10 Forecasting a catastrophic collapse is a key element in landslide risk reduction, but also a very
- 11 difficult task, owing to the scientific difficulties in predicting a complex natural event and also to
- 12 the severe social repercussions caused by a false or a missed alarm. A prediction is always
- 13 affected by a certain error, however when this error can imply evacuations or other severe
- 14 consequences a high reliability in the forecast is, at least, desirable.
- 15 In order to increase the confidence of predictions, a new methodology is here presented.
- Differently from traditional approaches, it iteratively applies several forecasting methods based 16
- 17 on displacement data and, also thanks to an innovative data representation, gives a valuation of
- 18 how the prediction is reliable. This approach has been employed to back-analyse 15 landslide
- 19 collapses. By introducing a predictability index, this study also contributes to the understanding
- 20 of how geology and other factors influence the possibility to forecast a slope failure. The results
- 21 showed that, contrarily to what is generally believed, geomechanics plays an indirect role in
- 22 landslide predictability; instead kinematics, and all the factors influencing it, is the key feature.
- 23 Keywords: landslides; forecasting; geomechanics; early warning; time of failure; slope failure
- 24

25 **INTRODUCTION**

- 26 Natural disaster forecasting for early warning purposes is a field of study that drew the media
- attention after events such as the 26th December 2004 tsunami of Sumatra. Predicting landslides, 27
- 28 with respect to other natural hazards, is a complex task due to the influence of many factors like
- 29 geomechanical properties, rainfall, ground saturation, topography, earthquakes and many others.
- 30 So far, few empirical landslide forecasting methods exist (Azimi et al., 1988; Fukuzono, 1985a;
- 31 Mufundirwa et al., 2010; Saito, 1969; Voight et al., 1988) and none furnishes a reliability degree
- 32 about the prediction, making them unsuitable for decision making.
- 33 In our research we present an approach to perform probabilistic forecasting of landslides
- 34 collapse. This has been achieved by reiterating several predictions using more forecasting
- 35 methods at the same time on multiple time series. This approach may have important
- 36 applications to civil protection purposes as it provides the decision makers with a level of
- 37 confidence about the prediction. Furthermore, this study, performed on 15 different case studies,
- 38 shows how the possibility or not to forecast the time of collapse of a landslide is not affected by
- 39 geomechanical or geomorphological features, like usually believed, as much as by circumstantial
- 40 conditions.

The inverse velocity forecasting method 41

- 42 Forecasting activity can be considered the fulcrum of early warning systems (Intrieri et al.,
- 43 2013), i.e. cost-effective tools for mitigating risks by moving the elements at risk away. For
- 44 many natural phenomena forecasting is common practice (for example for hurricanes;
- 45 Willoughby et al., 2007), while for others is, at present, impossible (earthquakes; Jordan et al.,
- 46 2011). Landslides lie in between. Their prediction is usually performed through rainfall
- 47 thresholds (Baum and Godt, 2010), but a more reliable approach should make use of direct
- 48 measures of potential instability, such as displacements (Lacasse and Nadim, 2010). A first issue
- 49 is that only a small percentage of landslides in the world is appropriately monitored. This also
- 50 causes an insufficient knowledge of the geomechanical processes leading to failure, which is
- 51 another responsible for our deficiencies in predicting landslides.
- 52 In spite of this, few empirical methods for predicting the time of failure based on movement
- monitoring data have been developed (Azimi et al., 1988; Fukuzono, 1985a; Mufundirwa et al., 53
- 54 2010; Saito, 1969) and further investigated on a physical basis (Voight et al., 1988). They are all

(c) Author(s) 2016. CC-BY 3.0 License.

