10	
11	ABSTRACT
12	Landslide is one of the most ravaging natural disaster in the world and recent occurrences in
13	Nigeria require urgent need for landslide risk assessment. A total of nine samples representing
14	three major landslide prone areas in Nigeria were studied, with a view of determining their
15	liquefaction and sliding potential. Geotechnical analysis was used to investigate the
16	liquefaction potential, while the slope conditions were deduced using SLOPE/W. The results
17	of geotechnical analysis revealed that the soils contain 6-34 % clay and 72-90 % sand. Based
18	on the unified soil classification system, the soil samples were classified as well graded with
19	group symbols of SW, SM and CL. The plot of plasticity index against liquid limit shows that
20	the soil samples from Anambra and Kogi are potentially liquefiable. The liquefaction screening
21	criteria also revealed that Anambra and Kogi are potentially susceptible to liquefaction,
22	whereas samples from Kwara are not susceptible to liquefaction. Samples from Kogi and
23	Anambra have lower values of MDD and OMC, ranging between 1.64-1.80 g/cm ³ and 8.0-12.3
24	% respectively. These values showed that the samples are granular material with soil having
25	anticipated embankments performance, subgrade and base material as poor-fair, fair-good an
26	good-poor, respectively. The direct shear strength test on the soil samples indicated that the
<mark>27</mark>	cohesion and angle of internal friction varies between 40-80 kPa and 24-35°. The Coefficient
28	of permeability vary between 8.71×10^{-5} and 1.18×10^{-3} . The factor of safety (FOS) values for
<mark>29</mark>	soils from Anambra, Kogi and Kwara are 1.452, 1.946 and 2.488, respectively. These values
30	indicate stability but care must be taken as the condition at the site shows that the slope is in its
31	state of impending failure. The FOS for dry slope was higher when compared to the FOS value \bigcirc
<mark>32</mark>	from wet slope. This was due to the effect of pore water pressure on the soil as it reduced the

33 shear strength of the soil. A reduced value of FOS was observed in the model under loading

- 34 conditions, which indicate that loading is also a contributing factor to the slope failure. It is
- 35 recommended that proper and efficient drainage system should be employed in these areas to
- 36 reduce the influence of pore water pressure in the soil.

39 1. INTRODUCTION

40 The effect of natural disaster in the world cannot be over-emphasized, as a number of failures 41 of embankments, natural slopes, earth structures and foundations have been attributed to the liquefaction of sands, landslides and slope instability. According to the report documented by 42 43 National Research Council (1985), case studies of landslides or flow failures due to liquefaction are the 1937 Zeeland coast of Holland slides involving 7 million cubic meters of 44 alluvial sands, and the 1944 Mississippi River slide near Baton Rouge containing about 4 45 million cubic meters of fine sands. Just to mention a few cases, failure of hydraulic fill dams 46 47 such as the Calaveras Dam (California) in 1918, Fort Peck Dam (Montana) in 1938, and Lower San Fernando Dam (California) in 1971, were triggered by the liquefaction of sands. Landslides 48 are a major hazard in Africa where resources worth several millions of dollars are lost annually 49 during seasons of heavy and light rains. In West Africa, landslides are caused primarily by 50 51 rainfall. Depending on meteorological and geomorphologic conditions, individual rainfall 52 events can trigger small or large slope failures.

One of the most recent natural disasters threatening Nigeria is landslide. In Nigeria, landslide 53 has done a serious destruction to physical structure and resulted in the loss of lives and 54 55 properties. For instance, the December 2005 landslides in Umuchiani community of Anambra state has led to the inhabitation of about 250 families, while over 20 communities in Awgu and 56 Oji-River Local Government Areas of Enugu State were thrown into serious difficulties by 57 landslides cutting off a portion of the Awgu-Achi-Oji River Federal road in October 58 2011. According to the report documented by State Emergency Management Agency (SEMA), 59 the landslide that occurred in Oko Community of Anambra State has rendered more than 150 60 61 people homeless. In addition, they reported that 15 buildings were destroyed, but no life was lost. In 2013, no fewer than nine persons were buried alive, while many others sustained 62 injuries in the landslide that occurred at Edim Otop community of Calabar metropolis (Figure 63 1). The landslide occurred after heavy rainfall which lasted for more than five hours. Landslides 64

