7 **Abstract.** The northern segment of the Kamchatka subduction zone (KSZ) experienced three tsunamigenic
8 earthquakes in the 20th century (Feb 1923, April 1923, Dec 1997), events that help us better understand the behavior
9 of this segment. Characterizing these historical earthquakes and tsunamis in turn contributes to interpreting the
10 prehistoric record, which is necessary to evaluate recurrence intervals for such events. A particular focus of this
11 study is the nature and location of the 5 December 1997 Kronotsky rupture as elucidated by tsunami runup in
12 southern Kamchatsky Bay. Some studies have characterized the subduction zone off Kronotsky Peninsula as less
13 seismogenic, as indicated by gravity-anomaly analyses, and have placed the 1997 rupture south of the promontory.
14 However, tsunami runup north of the peninsula, as evidenced by our mapping of tsunami deposits, requires the
15 rupture to extend farther north. Previously reported runup (1997 tsunami) on Kronotsky Peninsula was no more
16 than 2-3 m, but our studies indicate tsunami heights for at least 50 km north of the peninsula, ranging from 3.4 to 9.5
17 m (average 6.1 m), exceeding beach ridge heights of 5.3 to 8.3 m (average 7.1 m). For the two 1923 tsunamis, we
18 cannot distinguish their deposits in southern Kamchatsky Bay, but they are in sum more extensive than the 1997
19 deposit. A reevaluation of the April 1923 earthquake (and its tsunami) suggests that its moment magnitude should
20 be revised upward to Mw ~8. This revision makes the two 1923 events more like a pair, with the 1997 earthquake
21 filling a gap between them. Deeper in time, the 1700-year prehistoric record of tsunamis in southern Kamchatsky
22 Bay indicates that during this interval, there were no local events significantly larger than the 20th century
23 earthquakes. Together, the historic and prehistoric record suggests a more northerly location of the 1997 rupture, a
24 revision of the size of the April 1923 earthquake, and agreement with previous work suggesting the northern KSZ
25 ruptures in smaller sections than the southern KSZ. The latter conclusion requires caution, however, as we continue
26 to learn that our historic and even pre-historic records of earthquakes and tsunamis is limited, in particular as applied
27 to hazard analysis. This study is a contribution to our continued efforts to understand tectonic behavior around the
28 northern Pacific and in subduction zones, in general.

34 1 Introduction

35 References to the modest or small tsunamis of 15 December 2006 central Kurils (Ammon et al., 2008; Liu,
36 2009), when in fact this tsunami generated an average of 9.6 m runup over an along-rupture length of 390 km
37 (MacInnes et al., 2009), remind us that without post-tsunami or tsunami-deposit surveys, remote spots in the world
38 may experience large events without a written record. The case of the 5 December 1997 tsunami following the Mw
39 7.7-7.9 Kronotsky earthquake (Fig. 1, Fig. 2), however, is even more complex historically, because there was a post-
40 tsunami survey quickly following (Zayakin and Pinegina, 1998), though of limited extent. The local tide-gage record
41 for this 1997 tsunami is also incomplete, and deep-water pressure recorders deployed at the time were not positioned
42 to get distinctive recordings from a tsunami originating near Kronotsky Cape (Bourgeois and Titov, 2001). The
43 earthquake and tsunami occurred in the dark of a December night in an area with no permanent settlements.

68
69 In the summer of 2000, we conducted a field survey for historical and paleo- tsunami deposits in south
70 Kamchatsky Bay (Fig. 1), north of Kronotsky Peninsula. We expected to find evidence of historical Kamchatka
71 tsunamis such as 1923 (Table 1; Table S1), but not for 1997 Kronotsky because on the southern Kronotsky
72 Peninsula, the post-tsunami survey found evidence of quite limited runup. Thus we were surprised to find a sand
73 layer just at the surface, covered only by plant debris such as grass and leaves, distributed much as we have come to
74 expect of tsunami deposits, and at elevations of 5 m or more above sea level. No alternative other than a tsunami
75 from the 1997 earthquake and its aftermath could explain the layer and its distribution.

76 The implications of this case, where an earthquake was analyzed without full knowledge its tsunami, are
77 several. First, the fact that there was runup greater than that reported by a post-tsunami survey changes our view of
78 the tsunami as well as of the earthquake. Further, the size of the tsunami, based on its deposits and a corroborating
79 eyewitness account (acquired in 2001), constrains the rupture characteristics of this earthquake. The tsunamigenic
80 portion of this earthquake was in a “gap” between two 1923 tsunamigenic earthquakes, at least one of which was
81 locally larger than 1997.