- 55 based on the hypothesis that if a landslide follows a peculiar time-dependant geomechanical
- 56 behaviour (called creep; Dusseault and Fordham, 19940), it will display a hyperbolic
- 57 acceleration of displacements before failure; by extrapolating this trend from a displacement time
- series through empirical arguments, it is possible to obtain the predicted time of failure. However 58
- 59 such methods do not always produce good results.
- 60 One of the most famous methods is Fukuzono's (1985a), which derives from Saito's (1969),
- 61 from here on simply called F and S method, respectively. It requires that during the acceleration
- typical of the final stage of the creep (tertiary creep), the inverse of displacement velocity (v^{-1}) 62
- decreases with time. The collapse is forecasted to occur when the extrapolated line reaches the 63
- 64 abscissa axis (corresponding to a theoretical infinite velocity). Such line may either be convex,
- straight or concave (Fukuzono, 1985a). When it is straight this phenomenon is sometimes 65
- 66 referred to as Saito effect (Petley et al., 2008).
- 67 The possibility to find landslides showing the Saito effect has been related to the mechanical
- 68 properties of the sliding mass. However there is no general consensus on this issue.
- 69 According to some authors (Petley, 2004; Petley et al., 2002), in order to display the Saito effect,
- 70 landslides need to display a brittle behaviour (which indicates a drop from peak strength to
- residual strength value, deformation which is concentrated along a well defined shear surface, 71
- 72 sudden movements and catastrophic failure, usually associated with crack formation in strong
- 73 rocks); furthermore only brittle, intact rocks evolve in catastrophic landslides and therefore can
- 74 be predicted; for others (Rose and Hungr, 2007), on the opposite, landslides displaying the Saito
- 75 effect must have ductile failures in order to be forecasted (i.e. slower, indefinite deformation along a shear zone and under a constant stress, typical of sliding on pre-existing surfaces of soft 76
- 77 rocks), as brittleness is characterized by sudden, impossible to anticipate, ruptures.
- This complex subject is made even more difficult due to the influence of external factors 78
- 79 (rainfall, earthquakes, excavations), structural constraints (joints, faults, contacts with different
- 80 lithologies) and sometimes unknown elements within the mass (the conditions of the shear
- surface, the history of the landslide, the presence of rock bridges). Therefore it is often hard to 81
- 82 establish the mechanical behaviour and even more to find an exact correlation between the
- 83 mechanical behaviour of a landslide and the possibility to predict its failure.

The concept of predictability 84

- 85 Before assessing the influence of geomechanics on the predictability of a landslide it is first 86 necessary to address the concept of predictability. In literature (Azimi et al., 1988; Hutchinson, 2001; Mufundirwa et al., 2010; Rose and Hungr, 2007) there are papers that deal with 87 88 "predictions" made in retrospect, that is thorough post-event analyses showing the signs of a 89 critical pre-collapse acceleration; however whether such signs would have been unambiguous or 90 would have granted a sufficient lead time is often neglected. On the other hand in our research 91 we consider an operational definition of predictability (integrating the one of early warning 92 system; UNISDR, 2009) as the feature possessed by a landslide which allows one to forecast its 93 collapse with reasonable confidence and sufficiently in advance, permitting the dispatch of
- 94 meaningful warning information to enable individuals, communities and organizations
- 95 threatened by the hazard to prepare and to act appropriately and in sufficient time to reduce the
- 96 possibility of harm or loss. Therefore, displaying the Saito effect is not the only prerequisite for
- 97 an operational prediction, there is also the need for repeated time of failure forecasts fluctuating
- 98 around a constant time value placed not too close in the future. This has been achieved through
- 99 the reiterative approach and the graphical representation described in the following paragraph.
- 100 **METHODS**

© Author(s) 2016. CC-BY 3.0 License.

