Abstract. In this contribution we identify storm time-clustering in the Mediterranean Sea through a comprehensive analysis of the Allan Factor. This parameter is evaluated from long time series of wave height provided by oceanographic buoy measurements and hindcast re-analysis of the whole basin, spanning the period 1979-2014 and characterized by a horizontal resolution of about 0.1 degree in longitude and latitude and a temporal sampling of one hour (Mentaschi et al., 2015). The nature of the processes highlighted by the AF and the spatial distribution of the parameter are both investigated. Results reveal that the Allan Factor follows different curves at two distinct time scales. The range of time scales between 12 hrs to 50 days is characterised by a departure from the Poisson distribution. For timescales above 50 days, a cyclic Poisson process is identified. The spatial distribution of the Allan Factor reveals that the clustering at smaller time scales is present in the North-West of the Mediterranean, while seasonality is observed in the whole basin. This analysis is believed to be important to assess the local increased flood and coastal erosion risks due to storm clustering.

1 Introduction

In recent years the occurrence of different coastal storms in a short time has been studied in the context of storm driven erosion of beaches and dunes. Indeed it has been showed by different authors (Vousdoukas et al., 2012, Coco et al., 2014, Splinter et al., 2014; Karunarathna et al., 2014; Dissanayake et al., 2015) that storms occurring in quick succession may result in greater beach erosion than the cumulated erosion induced by single storms of far higher return periods.

In the events analysed in the aforementioned studies both the surge and the wave components played an important role. While studies that identify time-clustering of storm surges are available (e.g. Wadey et al., 2014, Haigh et al., 2016), there is no study, to the best knowledge of the authors, that analyses the clustering properties of wave storms alone. In micro-tidal environments, such as the Mediterranean Sea, wave storms are the principal driver of short term coastal erosion and flooding, hence it is important to understand the occurrence of clustering.

The Mediterranean Sea wave climate has been extensively studied (e.g. Sartini et al., 2015a) and it is known that throughout the basin winter is richer in cyclones and, in turn, in wave storms. However, regional differences are significant. Sartini et al.

(2015a) linked the seasonality of wave storms to local features of atmospheric pressure over the Mediterranean basin strongly suggesting that the local typical meteorological conditions determine different temporal regimes of storm waves.

The present work addresses the gap in the knowledge of the occurrence of time-clustering of wave storms by carrying out an analysis of wave storms sequences using the Allan Factor (hereinafter AF, Allan, 1966; Barnes and Allan, 1966), a well established technique to study the time behaviour of environmental processes. When the underlying process is characterised by clustering, the AF of a specific sequence of events is larger than 1 and shows a power-law behaviour at the time scales the exhibit departure from a Poisson distribution. The simplicity of the AF analysis made it popular in the study of time sequences of a number of physical processes such as earthquakes (Telesca et al., 2002, Cavers and Vasudevan, 2015), lightning (Telesca et al., 2008), rainfall (Telesca et al., 2007, García-Marín et al., 2008) or fires (Telesca and Pereira, 2010). However, the AF can be larger than 1 also for non-homogeneous Poisson processes, as shown in Serinaldi and Kilsby (2013). Hence it is important to distinguish clustering dynamics from cyclic Poisson processes. Methodologies that are suitable to achieve this are presented in Serinaldi and Kilsby (2013) and Telesca et al. (2012).

Here we analyse the AF on long time series of wave height in the Mediterranean Sea provided by hindcast re-analysis spanning the period 1979-2014 (Mentaschi et al., 2015). This analysis is validated and compared against the AF evaluated using the time series of wave measurements of the Italian national Sea Wave Measurement Network (Rete Ondametrica Nazionale, hereinafter RON). Subsequently we apply the methodology proposed in Serinaldi and Kilsby (2013) to gain an insight in the type of process that is described by the AF. The objective of this study is to identify the presence of time-clustering of wave storms in the whole Mediterranean basin and examine the time scales at which events are correlated as well as the spatial distribution of the clustering. To this end, after scaling properties of wave storms are identified, they are mapped over the Mediterranean Sea.

The paper is organised as follows: after this Introduction, Section 2 explains the methodology used for the AF analysis, Section 3 describes the datasets used, Section 4 illustrates the results and Section 5 discusses the results and draws the conclusions of this work.

2 Clustering analysis methodology

Sequences of natural events such as earthquakes, rainfall, wildfires, can be seen as realisations of stochastic point processes. A process of this kind describes events that occur randomly in time and it is completely defined by the times at which these events occur. Here time series of sea states are considered. Each sea state is defined by a set of spectral parameter, such as the significant wave height H_s , the peak period T_p , the mean period $T_{m-1,0}$ and the mean direction of propagation θ_m . Waves are always present on the sea surface, hence a sequence of storms need to be extracted from a time series of sea states by considering only events that satisfy a certain criterion. A storm is commonly defined as a sequence of sea states in which H_s exceeds a given threshold (e.g. Goda, 1988). In this work, a threshold for each node is defined by considering the local 98% percentile of the H_s distribution, regardless of θ_m (omnidirectional analysis, see Fig. 1 for threshold values of H_s obtained with the hindcast model used here). The time t_i at which the threshold is exceeded for the first time in each storm defines