82 This recent historical tsunami also helps us interpret earlier historical and well as prehistoric earthquakes
83 and tsunamis along the northernmost part of the Kuril-Kamchatka subduction zone. Tsunamis originating from this
84 region commonly have an impact not only locally but also on Hawaii, as did the February 1923 tsunami, and in
85 some cases even on the western coast of the Americas, as did the 2006 central Kurils tsunami.

86

87 **2 Background**

88 **2.1 The 1997 Kronotsky earthquake**

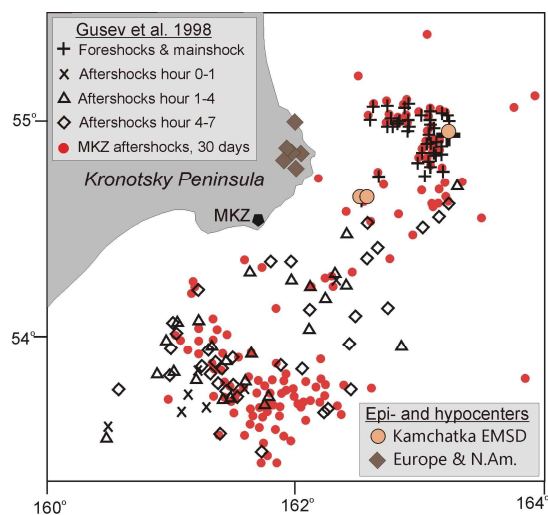

89 On 5 December 1997 at 23:26:51 local time (11:26:51 UTC), a large earthquake (Mw 7.7-7.9; we use 7.8)
90 shook the region of the Kronotsky Peninsula, Kamchatka, Russia (Fig. 1, Fig. 2; Gordeev et al., 1998). The
91 earthquake was characterized by a typical foreshock-mainshock-aftershock sequence (Gusev et al., 1998; Fedotov et
92 al., 1998; Balakina, 2000; Zobin and Levina, 2001; Kuzin et al. 2007; Slavina et al., 2007). Most studies of the
93 earthquake calculate a moment magnitude of 7.8 for the energy released in the first 60-80 seconds of the main
94 rupture (e.g., Zobin and Levina, 2001). Gusev and Shumilina (2004), in reassessing many Kamchatka earthquakes,
95 assign Mw 7.9 to Kronotsky 1997. In addition to the mainshock, and using GPS measurements, Gordeev et al.
96 (2001) calculate Mw 7.7 for deformation in the *pre-seismic* half month, and approximately Mw 7.9 for *post-seismic*
97 deformation; Bürgmann et al. (2001) calculate Mw 7.7 of (*post-seismic*) aseismic energy release in the 2 months
98 following the mainshock, also based on GPS data.

99 The locations of the mainshock and of any slip concentration for this earthquake have not been well
100 resolved, and with one early exception (Sohn, 1998), locators have not used tsunami data. Based on seismic data,
101 the locations of foreshocks and the mainshock/epicenter (Fig. 2) are in the northern part of the interpreted rupture
102 area. A number of analytical locations of the mainshock lie under the NE Kronotsky Peninsula (Fig. 2; Table S2).
103 Some analyses interpret the rupture to have propagated NE to SW (Petukhin et al., 1998), deepening toward the SW.
104 Gusev (2004) maps the entire aftershock zone as part of the 1997 event (Fig. 1). On the other hand, the linear zone
105 of aftershocks in the SW (Fig. 2) has been interpreted to be a separate stress zone (Kuzin et al., 2007) potentially
106 along a separate transverse fault (Slavina et al., 2007). In an analysis focused on GPS data, Bürgmann et al. (2001)
107 place the majority of the primary rupture energy in the southern half of the aftershock zone.