Natural Hazards and Earth System Sciences Discussions

65 induced by high-intensity or prolonged rainfalls constitute a major risk factor in Nigeria 66 especially because they have generally been poorly defined in the past. The landslides have the potential to damage human settlements, industrial development, cattle ranch, forestry and 67 68 agricultural activities. Landslide is nas movement on slope involving rock fall, debris flow, 69 topples, and sliding (Varnes et al., 1984). Landslide occurs as result of the presence of saturated 70 clay materials on the impermeable layer on steep slopes. Landslide that occurred on a slope is 71 influenced by gravity. The internal and external causes of landslide is presented in Table 1. The 72 presence of soil moisture also increases the pore water pressure and lessens the material 73 stability. A change in pore water pressure is regarded as the main triggering factor to land 74 sliding (Ngecu and Mathu, 1999 and Knapen et al., 2006). If an external load is applied to a 75 soil mass on a slope in the form of additional water or overburden, the pore water pressure will 76 build up such that mass and water will be expelled at weak points (Alexander, 1993).

Slope instability is the condition which gives rise to slope movements (Alexander, 1993). In 77 every slope, there are forces (stresses) that tend to instigate or cause movement (shear stress) 78 79 and opposing forces which tend to resist movement (shear strength), (Bromhead, 198-80 Alexander, 1993). Sliding occurs when shear stress is greater than shear strength. In normal 81 circumstances, the shear stress is balanced by shear strength and a state of equilibrium is 82 maintained (Alexander, 1993). However, this equilibrium can be disturbed by stress increments or weakening of frictional force. The failure of slope material depends partly on the strength of 83 frictional force between the sliding mass and the bedrock (Crozier, 1984; Alexander, 1993; and 84 85 Matsushi et al., 2006). Slope stability analysis can be performed using either total or effective stress. Total stress analysis is applicable to embankments and multistage loading problems 86 87 where the short term condition is critical, while effective stress analysis should be used for excavation problems where the long-term condition is critical (Duncan, 1996). The search for 88 89 the preparatory factors and cause(s) of an individual landslide or an attempt to designate the 90 state of instability is prompted to find an efficient way of responding to the problem by legal necessity, or simply by a desire for knowledge (Crozier, 1984). The danger of slope instability 91 92 can never be over emphasized in its destructive property. To understand and evaluate 93 liquefaction potential of soils and degree of slope stability, as as causes of landslide in the 94 area, three localities (Anambra, Kogi and Kwara state, Figure 3) that differ in geology and land use were studied. While slope failure and landslides are common and frequent in the 95 mountainous parts of Anambra and Kogi state because of their unique geology, long-time 96 97 residents report that the recent landslides at Oko, in Anambra state (Figure 1) is the first major

slope failures despite the much higher elevation and steepness of slopes in the area. These 98 99 differences in scale and frequency were the major motivating factors for the research.

100 2. GEOLOGICAL BACKGROUND

Nigeria is a part of Africa that forms the continental crust and lies in the Pan-African mobile 101 belt that has been affected by Pan-African events during the ages of orogenic, epeiorogenetic, 102 tectonic and metamorphic cycles (Rahaman, 1976). The geology of Nigeria can be subdivided 103 104 into the Precambrian Basement Complex and Cretaceous to Tertiary sedimentary basins. The Nigerian Basement Complex forms part of the Pan-African mobile belt and lies between the 105 106 West African and Congo Cratons (Figure 3) and to the south of Tuareg Shield (Black, 1980). It consists of gneiss migmatite complex, schist belt and granitoids (older granites) of the 107 Archea aleoproterozoic and Neoproterozoic (Annor, 1998). The Nigerian basement 108 109 (Fig.2.1) was affected by the 600 Ma Pan-African orogeny and it occupies the reactivated region which resulted from plate collision between the passive continental margin of the West 110 111 African craton and the active Pharusian continental margin (Burke and Dewey, 1972; Dada, 112 2006). About 50% of the total landmass of Nigeria is covered by sedimentary basins. These 113 basins are Bida Basin, Benue Trough, Chad Basin, Anambra Basin, Dahomey Basin and Niger Delta Basin. The basins generally develop over the Precambrian basement and dominated by 114 115 clastic deposit and in places, ironstone and organic coal-bearing sediments (Nguimbous Kouoh, 2012). The study area falls in both the Basement Complex and sedimentary areas. The 116 areas under sedimentary part of Nigeria are Oko in Anambra State and Agbaja in Kogi State, 117 118 while those in the Basement Complex are Eyenkorin and Asa Dam in Ilorin, Kwara State.