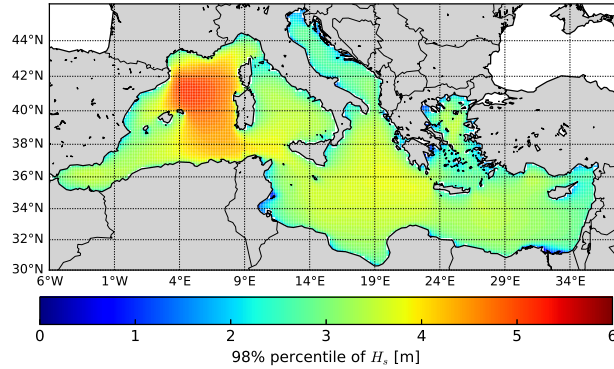

Figure 1. Value of significant wave height threshold in meters for the 98% percentile

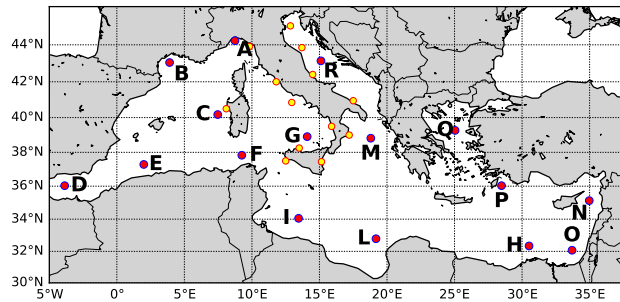

Figure 2. Hindcast control grid points (red circle) and RON buoys reference points (yellow circles)

the event as part of a point process. If the interval between two subsequent events is below 12 hours, the two are regarded as one event, this is common practice in analysing storms and the value is deemed appropriate for the Mediterranean Sea (e.g. Sartini et al., 2015a). Therefore, in each of the computational nodes over the Mediterranean Sea (see Fig. 2 for a map of the domain and the location of few control grid points used in this study to show the single point behavior of the AF), a point process is defined. An example for the control point A and for the years 2004 and 2005, is given in Fig. 3. In this figure it is evident that most of the storms, during the two years considered, occur between November and May, showing the pronounced seasonality that characterizes the basin. Fig. 4 shows the number of events defined in each month over the year in the hindcast record for the same reference point A during the period 1979-2014 as a function of the percentile threshold (different wave heights). The seasonal variability of the storms in the Mediterranean basin is again recognizable. Note that the difference in number of storms between the different percentiles considered is maximum in the most active months and, if the 99% is chosen, the differences among seasons are small, although the seasonal variability is still recognizable.

These point processes are studied by defining equally spaced time windows of duration τ and counting the events in each window. The result is a sequence of counts N_k ($k = 1, \dots, M$, where M is the number of time windows). The clustering of the events is then studied with the Allan Factor (Allan, 1966; Barnes and Allan, 1966), defined as the variance of successive counts

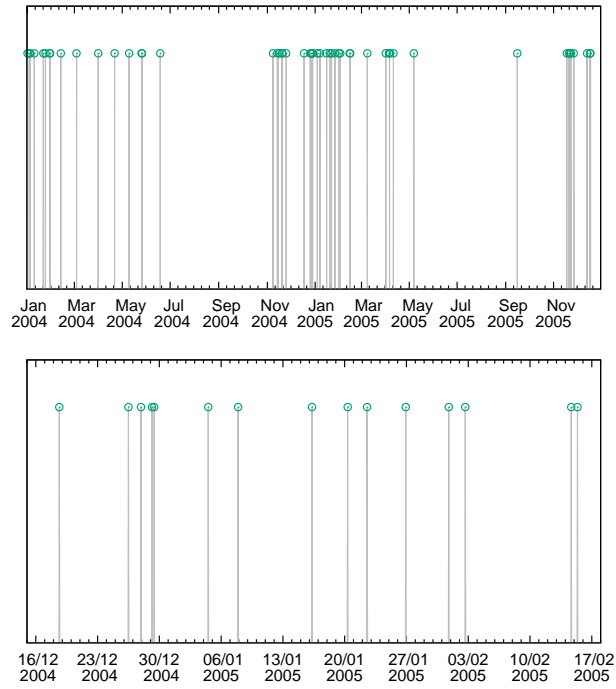

Figure 3. Storm occurrence for the Northern Thyrrhenian reference point (A): 2004/2005, top panel; zoom on winter 2004/2005, bottom panel

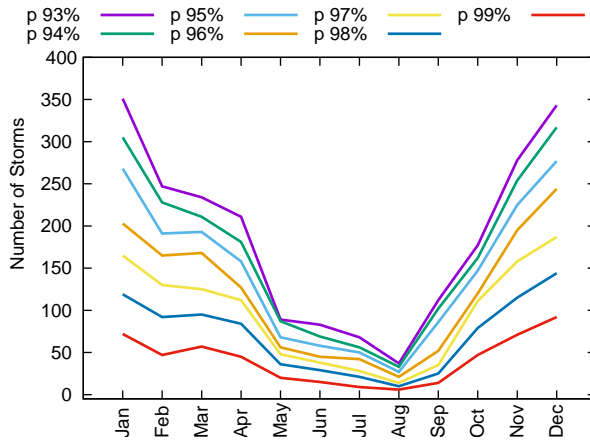

Figure 4. Number of Storms vs Threshold for the Northern Thyrrhenian reference point (A)

as:

$$AF(\tau) = \frac{\langle [N_{k+1}(\tau) - N_k(\tau)]^2 \rangle}{2 \langle N_k(\tau) \rangle} \quad (1)$$