108

109 **Figure 2.** Foreshocks (3-5 Dec 1997), mainshock
110 and aftershocks of the 5 December 1997 Kronotsky
111 earthquake (Gusev et al., 1998). Plotted foreshocks
112 and MKZ aftershocks include only cases where P and
113 S arrivals could be read from records of the nearest
114 station, MKZ. Locations of epicenters and
115 hypocenters are from various analyses, both local and
116 farfield as reported from the International
117 Seismological Center (Table S2). Slavina et al. (2007)
118 interpret the southwestern aftershock activity to be on
119 a separate, transverse fault; Kuzin et al. (2007) also
120 interpret the SW portion of the (extended) aftershock
121 region to be a separate stress zone
122

126 2.2 The recorded 1997 Kronotsky tsunami

127 The most complete contemporary record of the 1997 Kronotsky tsunami is from far-field tide gages. Both
128 proximal tide gages, in Ust' Kamchatsk and in Nikolskoe (Bering Island) (Fig. 1), were not functioning when the
129 tsunami arrived. The Petropavlovsk-Kamchatsky gage is very protected and shows a wave train with an amplitude
130 of about 0.01 m (Zayakin and Pinegina, 1998). The tide gage at Nikolskoye resumed recording after the first 10
131 hours of the tsunami, with a few cm of amplitude remaining (Zayakin and Pinegina, 1998). The far-field tsunami
132 had tide-gage amplitudes in Alaska/Aleutians and Hawaii in line with other tsunamis traveling to Hawaii from the
133 Russian Far East (Table S3; Fig. S4). The tsunami was recorded on at least 12 tide gages (Table S3), with the
134 highest amplitude (half of wave height) of 0.3 m at Kahului, Maui, Hawaii. Deep-water pressure sensors deployed
135 at that time in the north Pacific were all in tsunami shadows for this tsunami source, and in all cases, the modeled
136 and measured tsunami was within the noise level of the buoys (Bourgeois and Titov, 2001; no event page at
137 http://nctr.pmel.noaa.gov/database_devel.html).

138 A truncated post-earthquake and tsunami survey by helicopter took place on 9 December 1997 (Leonov,
139 1998; Zayakin and Pinegina, 1998). The survey reached as far north as Kronotsky Cape on the Kronotsky Peninsula
140 (Fig. 1) and found that the tsunami had not exceeded the unvegetated beach. At this time, the beach was covered
141 with a thin layer of ice and snow, which in places had been coated by the tsunami with a thin sand layer and
142 elsewhere had been broken up by the tsunami (Fig. 3). The team did not have surveying equipment and estimated
143 runup to be no more than 3 m (T. Pinegina notes), and the published report gave a maximum of 1-1.5 m. The
144 turnaround point in the survey was dictated by fuel and available daylight.

145 On 5 December 1997, two rangers were in a cabin near Big Chazhma River; one of them was interviewed
146 (in Petropavlovsk-Kamchatsky) by T. Pinegina 19 April 2001. They felt the earthquake that night, and the next day,
147 as was their custom, they went via snowmobile to survey the northern coastal part of Kronotsky reserve, to the Little
148 Chazhma River area. At the mouth of the Big Chazhma, they saw jumbled ice and seaweed on the snow; a cabin on

149 the south bank of the Little Chazhma River was partly wetted, and there was seaweed on the snow. Normally the
150 rangers crossed the river near this cabin, but the river was a jumble of ice and they had to go some distance upstream
151 in order to cross (on ice). On the other side, they could not continue north because there was water in the low spot
152 between beach and hill (see Fig. 4, our profile 100).

153 Based on results of the post-tsunami survey (reported to Sohn by V. Gusiakov), Sohn (1998) analyzed the
154 tsunami with regard to its earthquake source and concluded that the main rupture must have lain largely under land,
155 in order to explain the low runup accompanying a moment magnitude she calculated as $M_w 7.7$. However, the
156 tsunami amplitudes on tide gages in Hawaii indicate that there was substantial subsea deformation.
157

201 2.3 Historical record of earthquakes and tsunamis affecting the field area

202 The Kamchatka Peninsula has a short but rich historic record of large earthquakes and attendant tsunamis,
203 of which we discuss herein only 20th century tsunamis originating in or having been recorded in the field region of
204 southern Kamchatsky Bay (Table 1). In addition to locally originating tsunamis, Kamchatka is vulnerable to
205 tsunamis originating from Chile, less so from Peru, and not so much from Japan, Alaska, Aleutians and Central
206 America, due to directivity (e.g., see Table S1). Based on existing scant records in the vicinity of the field area
207 (Table 1), we can expect the 1960 Chile tsunami to have reached elevations of 3-5 m above sea level in the field area,
208 on the order of twice as high as the 1952 southern Kamchatka tsunami *at these same localities*.