- 101 The usual way to apply landslide forecasting methods based on displacements, is to obtain a
- 102 single predicted time of failure (t_f) and to update such prediction as soon as new data are
- 103 gathered (Rose and Hungr, 2007). This is a deterministic approach, since the real time of failure
- 104 (T_f) is predicted through a single inference.
- 105 On the other hand, in order to account for the uncertainty of the methods and complexity of the
- 106 phenomena, predictions should have a certain confidence (for example given by the standard
- 107 deviation of t_f). This is especially important for operative early warning systems. We achieved
- 108 this probabilistic approach by reiterating the equations from Saito (1969), Fukuzono (1985a) and
- 109 Mufundirwa et al. (2010) for finding t_6 using continuously new data. The latter method will be 110 called M method from here on.
- The predictions are plotted versus the time when they have been made (time of prediction, t_p). 111
- We call these diagrams prediction plots (Figure 1). A prediction is considered reliable when the 112
- 113 inferences oscillate around the same t_{f} . Figure 1 also shows that since reliable predictions usually
- 114 display an oscillatory trend, the most updated one is not necessarily the most accurate, contrarily
- 115 to what is usually believed (Rose and Hungr, 2007) in fact, the length of the dataset is more
- 116 important, from which T_f can be estimated through simple statistical analyses (like mean and 117 standard deviation).
- 118 Since in some cases a single forecasting method can fail to give satisfactory results, in order to
- 119 improve even more the confidence in the predictions, a multi-model approach is adopted together
- 120 with the probabilistic approach. In fact, according to the Diversity Prediction Theorem (Page,
- 121 2007; Hong and Page, 2008), diversity in predictive models reduces collective error. The highest
- 122 confidence, of course, is reached when all the employed method independently converge towards
- 123 the same result. For this research we confronted the results from S and F methods and from the
- 124 method by Mufundirwa et al. (2010). The equations used for the iteration are obtained from the respective authors and are: 125

$$t_{\rm r} = \frac{t_2^2 - (t_1 \cdot t_3)}{t_2 - (t_1 \cdot t_3)}$$

$$2t_2 - (t_1 + t_3)$$
, (1)

127 for S method, where t_1 , t_2 , t_3 are times taken so that the displacement occurred between t_1 and t_2 128 is the same as between t_2 and t_3 .

$$t_r = \frac{t_2 \frac{1}{v_1} - t_1 \frac{1}{v_2}}{\frac{1}{v_1} - \frac{1}{v_2}}, (2)$$

129 130

126

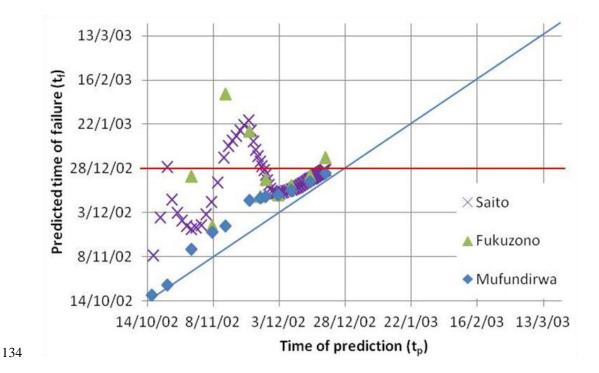

for F method, where
$$v_1$$
 and v_2 are the velocities at arbitrary times t_1 and t_2 .

$$t\frac{dD}{dt} = t_r \frac{dD}{dt} - B_{,(3)}$$

- $t \frac{dt}{dt} = t_r \frac{dt}{dt} b$, (3) for M method, where D is the displacement and t_r is the angular coefficient of the line represented in a $t \frac{dD}{dt} = f\left(\frac{dD}{dt}\right)$ space having B as the intercept. 132
- 133

135 Figure 1. This graph represents probabilistic predictions performed with 3 different forecasting methods (Fukuzono, 1985a; Mufundirwa et al., 2010; Saito, 1969) applied to the MB34-35' 136 137 displacement time series of Mount Beni landslide (Gigli et al., 2011). The black dashed line indicates the observed time of failure (T_f) and the grey diagonal line the equality between t_f and 138 139 t_p . Therefore the vertical distance between a point and the black dashed line indicates the 140 prediction error. The vertical distance between the blue line and a prediction above it is the life 141 expectancy of the landslide at the time of prediction. In this case the predictions obtained through 142 S and F methods give a good estimation of T_{f} , while the one from Mufundirwa et al. (2010) 143 consistently forecasts the collapse few days ahead.