In general term, a point process is called fractal when a number of the relevant statistics shows scaling with related scaling exponents (Lowen and Teich, 1995). This implies that the AF depends on τ with a power-law, with exponent α , which indicates the presence of clusters of points over a number of time scales τ . For a fractal process with $0 < \alpha < 3$ this power law reads
5 (Telesca and Pereira, 2010):

$$AF(\tau) = 1 + \left(\frac{\tau}{\tau_1}\right)^\alpha \quad (2)$$

where τ_1 is the fractal onset time that marks the lower limit for significant scaling behavior for the AF. For times smaller than τ_1 there is no significant time correlation, while for times greater than τ_1 a characteristic fractal trend can be derived from the value of the exponent. If the storms process is Poissonian, the arrival times are uncorrelated, hence α is expected to be zero and
10 the AF will be near unity. If non-poissonian processes are present over a significant range of time scales it will be possible to identify $\alpha > 0$ and $AF > 1$. Serinaldi and Kilsby (2013) demonstrated that cyclic, hence non-homogenous, Poisson processes show $AF > 1$ for time scales associated to cyclic components. It is therefore necessary to identify and separate the timescales at which clustering occurs from those at which the point process is poissonian. To this end it is necessary to compare the AF pattern found in the wave time series with that of a process of known properties. A cyclic Poisson process is generated here
15 with the same “integrate and fire” (IF) technique used in Serinaldi and Kilsby (2013). The cyclic components are selected by looking at the dominant harmonic components obtained with the Fourier analysis.

The exponent α is estimated for the time scales at which the process is not poissonian. Note different ranges of τ can reveal different time scaling (clustering) of the same process through different slopes of eq. (2) due to different kind of forcing (Telesca and Pereira, 2010).

20 3 Wave data

3.1 Wave hindcast

Wave hindcast in the Mediterranean Sea has been implemented on a time window covering 36 years, from the first of January of 1979 till the 31st of December of 2014 (www.dicca.unige.it/meteocean/hindcast.html). The wave model is forced by the 10-m wind fields obtained by means of the non-hydrostatic model WRF-ARW (Weather Research and Forecasting - Advanced
25 Research WRF) version 3.3.1 (Skamarock et al., 2008). In the present study a Lambert conformal grid covering the whole Mediterranean Sea with a resolution of about 0.1 degree in longitude and latitude has been used. Initial and boundary conditions for atmospheric simulations were provided from the CFSR (Climate Forecast System Reanalysis) database (Saha et al., 2010). Use of CFSR reanalysis data for wave modeling provides reliable results, even if sometimes extreme wave conditions are not properly modeled (Cavaleri, 2009; Cox et al., 2011; Splinder et al., 2011; Carvalho et al., 2012; Chawla et al., 2013). For
30 further details of the set-up and validation of the meteorological model readers can refer to Cassola et al. (2015, 2016).

Generation and propagation of sea waves have been modeled using WavewatchIII[®], version 3.14 (Tolman, 2009). A 336×180 regular grid covers the whole Mediterranean Sea with a resolution of 0.1273×0.09 degrees, corresponding to about $10km$

at the latitude of 45°N . Spectral resolution is characterized by 24 bins in direction and 25 frequencies ranging from 0.06 to 0.7Hz with a step factor of 1.1. The output has been recorded hourly in all points of the computation grid for integrated quantities (i.e. significant wave height H_s , mean period $T_{m-1,0}$, peak period T_p , mean direction θ_m , peak direction θ_p , directional spreading $\Delta\theta$). The validation of the wave hindcast has been carried out through extensive comparison of simulated quantities and wave buoy data (cfr. Mentaschi et al., 2013a, b, 2015) and has already been employed for different applications such as wave energy resource assessment (Besio et al., 2016) and extreme and wave climate analysis (Sartini et al., 2015a, b).

3.2 Buoy data

The Italian Sea Wave Measurement Network (Rete Ondametrica Nazionale RON) started operating in July 1989 (De Boni et al., 1992; Arena et al., 2001; Corsini et al., 2004). The locations of the buoys are indicated in Fig. 2. Until 1998 the network was made by eight pitch-roll directional buoys located offshore, in deep water conditions, of several sea areas equally spaced along the Italian peninsula. These original eight stations were: La Spezia, Alghero, Ortona, Ponza, Monopoli, Crotona, Catania and Mazara del Vallo. The statistical wave parameters (i.e. significant wave height H_s , mean period T_m , peak period T_p , mean direction θ_m) were originally retrieved every three-hours, below a station-dependent threshold for H_s , and every half an hour above this threshold. The wave data time series, measured by the RON buoys, that have been analysed in the present study, cover a time window of 20 years, from the summer of 1989 until the spring of 2008 for the original eight buoys. For the cluster analysis performed using the RON records, data every three hours were considered for all the stations.

4 Results

4.1 Comparison between hindcast and buoy measurements

In order to assess the reliability of the hindcast time series related to storm cluster analysis, the results of AF for the RON buoys are analysed and compared to the corresponding grid points of the hindcast model. These results are shown in Figs. 5-6. Results obtained on the basis of the RON data and hindcast series show a good qualitative and quantitative agreement especially for lower threshold conditions (98% percentile) while for higher threshold (99.5% percentile) tend to present stronger differences, e.g. in Alghero (see Fig. 5). These findings can be explained by the fact that increasing the threshold limit would select just the most energetic wave conditions that are the most difficult to be reproduced by numerical models (a.o. Cavaleri, 2009) and sometimes to be recorded by wave buoys (breakdown, damages or even loss of the instrumentation). Also, differences are usually larger for smaller time scales, i.e. $0.5 < \tau < 50$ days and for the 99.5% percentile (e.g. Alghero and Mazara in Fig. 5). These results confirm that the hindcast data and the wave buoys show very similar scaling properties.