Table 1. 20th CENTURY TSUNAMIS AFFECTING THE KAMCHATSKIY BAY COAST OF KAMCHATKA*

***Bold: tsunamis most likely to leave a sedimentary record in south Kamchatskiy Bay;** see Supplemental Table 1 for a more complete list of tsunamis and Supplemental Table 4 for specifics in 1923 cases. Primary sources: Zayakin and Luchinina, 1987; NCEI (formerly NGDC) Natural Hazards Data, online (see references)

[^]Kamchatka Mw's from Gusev and Shumilina, 2004; G&S 8.2 for 14Apr23 is based on tsunami; see text discussion

[#]The 20-m and 11-m numbers are from higher-relief shorelines than the other measurements

209
210

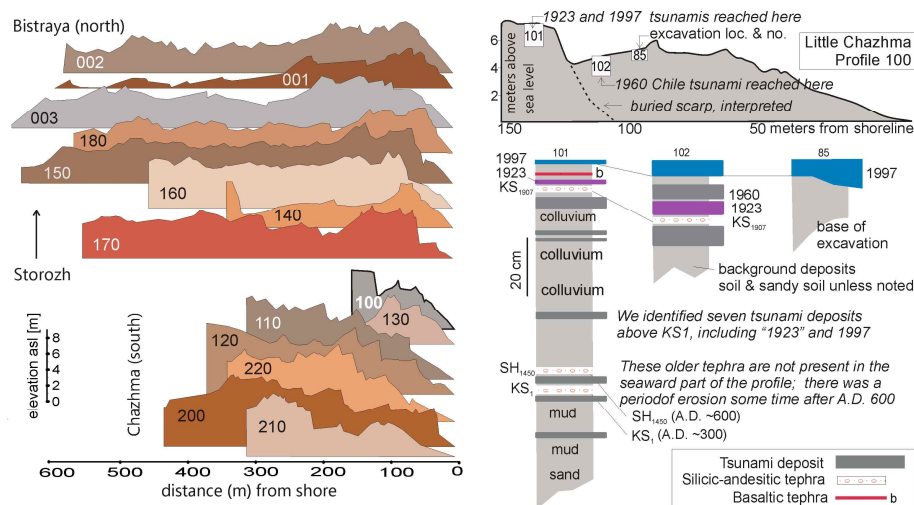

211 The largest documented local tsunamis from earthquakes near Kronotsky Peninsula (Fig. 1; Table 1) are
 212 two from 1923, both having local as well as farfield records (Table S4); both may have been large in south
 213 Kamchatskiy Bay. There was also a 24 Feb 1923 Mw 7.6 earthquake in this area (Fig. 1; Gusev, 2004); however, it
 214 has no historical tsunami record in the near or far field. [The Mw 8.0 1917 earthquake along the Bering fracture
 215 zone (Fig. S1) also did not produce an observed tsunami.] The 3 Feb 1923 Kronotsky Bay earthquake (Mw 8.5) was
 216 located south of Kronotsky Cape (Fig. 1). The 14 April 1923 north Kamchatskiy Bay earthquake (Mw 7.3 in NCEI
 217 catalogue) generated a high tsunami near Ust-Kamchatsk (Table 1; Table S1). Based on tsunami amplitudes, Gusev
 218 and Shumilina (2004) suggested this April 1923 earthquake had a moment magnitude of 8.2 (Table S1, Fig. S2).
 219 Based on the estimated locations of the February and April sources (Fig. 1) and the recorded tsunami runup in Ust-
 220 Kamchatsk (Table 1), we might reason that in south Kamchatskiy Bay the April 1923 tsunami may have been larger.
 221 However, Zayakin and Luchinina's catalogue records that the February 1923 tsunami went 4-5 km up the Chazhma
 222 River (Table 1).

223 The record of earthquakes and tsunamis on Kamchatka prior to the 20th century is spotty but improving
 224 (Zayakin and Luchinina, 1987; Godzikovskaya, 2010); the earthquake catalogue from the second half of the 19th
 225 century is not as complete as from before or after (Gusev and Shumilina, 2004).
 226 Earthquakes on 17 May 1841 and 17 October 1737 originated in the region of the 1952 south Kamchatka great
 227 earthquake, so likely did not have significant effect in southern Kamchatskiy Bay (see Table 1, 1952 runup). Other
 228 tsunamis that may have affected south Kamchatskiy Bay are an autumn 1849 tsunamigenic earthquake in the vicinity
 229 of the Komandorsky Islands (Godzikovskaya, 2010) and a 1791 event which has an intriguing account of having
 230 affected the mouth of the Kamchatka River (Ust-Kamchatsk), reaching 7 km upstream (Zayakina and Luchinina,
 231 1987).