2.1 Location of the study are 119

2.1.1 p, Anambra State 120

Oko is situated in Orumba North Local Government Area (LGA) of Anambra state. It is 121 geographically situated between 6°02'37.34" N and 7° 04'54.32" E and has humid climatic 122 123 condition. The average annual rainfall in Oko is about 2,000 mm. Most rainfall occurs in welldefined rainy seasons of six to seven months (April to October) and is typically concentrated 124 in high intensity storms and often causes flooding and erosion leading to the formation of 125 gullies. Oko is a rain forest area and is characterized by vast undulating landscape and of 126 alluvial plain. Greater part of its vegetation is made up of forest (tropical vegetation). 127

128

2.1.2 baja, Kogi State 130

Agbaja is the locality of a large iron ore deposit in Kogi State, central Nigeria. It is located on 131 a plateau about 300 km south of the capital Abuja, and more importantly about 70 km from the 132 133 heavy duty railway to the sea at Itakpe which is about 70 km to the south. It is geographically 134 situated between 7°56'53.33" N and 6°39'38.40" E. The land rises from about 300 m along the Niger Benue confluence, to the heights of about 500 m above sea level in the uplands. Agbaja 135 136 Plateau, which ranges from 335-366 m above sea level, is one of the predominant forms in the state. The state is drained by the Niger and Benue rivers and their tributaries. 137

2.1.3 Asa Dam ard Fyenkorin, Kwara State 138

The sample localities are located in Ilorin metropolis which is a Basement Complex terrain that 139 140 has undergone deep weathering. The Nigeria Basement Complex is a group of igneous and 141 metamorphic rocks of Precambrian age (Kogbe, 1975). It is largely undifferentiated and constitutes about 50 % of the bedrock in Nigeria. Large outcrops of granite and gneisses with 142 143 cross-cutting pegmatites are compon (Alao, 1983). The general trend of the outcrops in the area is SW-NE with a west dip. 144

3. MATERIALS AND METHODS 145

146 3.1 Site visit and Data collection

Oko area in Anambra State, Agbaja Hill in Lokoja, Kogi State as well as Asa Dam and 147 Eyenkorin (Ilorin metropolis) in Kwara State of Nigeria were visited for soil sampling and to 148 evaluate existing conditions of slopes situated in the site. The weathered surface as removed 149 150 and the outcrop was horizontally dug inward in order to obtain fresh samples. The effective soil sampling depth was determined using a screw soil auger, a surveying tape, depths of recent 151 landslides and slope remodelling. However, in areas where landslides had occurred, the 152 samples were collected from the sides of scar. In special cases, selection of sample locations 153 154 were based on indications of slope instability, mainly soil creeping and cracking. Coordinates 155 of the sampling pits (sites) and photographs were taken during field visits to provide additional records. The collected fresh soil samples were transported to the Mechanical Engineering 156 Department's soil laboratory, University of Ilorin, Nigeria for geotechnical tests in order to 157 access the probable mechanical behaviour. The investigated shear strength parameters of the 158 159 soil samples were later used in slope stability evaluation.