4.2 Comparison with a simulated non-homogeneous point-process

The AF patterns of both the model and data, show a consistent behaviour across the Mediterranean basin. The AF is greater than one for τ greater than 12-24 hours (0.5-1 days) and a distinct slope is recognizable, generally between 0.5 to 20-50 days

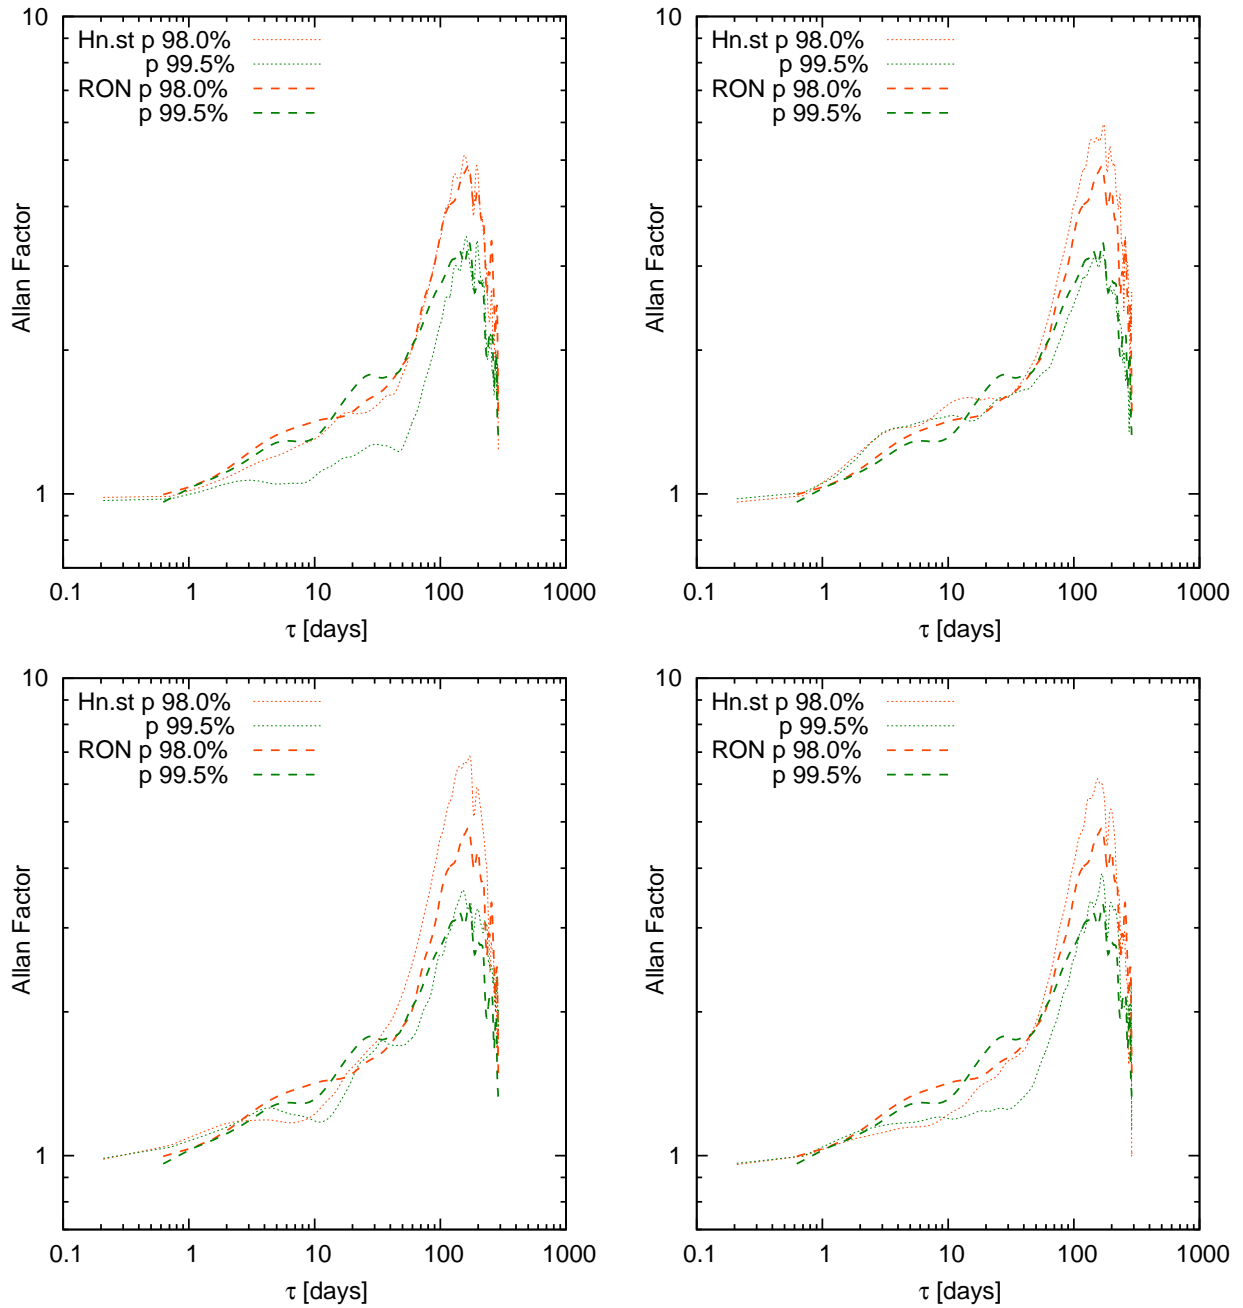

Figure 5. Comparison of Allan Factor between RON and Hindcast data series for different threshold percentiles (98% and 99.5%)