232 **3 Methods**

233 We measured 15 topographic profiles (Fig. 4) perpendicular to the shoreline along the coast of southern
 234 Kamchatsky Bay (Fig. 1), and made 117 excavations along these profiles in order to document historical and
 235 paleotsunami deposits. We used a surveying rod with a transit level (hand level and tape for profile 001 and upper
 236 part of profile 120) (methods as in Bourgeois et al., 2006).
 237

238 **Figure 4.** Left. Topographic profiles measured in southern Kamchatskiy Bay (locations on Fig. 1, arranged from
 239 south (bottom) to north (top), except 001 and 002 reversed to reveal topography. Distances and elevations are
 240 measured from 0 at the water line, corrected to low tide. Right. Chazhma Profile 100 used as a key to collected
 241 profile data and interpretations (*interpretation in italics*); background deposits are soil or sandy soil, unless noted.
 242
 243

244 Tsunamis create sedimentary deposits as they flood the coast with turbulent, turbid water. The general
 245 characterization of a tsunami deposit in sandy coastal systems is a sand sheet that typically thins and fines landward,
 246 following topography (Bourgeois, 2009). Many factors, from sediment availability to coastal topography and
 247 roughness to the velocity profile of incoming and outgoing waves, play a role in sedimentation. Kamchatka field
 248 sites are primarily sandy, vegetated coastal plains and associated peat marshes, where availability of sand and the
 249 vegetative cover maximize the likelihood of generating and preserving tsunami deposits. (Many historical
 250 Kamchatka tsunamis have occurred during winter snow cover; deposits would have been “let down” onto a
 251 vegetative mat as the snow melted.) The maximum distance inland of a tsunami deposit (*sediment inundation*, Fig.
 252 5) and the deposit’s elevation at sediment inundation (*sediment runup*, Fig. 5) represent minimum estimates of
 253 tsunami extent for several reasons. Tsunami deposits can only be more limited (not more extensive) than water
 254 runup and inundation, the final limit of a deposit is not always located in the field, and thin deposits may not be
 255 identified or preserved.

256

257

258

259

260

261

262

Figure 5. Terminology for sediment runup and sediment inundation, and interpretation of deposits from 1997 and 1923, using example of an actual profile (Storozh 160; vertical exaggeration ~10). Note that near the shoreline, both tsunamis had to exceed a point (H) higher than “sediment runup” (h) and that, although the minimum sediment runup for 1923 is not much greater than for 1997, 1923 had to have been higher to generate greater inundation. Distances and elevations are from surveying.

275

276

Primary age control in excavations is provided by dated regional and local marker tephra layers (Table 2), which in general have been well studied on Kamchatka (e.g., Braitseva et al., 1997), although tephra in the south Kamchatsky Bay area had not previously been examined. Based on our own and previous work, as well as on more recently published isopach maps (Kyle et al., 2011; Ponomareva et al., 2017), the three most consistently present layers in the sections are KSht₃ (A.D. 1907 — we label KS₁₉₀₇ on diagrams)—most useful for studying the historical record, SH₁₄₅₀ (A.D. ~600) and KS₁ (A.D. ~300), the latter used as the lower boundary for our tsunami statistics. In more northern profiles, SH₂ (A.D. ~1130) is commonly present. Recent work around Shiveluch volcano and Kamchatsky Peninsula (Fig. 1) has led to redesignation of Shiveluch tephra and to more definitive model ages of these tephra (Ponomareva et al., 2017). In addition to the silicic marker tephra (Table 2), there are local basaltic-andesitic tephra layers, which can be from Kliuchevskoi, Bezymianny, Tolbachik or Gamchen volcanoes; we used these tephra only as local field guides. In the northernmost of our profiles, a historic ash from Bezymianny 1955 (year before the 1956 paroxysmal eruption) is locally present and a factor in distinguishing the Kamchatka 1952 from the Chile 1960 tsunami deposits.