144 TIME OF FAILURE PREDICTION

145 In order to find a relation between the predictability of a failure and the geological features of the 146 landslide, S, F and M methods have been applied to a number of different real case studies. Some

geological features of interest relative to such cases are reported in TABLE 1, when they were

148 known or applicable.

149 A few representative examples of prediction plots are showed in Figure 1 and Figure 2. Mount

150 Beni landslide is a 500.000 m³ topple that evolved as a rockslide (Gigli et al., 2011). It developed

151 on a slope object of quarrying activity. The predictions oscillate quite regularly around the

152 observed time of failure (T_f , black dashed line in Figure 2). It is this convergence that permits to

- 153 correctly forecast the collapse a priori at least since late November, i.e. a month before the
- failure. The three methods are similar to the point that S and F previsions can be partially
- 155 overlapped. M previsions overlap as well but only in the final part. The M method alone would

© Author(s) 2016. CC-BY 3.0 License.

- 156 not be sufficient for spreading a reliable alarm as the single forecasts do not converge but move
- 157 forward to a different time of failure as the time passes by.
- 158 Similar behaviours can be observed also for the cases of Figure 2 that display landslides with a
- 159 different array of geological features (as seen in TABLE 1). The best results are obtained when
- 160 the forecasts oscillate around T_f with sufficient time in advance (as for Vajont and, limited to F
- method, for Liberty Pit) or when they consistently give the similar t_f (as for the artificial 161
- 162 landslide E). In other cases (Avran valley and, limited to S and M method, for Liberty Pit) the
- 163 predictions are too scattered or simply never converge toward a single result, thus making it
- 164 impossible to foresee a reliable time of failure.
- 165
- 166 The results of the prediction plots can be roughly summarized reporting the mean and standard
- deviation of the forecasts for each method (Figure 3). 167

TABLE 1. LANDSLIDE CASE HISTORIES

| Name | Material | Type | Brittleness | Volume | Predisposing | Trigger | History | Basal | Ref. |
|-------------------------------|--|---------------------------------------|--------------------------|---------------------|--|-----------------------------------|----------------------------------|---|-----------|

[†] The case of Stromboli is not relative to a landslide, rather to a volcanic bulging preceding a vent opening that was forecasted in a similar fashion of a landslide and therefore here included.

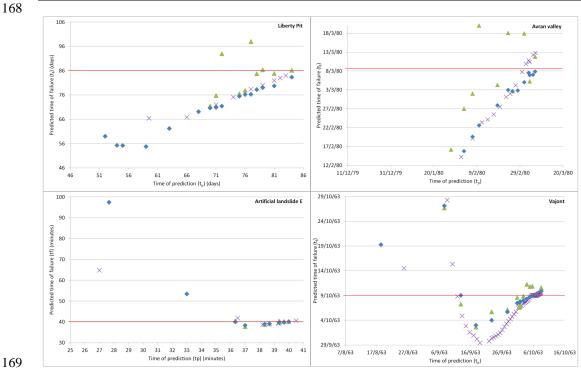

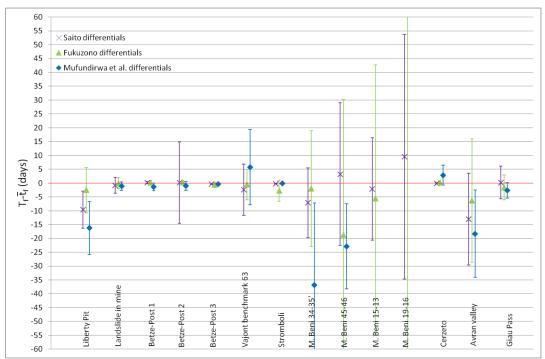

Figure 2. These graphs show how iterating forecasts performed through multiple forecasting methods increases the confidence when estimating the actual time of failure (T_{f} , black dashed line). The purple crosses represent forecasts performed with S method, the green triangles with F method and the blue squares with M method. Note that F forecasts for Avran valley landslide include other less accurate values not showed in the graph as they are out of scale.