in many of the stations. For larger values of τ , the AF increases to reach a maximum at 180 days. It is necessary to clarify the nature of the processes described by the AF patterns seen and, in particular, it is necessary to identify if deviation from a cyclic

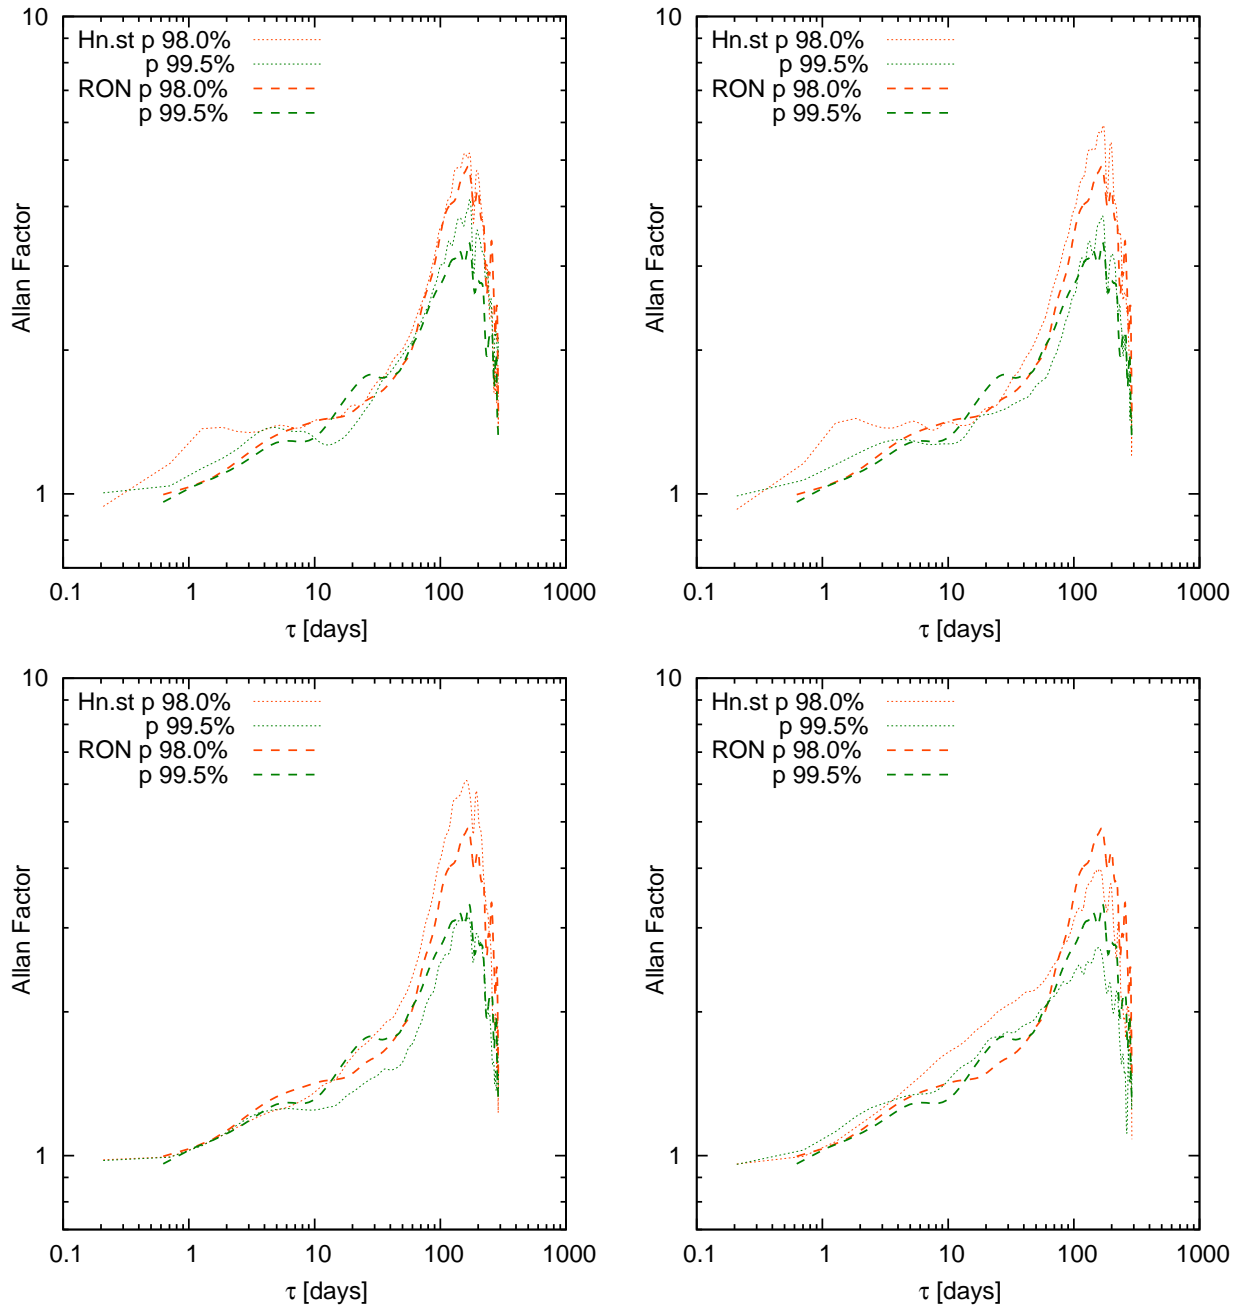

Figure 6. Comparison of Allan Factor between RON and Hindcast data series for different threshold percentiles (98% and 99.5%)

Poisson-Process is present. To this end, the AF pattern found from hindcast time series is compared with that of a simulated non-homogeneous Poisson process. This is generated using the IF technique employed in Serinaldi and Kilsby (2013). The rate

function of the simulated non-homogeneous Poisson process is generated as a sum of sinusoidal components with amplitudes, periods and phases obtained from the Fourier analysis of the reference signal. A Monte Carlo simulation of 1000 time series is then carried out and the simulated population of AF is compared with the reference one. Hindcast points A, G and O (see Fig. 2) are chosen for this analysis because they show different AF patterns in the time scales $\tau < 50$ days.

This analysis reveals that, as expected, the dominant cyclic component for all the considered time series is the one with 1-year period. This was also noted for the RON data in Briganti and Beltrami (2008), where the amplitude of the annual cycle component was estimated to be around 0.25 m in Alghero, which is consistent with what found in the present work. Together with the annual cycle also the components with periods of six, three, one months and one week have been considered to simulate the non-homogeneous Poisson processes. The results of the comparison are shown in Fig. 7. For all three points it is clear that the simulated cyclic Poisson process well explains the pattern of the AF at $\tau > 50$ days in all cases. As expected, this is the signature of the annual cycle, which strongly influences the occurrence of above-threshold events. The AF departs from the Poisson distribution at $\tau < 50$ days, above all in points A and G. The departure from a poissonian behaviour at these time scales occurs even at very low values of α , as for example in point O. However, data often show oscillations, above all for $\alpha < 0.1$, and it is not possible to make conclusions about the existence of a clustering regime.