160

3.2 Geotechnical analysis 162

163 Preliminary geotechnical classification and identification tests such as moisture content, bulk density, specific gravity, grain size distribution, hydraulic conductivity, particle density, bulk 164 165 density, liquid limit, plastic limit, and plasticity index, compaction and shear strength tests were 166 carried out on the soil samples based on the British Standard (BSI 1377:1990). Each geotechnical test was performed twice on the same soil sample under the same condition in 167 168 order to determine the reliability of the geotechnical test results. The result of the Atterberg 169 consistency limits were plotted after Seed et al. (1983; 2003) in order to deduce whether the 170 soils are susceptible to liquefaction. The boundaries in the gradation curves for soils susceptible to liquefaction, as proposed by Tsuchida (1970) were also used to determine whether the soils 171 are susceptible to liquefaction. 172

3.2.1 Grain Size Analysis 173

Mechanical and hydrometer methods were used to determine the grain size distributions. The 174 mechanical method (wet sieving) was employed in malysis of particles that are greater than 175 0.075 mm in diameter. A calibrated (ASTM 152H) hydrometer was used to analyse the finer 176

177 grains (d < 0.075 mm) in the laboratory.

3.2.1.1 Procedures for mechanical method (wet sieving 178

The soil particles were gently separated from each other. The sieve set (stack of sieves) were 179 arranged in descending order from the top with a retainer beneath it. 100 g of each soil sample 180 was weighed and poured into the sieve stack. The soil filled sieve stack was placed on the 181 182 mechanical sieve shaker for about 10 minutes. The sieve stack was later separated and the soil 183 fraction retained by the mesh of each sieve was retrieved. The soil fraction retained by each sieve was weighed and the statistical data of the grain size analysis was computed. 184

185 3.2.1.2 Procedures for hydrometer method

The sieved clay and silt from the sieve washing was collected in a container and allowed to 186 187 settle. The supernatant water was decanted and the mud residue was dried in the drying oven for about 24 hours. 500 g of the dried mud was soaked in distilled water for 24 hours and mixed 188 189 properly in a stirrer with a dispersive agent (hexametaphosphate) added to avoid flocculation 190 of the grains. The suspension was poured into 1 litre measuring cylinder and mixed before the soil grains were allowed to settle in the suspension. The hydrometer was later inserted into the 191 water in the measuring cylinder and its reading was recorded periodically. As the settling 192 193 proceeds, the hydrometer sinks deeper into the solution. The temperature at each hydrometer

194 reading was recorded and then a statistical data sheet was produced showing the results of the 195 analysis. The clay and silt percentage in the samples were then calculated from the graph obtained by plotting percentage passing against the grain diameters. 196

3.2.2 Atterberg limits determination 197

To determine the liquid limit of the soil samples, the fraction of the soil that passed through the 198 425um sieve was weighed (230 g) on a weighing balance and carefully mixed with clean water 199 200 in order to form a thick homogeneous paste. A groove was cut through the paste (soil sample) that was placed inside the Casangrade's apparatus cup and the numbers of blows were counted 201 and recorded until the groove in the soil closes. The moisture contents were determined and 202 the moisture contents were plotted against the numbers of blows in order to determine the liquid 203 204 limit. To determine the plastic limit, soil sample was also taken from the soil sample that passes 205 through the 425µm sieve and weighed on the balance. Then it was thoroughly mixed with water using the hand until it becomes homogenous and plastic enough to form ellipsoidal-circular 206 207 shape (i.e. ball). The ball-shaped soil was rolled in a rolling device until the thread cracks or 208 crumbles at about 4 mm diameter. The crumbled sample (4 mm) was then air-dried thus the 209 moisture contents were determined.