175

Figure 3. This graph represents for each method the differential between the mean of the forecasts (\bar{t}_f) and the actual time of failure (T_f) . Negative values are safe predictions as anticipate the time of failure. The standard deviations of the forecasts are represented as error bars. For Betze-Post and Mount Beni landslides, time series from different measuring points are reported. The rock mass failure, Asamushi landslide and the artificial landslides are not shown as were monitored in a different time scale (hours or minutes).

182

183 **PREDICTABILITY INDEX**

In order to evaluate the performance of S, F and M methods and to relate it to the characteristics of the reported examples, an arbitrary scoring system has been implemented and attributed to each prediction plot (considering that every time series has a prediction plot for each forecasting method and that for some case studies more than one time series was available). This permits to quantify the predictability of a collapse based on the prediction plot. A score from 1 to 5 has been assigned according to the following criteria:

- 1 point: the prediction plot never converges on a single t_f (typically t_f increases at every new datum available).
- 2 points: the predictions vary considerably at every new iteration. An average time of failure (\bar{t}_f) can be extracted but with high uncertainty.
- 3 points: the predictions oscillate around T_f , although with a certain variance.
- 4 points: the predictions have a low variance although \bar{t}_f is slightly different than T_f . Note that when the variance was low, \bar{t}_f and T_f never differed greatly.
- 5 points: the prediction plot is clearly centred on T_f therefore the reliability of \bar{t}_f is high.

© Author(s) 2016. CC-BY 3.0 License.

198 By summing the scores obtained from S, F and M prediction for each time series, what we call

199 the Predictability Index (P_i) is obtained (TABLE 2). By using 3 forecasting methods, P_i ranges 200 from 3 (impossible to predict the time of failure) to 15 (the time of failure can be predicted in

advance and with a high reliability). Though a certain degree of subjectivity is unavoidable when 201

202 assigning the scores, what matters here is the relative difference of P_i between the case studies.

203 In such a way it is possible to understand in which conditions a landslide is more or less

204 predictable.

206 **DISCUSSION**

TABLE 2 shows how the most predictable events ($P_i > 8$) can display very different features and are quite irrespective of the shape of the inverse velocity plot, the volume, the brittleness of the material, the history of the landslide and so on (see also TABLE 1).

210 A comparison between Figure 3 and TABLE 2 illustrates how the mean and standard deviation

211 of the forecasts alone are not enough to represent the quality of predictions and, consequently,

212 the predictability of a landslide. In fact the importance of a single forecast strongly depends on

213 the time when it is made; for example, given the same set of forecasts $(t_{f,i})$, a higher P_i is

obtained if the first predictions done are the farthest from T_f while the final ones tend to converge

to it; in this way the prediction plot assumes an oscillatory shape (as for S and F forecasts in

Figure 1). Conversely, if the same forecasts are made with a different order so that they get

217 closer and closer to T_f as time passes by (that is $|t_{f,i} - T_f| < |t_{f,i-1} - T_f|$), then there is no $t_{f,i}$

218 prevailing on the others and it is not possible to define a more probable time of collapse (as for 219 M forecasts in Figure 1). However the average and standard deviation of $t_{\rm f}$ are the same for both

219 M forecasts in Figure 1). However the average and standard deviation of t_f are the same for both 220 cases and this explains why these two statistics alone are not as informative as a prediction plot. 221 From TABLE 2 it is also possible to assess which method gives the best results. The sum of the

scores for S, F and M is 119, 115 and 63 respectively. Overall S and F perform similarly, but for

223 a specific case study their effectiveness can be very different, therefore their result are 224 independent and not redundant; there is no indisputable clue suggesting when F method is more

225 performing than S and vice versa; nonetheless it appears that S is negatively influenced when the 226 displacement curve is not regularly accelerating (Liberty Pit, Stromboli), whereas for F a few

227 aligned points in the final tract in the inverse velocity plot are sufficient for predicting the failure;

228 however F forecasts are more disturbed when displacement data are noisy, since they use their

- derivative (velocity) as input. Eventually M forecasts generally perform more poorly and rarely
- 230 (i.e. artificial landslides B and C) surpass those obtained from S and F methods.