4.3 AF results over the Mediterranean Sea

Results from the control points located over the basin (see Fig. 2) are shown in Figs. 8-11. The analysis of the AF curves reveal that these can be divided in two groups:

a) The first group shows clearly the slope corresponding to the departure from the Poisson regimes. The change in regimes occurs at around $\tau = 50$ days in most cases. α varies significantly from point to point. A well-defined slope, is very evident at points A (North Tyrrhenian Sea), B (Gulf of Lyon), D (Alboran Sea), and E (Algerian Sea). In all these cases a uniform value of α can be defined and the exponent value is in the interval $0.15 - 0.3$. In other cases the slope is not so well defined or it is significantly smaller than 0.2. Points that show either or both characteristics are point R (Adriatic Sea), C (West Sardinia), F (Tunisian coast), G (South Tyrrhenian Sea), M (Ionian Sea) and Q (Aegean Sea). At point Q (Aegean), α is virtually naught.

b) In the second group only the cyclic Poissonian regime is clearly recognizable, generally for $\tau > 20$ days. At smaller scales the slope that is associated with the departure from the Poisson distribution is not present. This is the case of the southern Mediterranean points H (Egypt), I (Western Libia), L (North-East Libia), O (South East Mediterranean Sea) and P (Southern Turkey).

The spatial distribution of the slope for small time-scales is shown in Fig. 12. This figure has been obtained by determining the best fit value of α at different time scales. In order to take into account the local differences in determining the transition between slopes and the different regimes seen in the representative points, the slope has been estimated using four different ranges of τ . Clustering in the range $12 < \tau < 72$ hours (3 days) is presented in panel a), for $12 < \tau < 120$ hours (5 days) results are showed in panel b), finally panel c) shows the results for $12 < \tau < 240$ hours (10 days). Within this range the small-scale