3.2.3 Procedures for compaction test 210

3 kg of soil sample was weighed and poured into the mixing pan. 120 cm³ (4 %) of water was 211 212 measured, added and mixed with the soil in the mixing pan using a hand trowel. The cylinder 213 mould was placed on a base plate, then a representative specimen of the soil was put into the 214 mould and compacted with 25 evenly distributed blows of the rammer. This represents the first layer. After the compaction, the volume of soil in the mould reduced, more soil specimen was 215 216 added into the mould and compacted with another 25 evenly distributed blows. The extension collar was fixed unto the mould. This is mainly for the last layer and removed after the last 217 218 layer was made and aided to achieve a smooth level surface. The mould was filled with more 219 of the soil specimen and compacted to make the third layer. This is for standard Proctor, and five layers of the soil specimen with 55 evenly distributed blows of the rammer makes the 220 221 modified Proctor. The mould with the soil was weighed and the soil was sampled at the top and bottom of the mould for water content and the dry density determination. The mould was 222 223 emptied into the mixing pan and another 120 cm³ (4%) of water was added to the soil and mixed. The same procedure was repeated for all the samples. The dry densities were plotted 224 225 against water contents for the standard Proctor and modified Proctor in order to determine the Nat. Hazards Earth Syst. Sci. Discuss., doi:10.5194/nhess-2016-297, 2016 Manuscript under review for journal Nat. Hazards Earth Syst. Sci. Published: 26 October 2016

- maximum dry densities (MDD) and optimum moisture contents (OMC) of the soil samples in 226
- 227 each situation.
- 228 3.2.4 Shear strength determination
- 229 Two 3 kg of both soil samples (standard and modified Proctor for each soil sample) were weighed and mixed with the corresponding optimum moisture content. The soil samples were 230 then compacted as described in babove procedure. A square sampler was then gently used 231 to collect a representative sample. Each collected sample was placed in a shear box and a load 232 233 was placed on it both in horizontal and vertical positions and the demonstration dial gauges were set at zero. A set of normal loads of 5 kg, 10 kg, 15 kg and 20 kg were pled one after the 234 other in successive tests. The readings on the load dial units were recorded, and the procedure 235 was repeated for the standard Proctor and modified Proctor for other samples. The shear 236 237 strength results were presented as stress-strain curves and the shear stress was plotted against the normal stress, thus the angle of cohesion and angle of internal friction were determined. 238 3.3 Method of slices using SLOPE/W softwar 239 240 The slope model was analysed using SLOPE/W and SEEP/W software with the aim of giving the state of the slopes with their factor of safety using Limit Equilibrium Method (LEM).The 241 software computes the factor of safety (FOS) for various shear surfaces (SS), for examp 242 243 circular and non-circular. However, only the circular SS was automatically searched. The 244 method of slices was considered in relation to its application to SLOPE/W and traditional methods of analysis. According to Abramson et al. (2002) slices method is widely used by 245 246 much computer software because it can accommodate geometry of complex slope, different 247 soil conditions and influence of external boundary loads. Conventionally, the weight of soil lying at a particular point should influence the stress acting normal to that point on sliding 248 surface. Theoretically, the basic principle of slices method is the potential slide mass, which is 249 250 subdivided into several vertical slices and the equilibrium of individual slice can be evaluated 251 in terms of forces and moments. This would allow easy estimation of the allowable safety factor 252 of a slide mass. In this study, two soil layers obtained from shear strength test, with different strength parameters were used for slope stability analyses. This same shear strength parameters 253 254 were used in both dry and wet conditions. Similarly, two unit weight of soils, one above the 255 groundwater table (GWT) and the other below the GWT were considered. The complete set of input parameters used in the study are shown in Table 9. The three different conditions 256 considered for slope stability analyses are dry slope, wet slope and dry slope with external 257 258 loads. The analysed load conditions were defined as:

• Case 1: Completely dry slope, i.e. no GWT inside the model, 259

- Case 2: Completely saturated slope, i.e. GWT on the surface (hydrostatic pore pressure), 260
- Case 3: Dry slope with external forces, i.e. q = 40 and 50 kPa. 261
- The stability of the dry slope was first analysed in SLOPE/W. The minimum factor of 262 safety (FOS), critical slip surfaces (CSS) were searched by entry and exit option as well as 263 264 groundwater table (GWT) level shown in the model using limit equilibrium (LM) principle. The CSS was searched from thousands of possible SS by defining the input of 15 265 266 slices, 1500 iterations, 15 increments for entry, 10 increments for exit and 5 increments for radius. In addition to the limit equilibrium methods (LEM), the Bishop's and Janbu's simplified 267 268 methods as well as the Spencer and Morgenstern-Price (M-P) factors of safety were used for rotational and irregular surface failure mechanisms. 269