276

Table 2. Marker tephra layers younger than 2000 years old in shoreline profile sections, southern Kamchatsky Bay*

Code Field/Classic [^]	Code New*	Source volcano	Modeled age* (years B.P.)	Assigned age* (calendar years)	Field description	Field thickness
KSht ₃	KSht ₃	Ksudach	Historical	A.D. 1907	Light to medium gray, fine to very fine sand	0.5-2 cm
SH ₂	SH#6	Shiveluch	817 +59/-57	A.D. 1134	White (faint gray, yellow white), fs-vfs, has pumice	0.5-1 cm; distinct toward north
SH ₁₄₅₀	SH#12	Shiveluch	1356 +52/-45	A.D. 596	Pale yellow, yellow gray, lt gray, vfs-ms, salt & pepper—grainy	1-2.5 cm; typically 1-2 cm
KS ₁	KS ₁	Ksudach	1651 +54/-61	A.D. 298	Lt brown, beige, "coffee cream"; thin gray cap; si-vfs	1-3 cm; usually not >2 cm

277

278 For the prehistoric record of tsunami runup and inundation, topographic profiles would not necessarily be
279 the same as in the recent past must be reconstructed to account for succeeding topographic changes in elevation and
280 distance along the profile. While we cannot typically reconstruct profiles that have been changed by erosion, we can
281 reconstruct profile progradation (building seaward), which affects profile width. Our method uses preserved tephra
282 as discussed, e.g., in Pinegina et al. (2013) and MacInnes et al. (2016). Changes in elevation are quantified by
283 determining the age and elevation of the lowest former soil horizon above marine sand in any excavation (as in
284 Pinegina et al., 2013).

285

286 3.1 Field localities

287 The southern field site (Fig. 1), which we call “Chazhma,” is a narrow strip (~400 m wide or less) of
288 Holocene accumulative coastline along a rugged coast just north of the Kronotsky Peninsula. The two profiles near
289 river mouths (Chazhma 210 and Chazhma 130; Fig. 4) maintain lower elevations (< 4 m) over much of their
290 distance, though both reach elevations of more than 6 m above sea level. The other five profiles rise, typically in
291 sharp steps indicative of Holocene uplift events (e.g., Pinegina et al., 2013), reaching typical maximum levels of 8-
292 10 m (Fig. 4). Net uplift on these profiles is consistent with longer-term uplift of Pleistocene terraces on the
293 Kronotsky Peninsula (Melekestsev et al., 1974).

294 The northern field site, which we call “Storozh,” extending north to the Bistraya River (Fig. 1), is a broader
295 strip (typically 600 m wide) of Holocene accumulative coastal plain associated with active and drowned river
296 mouths. Two of these profiles (140, 001) drop in elevation behind one or more beach ridges (Fig. 4). The other
297 seven profiles are typified by a series of beach ridges, of which the seaward ridges are higher, reaching typically 6-7
298 m, with an average elevation of the profile in the range of 4-6 m (Fig. 4). Such profiles indicate mild subsidence or
299 no vertical change in the late Holocene.

300

301 4 Results -- 20th century tsunami deposits

302 In field season A.D. 2000, the sand we interpret to have been deposited by the 1997 Kronotsky tsunami
303 formed a sheet-like layer at the surface, buried only by grass, leaves and other dead vegetation. The deposit we
304 interpret to be “1923” (from one or both of two tsunamis in 1923) lies above the marker tephra KS_{1907} with less soil
305 thickness between KS_{1907} and “1923” than between the top of “1923” and the base of the modern turf. Our
306 interpretation of “1923” as well as a rare sand layer between “1923” and 1997, which we assign to the 1960 Chile
307 tsunami, is discussed below.

308 Using identified and mapped tsunami deposits, we calculate minimum sediment runup and inundation on
309 each of the 15 profiles (Table 3, Figure 6), correcting for tide at the time of survey. We determine minimum
310 sediment runup (h) by the presence or absence of distinct 1997 and “1923” deposits on each profile. We distinguish
311 between profiles where the farthest landward excavation still contains the 1997 or “1923” deposit and ones that do
312 not. If no deposit is present in one or more excavations landward of ones with a deposit, the limit of sediment
313 inundation (L) occurs within the measured profile (Fig. 5, example of 1997) and actual tsunami runup is estimated
314 from sediment runup. For profiles where a particular tsunami deposit extends beyond all excavations (Fig. 5,

315 example of 1923), the actual size of the tsunami could be, in some cases, significantly greater than our sediment-
316 runup and inundation minima. We also report the maximum height the tsunami had to exceed (H) as it traveled
317 along (across) a profile. Note that maximum elevations and inundation distances are affected by elevations and
318 distances along actual profiles (Fig. 4). In a few cases, the farthest inland excavation was at a low elevation that
319 could have been reached via the river rather than over the profile (Table 3, Fig. 6).