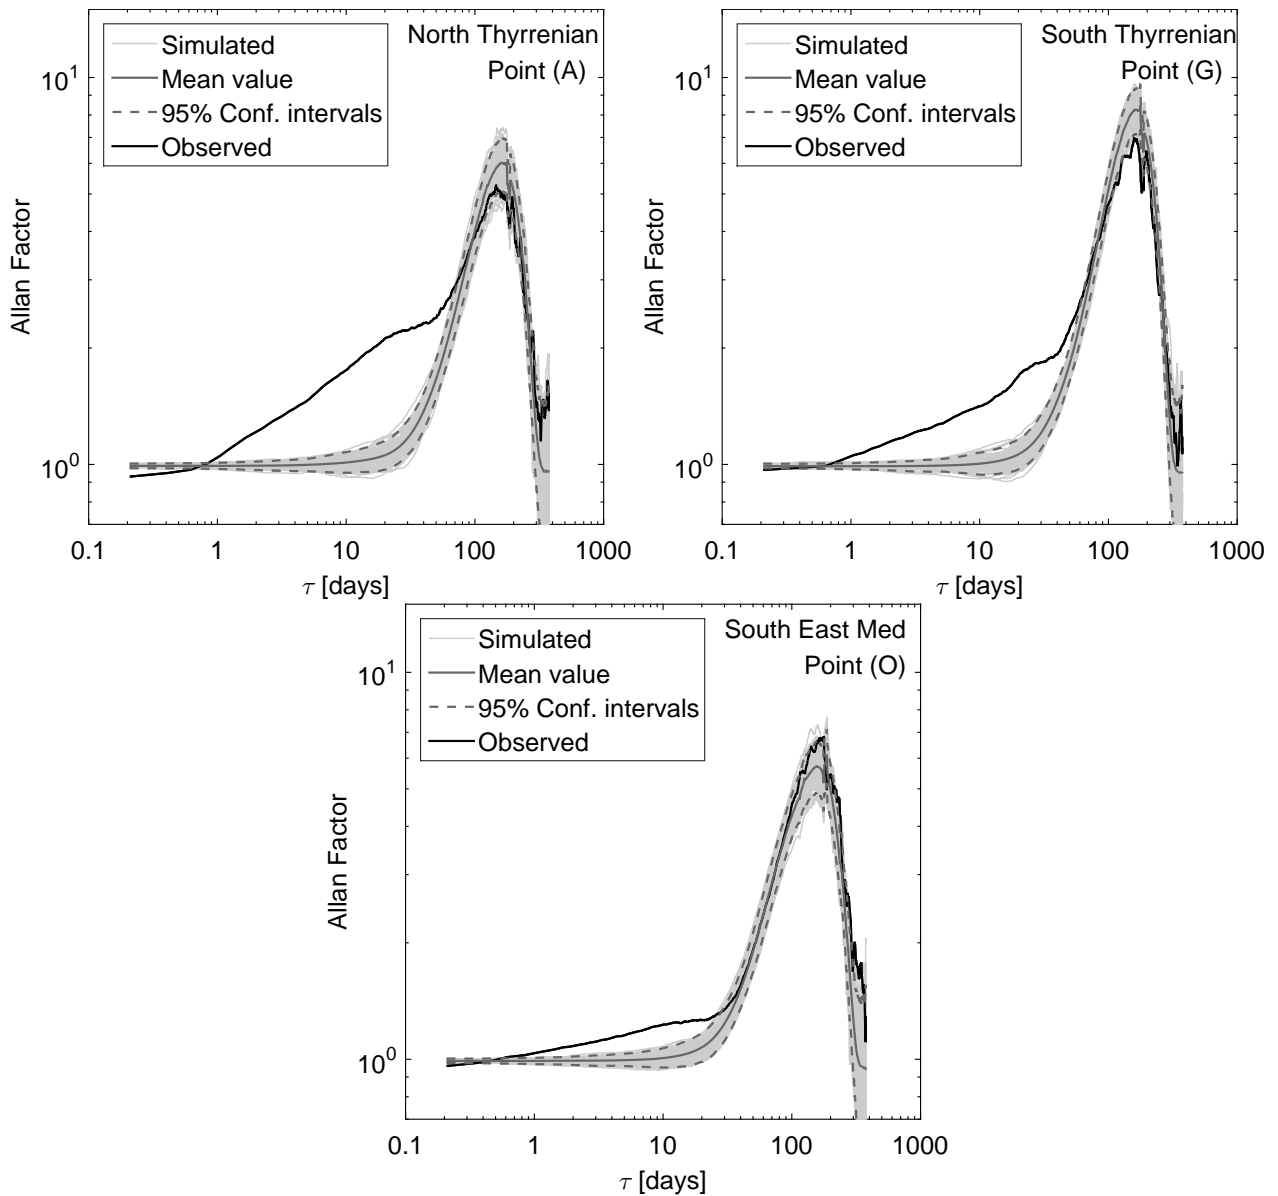

Figure 7. Comparison of Allan Factor between Hindcast data series for 98% percentile (black line) and 1000 simulated cyclic Poisson processes (grey lines). The AF corresponding to the 95% percentile of the AF distribution is also plotted (dashed line). Top left, point A (Northern Thyrrhenian). Top right Point G (South Thyrrhenian). Bottom Point O (South East Med).

slope is higher in the North-West Mediterranean Sea and, in particular in the North Thyrrhenian Sea and in the Balearic Sea. Here α reaches values up to 0.3. Areas with α around 0.2 are present in the Adriatic Sea, on the Syrian and Lebanese coast and along the Tunisian coast. The effect of widening the range of τ is to decrease the best fit value of α . This effect reduces the