4. RESULTS AND DISCUSSION 270

- 271 4.1 Grain size distribution and soil classification
- The results of grain size analysis is shown in Figure 4 and Table 2. The grain size distribution 272 273 curves show that the soil samples consist of all fractions ranging from gravely to clayey. The clay content is found between 2-34 % in all the soil samples. The soil sample from Asa Dam 274 275 road in Ilorin, which is plastic in nature has the highest clay content of about 34 %. Soil samples from Lokoja and Anambra states have very low fine content ranging from 2-12 % and are not 276 plastic in nature. The sand fraction dominated the samples (constituted about 70-80 % of the 277 samples) especially those gotten from Lokoja and Anambra states. Similarly, the grading 278 279 coefficient (Cu = D60/D10) varies from 5-275, except for the sample from Asa Dam 1 with Cu 280 of 2000. Based on the Unified Soil Classification System (ASTM D2487 1992), all the soil samples are classified as well graded with group symbols SW, SM and CL (Figures 4 and 5; 281 Table 2). ζ 282

4.2 Atterberg limit 283

The summary of results obtained from moisture con liquid limit, plastic limit and plasticity 284 index analyses are presented in Figure 6 and Table 3. The plasticity charts (Figure 7) used 285 to classify the samples and most of the samples are above A-line (Figure 8). Eyenkorin 1, 2 286 287 and Asa Dam 1, 2 are in the region with symbol CL, thus they are classified as inorganic clays of medium compressibility. Anambra 1, 2 and Lokoja 1, 2 and 3 falls in the CL-ML region and 288 thus they are classified as cohesionless and inorganic silts of low compressibility. 289

4.3 Compaction test 291

- 292 The compaction to t standard state condition yielded maximum dry densities (MDD) of 293 **1.84g/cm³ and 1.88g/cm³** for Eyenkorin 1 and 2, respectively (Figure 9). The optimum moisture content (OMC) for Eyenkorin (in Kwara state) 1 and 2 are 14.0 % and 13 %, respectively. 294 295 Samples from Lokoja (Kogi state) a ko (Anambra state) have lower values of MDD and OMC, ranging ween 1.64-1.80 g/cm³ and 8.0-12.3 %, respectively. These values when 296 297 compared to Table 4 show that the samples can be described as granular material with soil having anticipated embankments performance as poor to fair, value as subgrade material as fair 298 299 to good and value as a base course as good to poor (Table 5).
- 4.4 Shear strength and permeability $\langle \mathcal{L} \rangle$ 300
- The summary of shear strenger and permeability results, as well as their pretations are 301 302 tabulated in Tables 6 and 7. The direct shear strength test on the soil samples show that the cohesion and angle of internal friction varies between 40-80 kPa and 24-35°. The Coefficient 303 of permeability of the soil samples vary between 8.71×10^{-5} and 1.18×10^{-3} . 304
- 305 4.5 Liquefaction susceptibility

The results of liquefaction studies after Seed et al. (1983; 2003) are depicted in Figures 10 and 306 307 11. Liquefaction involves the temporary loss of internal cohesion of material, such that it behaves as a viscous fluid rather than as a soil (Alexander, 1993). Soils containing a high 308 309 percentage of sand and silt will deform more quickly than those containing high percentage of 310 clay. Due to their cohesive strength, clays adjust more slowly to increase pore-water pressure 311 than unconsolidated soils. The plot of plasticity index against Liquid limit after Seed et al. (2003) shows that the soil samples from Anambra and Lokoja are potentially liquefiable 312 he liquefaction screening criteria after Andrews and Martin (2000) also shows that Oko 313 (Anambra), Eyenkorin (Kwara) and Lokoja (Kogi) are potentially susceptible to liquefaction, 314 315 whereas samples from Asa Dam 1 - 2 (Kwara) are not susceptible to liquefaction (Figure 11).