320

321 4.1 1997 tsunami

322 Sediment runup data (Table 3, Fig. 6) indicate that north of the Kronotsky Peninsula the 1997 Kronotsky tsunami
323 ran up to as much as 9.5 m, averaging 6.1 m, with moderate inundation distances of 100-300 m. The general pattern
324 over about 100 km of coastline, including post-tsunami survey observations on Kronotsky Peninsula itself, is
325 relatively smooth. The maximum elevation reached by the tsunami deposit is higher on southern (Chazhma) profiles.
326 However, lower runup numbers on northern profiles may be an artifact of their lower elevations (Figure 4);
327 inundation distances are greater on these profiles (Table 3). On some profiles the 1997 deposit is absent.

328

329 4.2 1923 tsunamis

330 Sediment runup and inundation data for “1923” indicate that this tsunami was larger than 1997. The deposit we
331 interpret as from 1923 is usually thicker and more extensive, and never less extensive, than the deposit from 1997.
332 The “1923” deposit is present on all measured profiles whereas the 1997 deposit is missing on six (Table 3, Fig. 6).
333 Only on profiles where the sediment limit was not found (e.g. 100), or where profiles dropped to low elevations at
334 their landward extent (001, 180, 160, 140, 100, 130, 210) were “1923” deposits at similar or lower elevations than
335 1997, and in many of these cases (001, 180, 160, 130), inundation distances for “1923” were longer. Even in the
336 few cases where our field observations did not distinguish the two by sediment runup or inundation, the “1923”
337 deposit was coarser and/or thicker than 1997.

338

339 **Figure 6.** Water (Zayakin and Pinegina, 1998) and
340 sediment runup (this paper, Table 3) for the 1997
341 Kronotsky tsunami on and north of the Kronotsky
342 Peninsula, southern Kamchatsky Bay (locations on Figure
343 1). Water runup was not measured with instruments but
344 estimated; tsunami did not exceed the unvegetated beach
345 (e.g., Fig. 3); it could have been somewhat higher than
346 reported, shown by dashed blue line. Sediment runup is
347 also illustrated for the tsunami deposit closely above KS₁₉₀₇,
348 which we interpret as from 1923 February or April (see
349 text discussion). Sediment inundation is given in Table 3,
350 as well as latitudes and longitudes for the 15 profiles.
351 Figures 4 and 5 illustrate methods and terminology.
352

h - elevation of excavation m a.s.l.; equals "sediment runup" (maxima in bold)

L - distance from the shoreline, m; equals "sediment inundation" (maxima in bold)

H - highest elevation, m a.s.l., between shoreline and excavation; must be exceeded where there is a deposit (max. in bold)

*If the tsunami reached a low inland point via the river (indeterminate), H from the profile is not relevant.

353
354

355 4.3 Chile1960 deposit

356 Between "1923" and 1997 deposits on a few profiles (Table 3), there is a thin, patchy and less extensive deposit
 357 which we attribute to the 1960 Chile tsunami (e.g., Fig. 4, right). We favor 1960 over 1952 Kamchatka because the
 358 1960 tsunami was larger than 1952 in the Kamchatsky Bay region (Table 1). Also, The more locally generated 1952
 359 tsunami dies off in amplitude along strike of the rupture (MacInnes et al., 2010), whereas the Chilean tsunami on
 360 Kamchatka is little affected by latitude (Zayakin and Luchinina, 1987). Supporting the 1960 interpretation, in one
 361 excavation on profile 001, this intermediate tsunami deposit lies above the Bezymianny 1955 tephra layer.

362

363 4.4 Historical tsunami deposit close below KS_{1907}

364 In many excavations (e.g., Fig. 7), there is a tsunami deposit within a few cm of the base of $KSht_3$ and which is
 365 comparable to 1997 and 1923 in thickness and extent. Although pre-1907 sedimentation rates are difficult to
 366 determine this tsunami deposit must fall within the historical period, which extends back to 1737. However, the
 367 more complete historical records are from southern Kamchatka, and the second half of the 19th century record is
 368 particularly spotty (Gusev and Shumulina, 2004). Thus we cannot assign a specific event to this deposit.