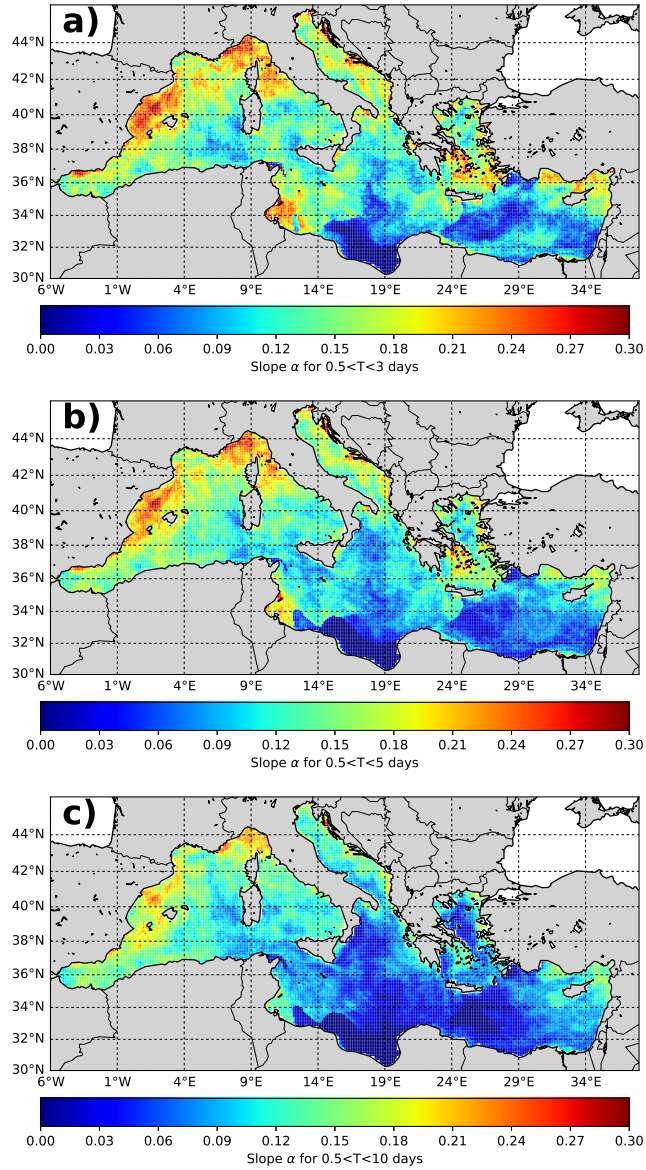

Figure 12. Spatial distribution of the exponent α for the whole Mediterranean basin

regions that show α significantly higher than zero in particular in the Adriatic Sea and on the East Coast of Tunisia. When the interval $12 < \tau < 240$ hours (0.5-10 days) is used (Fig. 12 panel c) the best fit of α is significantly higher than zero only in the North-West Mediterranean Sea with the average α around 0.2 and zones with $\alpha > 0$ are present in the East part of the Adriatic

5 Sea and on the Syrian coast.

5 Discussion and conclusions

The results presented highlighted the presence of a departure from the Poisson distribution for time scales shorter than $\tau < 1200$ hours (50 days). This regime is characterised by $\alpha = 0.15 - 0.3$ and is more evident in the North-West of the Mediterranean Sea. In the rest of the basin α is closer to zero and the AF pattern is characterised by oscillations, without a well defined regime.

5 For $\tau > 50$ days the arrival of above-threshold storms is dominated by the effect of seasonal and inter-seasonal oscillations and can be described as a cyclic Poisson process. Similar scaling regimes have been observed in other phenomena with seasonal behaviour, e.g. fires (Telesca and Pereira, 2010). These results match with the findings by Sartini et al. (2015a), who found that the northern basin RON buoys (e.g. Ponza and La Spezia buoys in the Tyrrhenian Sea) showed lower seasonality than the buoys in the south basin (e.g. Crotona, in the Ionian Sea). La Spezia buoy, for example is located in the Ligurian Sea, a region
10 where departure from the Poisson distribution is higher. Although in the region the cyclogenesis in the Gulf of Genoa shows marked seasonality, cyclones are present throughout the year (Lionello et al., 2006, Sartini et al., 2015a). This persistence of cyclonic events helps in explaining the behaviour at smaller scales (i.e. $\tau < 1200$ hours, 50 days). The clustering at scales of days indicates that meteorological conditions favour the occurrence of multiple events in few days. It is not a case that this behaviour is seen in the most active cyclonic region of the Mediterranean Sea, e.g. the North West according to Lionello et al.,
15 2016. Similar considerations apply to the North Adriatic Sea. In other parts of the basin, where these persistent conditions do not occur, the arrival of storms is well described as a cyclic-Poisson process.

The values of α found in the present study do not allow to draw conclusions on whether this deviation from a Poisson distribution is large or small for the phenomenon at hand, as there is no comparison with other basins. Because of this, it is important to analyse further basins.

20 The clustering at the time scales found has the potential to exacerbate local beach erosion generated by individual storms, as shown in Dissanayake et al. (2015), hence it will be important to understand the implication of these time regimes on the dynamics of the Mediterranean coastal regions.

Author contributions. G. Besio and L. Mentaschi developed the wave hindcast and the Allan Factor analysis for the Mediterranean Sea; R. Briganti coordinated the work and gave the theoretical ideas to develop the analysis; A. Romano and P. De Girolamo developed the analysis for the RON buoy dataset and carried out the comparison with the simulated non-homogeneous Poisson point process. All the authors participated actively in the preparation and writing of the manuscript.

Acknowledgements. The work described in this publication was supported by the European Community's Horizon 2020 Research and
5 Innovation Programme through the grant to HYDRALAB-PLUS, Contract no. 654110. R. Briganti expresses his gratitude to the Engineering and Physical Sciences Research Council (EPSRC) for providing the funding through the FloodMEMORY project (Grant number: EP/K013513/1). The authors would like to thank Dr Wahl and an anonymous reviewer for having contributed to the improvement of the manuscript. The authors are grateful to Dr Francesco Serinaldi for the proficous discussion during the revision of the manuscript and for having made available the routines for the simulation of cyclic Poisson processes.