316 Boundaries in the gradation curves for soils were used to determine liquefaction susceptibility of the soil samples (Tsuchida, 1970). Boundary most susceptible to liquefaction is in the sand 317 318 region, with about 60-80 % of sand, whereas boundary for potentially liquefiable soil is in the 319 region of 20-40 % sand (Tsuchida, 1970). Soils with a higher percentage of gravels tend to mobilize higher strength during shearing, and to dissipate excess pore pressures more rapidly 320 than sands. However, there are case histories indicating that liquefaction has occurred in loose 321 322 gravelly soils (Seed, 1968; Ishihara, 1985; Andrus et al., 1991) during severe ground shaking

Natural Hazards and Earth System Sciences Discussions

323	or when the gravel layer is confined by an impervious layer. Based on Tsuchida (1970)
324	classification, it can be deduced that soil samples from Anambra 14 korologia have % of
325	sand ranging from 72-96 %, thus they are liquefiable in nature (Figure 12; Table 5). Anambra
<mark>326</mark>	2 has 63 % of sand which is potentially liquefiable, based on the classification proposed by
<mark>327</mark>	Tsuchiba (1970). Some of the soil samples fall outside Tsuchida's boundaries and Walker and
328	Steward (1989) documented that non-plastic and low plasticity silts, despite having their grain
329	size distribution curves outside of Tsuchida's boundaries for soils susceptible to liquefaction,
330	have a potential for liquefaction similar to that of sands. In addition, they further stated that
331	increased plasticity will reduce the level of pore pressure response in silts. This reduction,
<mark>332</mark>	however, is not significant enough to resist liquefaction for soils with plasticity indices of ≤ 5 .
222	4.6 Landslide and slope stability \bigcirc
334	Slope angles, slope length play important roles in the stability of slopes. The slope angle is
335	regarded as the major topographic factor in determining stabil
336	of the terrain influencing slope instability were measured. The characteristics recorded
337	included slope length, angles, and altitude. The slope angles can be classified as steep angle as
338	they are close to $60-70^{\circ}$ in the study areas. Though the embankment slopes in Asa Dam area
<mark>339</mark>	and Eyenkorin area have values in the range of 30-35° and are classified as moderate angles.

The factor of safety (FOS) gotten from SLOPE/W software were used to classify the slopes into safe, state of impending failure and failed slopes. Several authors have proposed different values for slope classification. The general and acceptable value for stable slope is 1.5, whereas a value less than 1 is always classified as from 1.366 - 2.488 (Figure 13-19; Table 10). The value of 1.366 is from the Oko area in Anambra state where landslide occurred. The maximum value of 2.488 was obtained at Asa Dam, which is an embankment slope and it depicts stable slope. The FOS for dry slope was higher when compared to the FOS values from wet slope (Figure 13). This was due to the effect of pore water pressure on the soil as it reduced the shear strength of the soil. Figure 14 shows the critical slip surface (CSS) and factor of safety (FOS) for non-optimised wet slope. The slip surface was at the top of the slope (Figure 13a) whereas in Figure 13b, it shows the CSS passing through ground water table (GWT), thus making the slip surface size bigger and occupies all of the entry point. Since suction effect has not been considered in the analysis, the located GWT has serious effect on the FOS. Figure 14 shows an increased in the geometry, and the CSS and FOS was affected drastically. The reduction in FOS from 2.51 to 1.45 (Figure 13) is

356 equilibrium methods computed the values of FOS slightly lower than 1.5 which depict

357 instability. The pore pressure at the toe causes reduction in the effective normal stresses, and

hence the shear strength. 358

Two of the primary assumptions of Bishop's simplified method ignores interslice shear forces 359 and satisfies only moment equilibrium. However, not considering shear forces in the General 360 361 Limit Equilibrium (GLE) terminology mean that lambda (λ) is zero. As a result, the Bishop's 362 Simplified factor of safety falls on the moment curve in Figure 17 where lambda is zero. 363 Janbu's Simplified method also ignores interslice shear forces and only satisfies force equilibrium. The Janbu's Simplified factor of safety consequently falls on the force curve in 364 365 Figure 17 where λ is zero. The Spencer and Morgenstern-Price (M-P) factors of safety are 366 determined at the point where the two curves cross. At this point the factor of safety satisfies both moment and force equilibrium. Whether the crossover point is the Spencer or M-P factor 367 of safety depends on the interslice force function. Spencer only considered a constant X/E ratio 368 369 for all slices, which in the GLE formulation corresponds to a constant (horizontal) interslice 370 force function.