Interestingly, different displacement time series belonging to the same landslide can display
 different behaviours. This is a strong evidence that, even though the geological features do

influence the predictability of a landslide, assuming that they keep the same for the whole

234 landslide, other factors must determine the quality of the predictions. The last column of TABLE

235 2 shows for each time series what such factors could be, such as lithology (the asymptotic trends

of the cases of Avran valley and Giau Pass can be explained as consequences of a lowly brittle

material according to Petley's experiments; Petley, 2004), external forces (excavation in open pit

238 mines, volcanic activity, rainfall), local effects (structural constraints, displacement measured 239 relative to internal or lateral fractures not representing the general instability of the landslide),

240 quality of data (length of the time series, frequency of the observations, level of noise,

241 representativeness of the monitored point) etc.

All these case histories show that the main responsible for the predictability of a landslide, and secondary also for the presence or not of the "Saito effect", is connected to geology but not

simply and directly. Instead both depend on the kinematics of the landslide, which in turn

245 depends on the geological conditions. In the complex relation between geology and kinematics

- the aforementioned factors may intervene and asymptotic trends in the inverse velocity plot have
- been encountered also for first failure ruptures (as found in some time series of Mount Benilandslide).
- Finally, the prediction plots clearly show that, contrarily to what is generally believed (Rose and
- Hungr, 2007), the last forecasts are not necessarily the most accurate and that past ones (starting
- from the initiation of the tertiary creep) are essential to estimate the correct time of failure. In
- 252 fact older forecasts can be more accurate and in any case furnish precious information about the
- 253 general reliability of the final prediction, as explained above. The integration of more forecasting
- 254 methods further raises reliability of the predictions, which is of great importance for early
- 255 warning systems, in particular when evacuations are envisaged.
- 256

257 CONCLUSIONS

- 258 In conclusion, the results of the study are the following:
- Prediction plots are introduced as graphs showing the evolution of collapse forecasts with
 time. Such plots provide more information than simple average and standard deviation of
 the forecasts and improve the reliability of the final prediction.
- A predictability index (*P_i*) has been introduced as a scoring system based on the description of the prediction plot.
- The predictability of a landslide depends firstly on its kinematics and then on what determines it (geology, external forces, local effects etc.).
- Landslide collapses can be forecasted whether they are in highly or lowly brittle
 materials, in rock or in earth material, of different types, with different sliding surface
 geometries, volumes and triggers.
- Contrarily to what is generally assumed (Voight, 1988; Rose and Hungr, 2007),
 landslides can be forecasted also with external forces acting.
- The asymptotic behaviour of the inverse velocity curve does not imply that the landslide cannot be correctly forecasted, even though it can hinder the prediction.
- The asymptotic behaviour may be induced by external factors, lithology and local effects, rather than only by crack propagation. In fact asymptotic trends have been found in first time failures and in both brittle and lowly brittle materials. The crack propagation explanation is not neglected, but it may not represent the general rule.
- Most recent displacement monitoring data increase the confidence when estimating the
 time of failure but do not necessary provide more accurate predictions than the older ones
 (provided that they start from after the initiation of the tertiary creep).
- The developed approach integrates more forecasting methods to further improve the reliability of the prediction.
- 282

283 AUTHOR CONTRIBUTION

- E. Intrieri developed the idea and performed the analyses. G. Gigli supervised and improved themanuscript.
- 286

287 ACKNOWLEDGEMENTS

- 288 The authors are thankful to Antonio Intrieri for his important technical contribution when
- 289 computing the calculations needed for this work.