371

5. CONCLUSION 372

373 Liquefaction was suspected as the main cause of the landslide that occurred in Oko area of Anambra State. The results from gradation curve which gave over 80% sand for the samples 374 375 from Lokoja and Anambra suggested that liquefaction is possible in the area if necessary 376 vibration is generated either from blasting or trucks/vehicular movement. In addition, from the satellite image, the terrain is rugged in nature and the slope is steep which can facilitate 377 378 landslide by gravity. The results from the Atterberg limits show mixed values and therefore 379 making it difficult to use the values in the liquefaction interpretation. The liquefaction effects 380 on the soils has been proven to be one of the strong factors in the failure of these sites especially 381 the site at Oko area in Anambra State. With necessary vibration, liquefaction in those sites could be a serious issues because of the composition of the grains (70-90%) sand and low 382 plasticity. The FOS values for Anambra 1-2, Lokoja 1-3, Eyenkorin 1-2 and Asa Dam 1-2 are 383 384 1.452, 1.946, 2.196 and 2.488, respectively. These values indicate stability but care must be 385 taken as the condition at the site shows that the slope is in its state of impending failure. Optimisation effects was also tried and the results shown that loads on these slope might 386 contribute to the failure of the slopes. 387

389 AUTHOR CONTRIBUTION

- 390 Dr Omoniyi Ige supervised the field work and writing of the manuscript. Tolulope Oyeleke
- 391 and Temitope Oloniniyi carried out the fieldwork. Christopher Baiyegunhi carried out data
- 392 processing and writing of the manuscript, while Luzuko Sigabi was involved in data processing
- 393 and correction of manuscript.

394 ACKNOWLEDGEMENT

- 395 The authors wish to thank Mr Ojuola Raymond of Rafworld Geological Services Limited,
- 396 Abuja, Nigeria for accommodation and assistance during fieldwork.

397 CONFLICT OF INTERESTS

- 398 The authors declared that there are no conflicts of interest concerning the publication of this
- 399 research work.
- 400

Table 11: Sum	mary of the revi	ewed meratures o	in slope stability and fai	ndshde.
Authors	Locality	Methodology	Research Interest	Findings
Okogbue, 1992	Nanka, Anambra State	Geotechnical studies	Causes of 1988 Nanka landslide	Over consolidation of very highly plastic mudstone layer
Ashiru <i>et</i> <i>al.</i> , 2014	Nasarawa Northeastern Nigeria	3 LEMs: Stability chart, SLOPE/W and traditional methods	Stability of slopes on Black Cotton Soils	Dry- stable Wet- unstable
Ako <i>et al.</i> , 2014	Nkomon District Benue State	Interview, Field observation and Laboratory studies	Causes of Nov. 13 th , 2010 landslide in Azenge Mountain in Imande Ukusu, Benue State	Highly fractured gneisses, granite and basaltic rocks and 2 grains type. Also, other causes are geological, morphological and human factors contributed
Ogbonnaya, 2015	Southeastern Nigeria	Geotechnical studies	Differentiation between landslides from sedimentary and metamorphic terrain	Sedimentary terrain- shallow volume movement, material slumps and short run out Metamorphic terrain- complex translational and rotational landslide
This study	Oko in Anambra state, Lokoja in Kogi state, and Asa dam and Eyenkorin both in Kwara state, Nigeria	Field observation, geotechnical studies and SLOPE/W	Evaluating liquefaction potential, causes of landslide and degree of slope stability	Soil samples from Anambra and Kogi are potentially liquefiable, whereas those from Kwara are not susceptible to liquefaction. The factor of safety (FOS) values shows that the slope is in its state of impending failure. Liquefaction is inferred as the main cause of the landslide in the areas.