369

370 **5 Discussion – 1997 and “1923” Deposits**

371 **5.1 1997 tsunami**

372 Our observations are consistent with 1997 being a seismogenic tsunami source with significant rupture energy
373 expended in the northern portion of the zone of aftershocks. The extensive and relatively smooth distribution of
374 runup (Table 3; Fig. 6) and the ratio of maximum runup to distance over which the tsunami had significant runup
375 (on the order of 10^{-5}) indicate that this tsunami was typical of a seismogenic source rather than a landslide source (cf.
376 Okal and Synolakis, 2004). The far-field tide-gage records (e.g., Hilo, Table 1) are also indicative of a broad rather
377 than a point source. Given that the post-tsunami survey reported runup that did not exceed the beach on the
378 Kronotsky Peninsula and that the deposits we mapped north of the peninsula are from the 1997 tsunami, *any source*
379 *model must explain low runup on the peninsula and relatively high runup north of the peninsula*. Source region
380 models by Bürgmann et al. (2001) and Llenos and McGuire (2007), e.g., do not include the northern aftershock area,
381 and such models have been used to interpret Kamchatka subduction-zone behavior (e.g., Song and Simons, 2003;
382 Bürgmann et al., 2005; Llenos and McGuire, 2007; Bassett and Watts, 2015). On the other hand, source regions by
383 Gusev et al. (1998; also Gusev, 2004) and Levina et al. (2013) tend to include the entire aftershock zone,
384 overlapping Feb 1923 in the south but also filling the gap between Feb 1923 and April 1923 (Fig. S1). Zobin and
385 Levina (2001) favor most mainshock energy being generated in the middle zone defined by fewer aftershocks (see
386 Fig. 2); Slavina et al. (2007) interpret the southwestern aftershock activity (Fig. 2) to be on a separate, transverse
387 fault; Kuzin et al. (2007) also interpret the SW portion of the (extended) aftershock region to be a separate stress
388 zone. A recently published finite fault model resolves to most deformation being under the Kronotsky Peninsula,
389 with most energy release focused in the north (Hayes, 2017;
390 <https://earthquake.usgs.gov/earthquakes/eventpage/usp0008btk#finite-fault>).

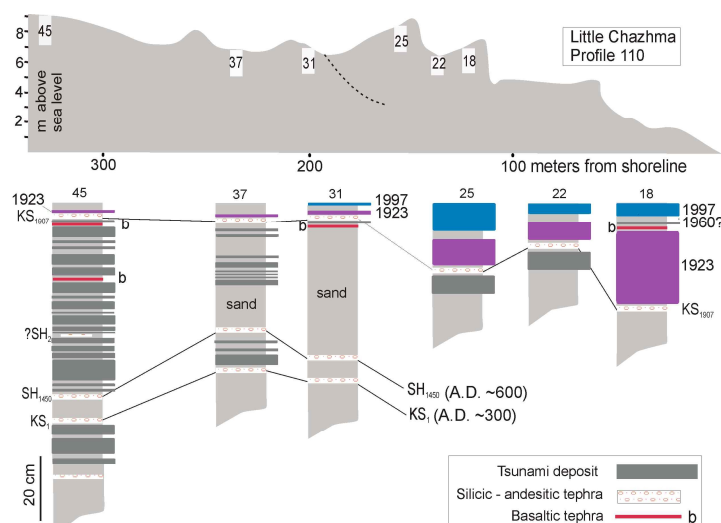

391

392 **5.2 1923 tsunamis**

393 There are reasons to favor either or both the 3 February 1923 and the 13 April 1923 Kamchatka tsunamis as the
394 generator(s) of the deposit above KS_{1907} that we identify as “1923.” Given what is known, south Kamchatsky Bay is
395 the place most likely to have *comparable* runups from each. Both tsunamis have a record in Hilo, but one is runup
396 and the other tide-gage amplitude (Table 1). There is no case on Kamchatka of a pair of similarly measured records
397 from the same locality with which to compare the two tsunamis, with the exception of observations that the April
398 tsunami generated more damage at the Tsutsumi fish plant southeast of Ust-Kamchatsk (Table S4). The 3 February
399 tsunami was larger in most catalogued locations (Table S4) but apparently smaller than April 1923 in *north*
400 Kamchatsky Bay. The two 1923 tsunamis both occurred while the ground would have been snow covered so that
401 following snowmelt, it would be nearly impossible to distinguish two different deposits in this case. The source
402 regions of the two 1923 Kamchatka tsunamis have been mapped (Fig. 1) but are not easy to constrain in detail other
403 than that the February earthquake was south of Kronotsky and the April earthquake north of it. The February
404 earthquake has been catalogued as Mw 8.3 and the April earthquake as Mw 7.3 (Table S3), but the local and far-
405 field tsunami runup for April 1923 suggests it was significantly larger (Gusev and Shumilina, 2004); Gusev suggests

14

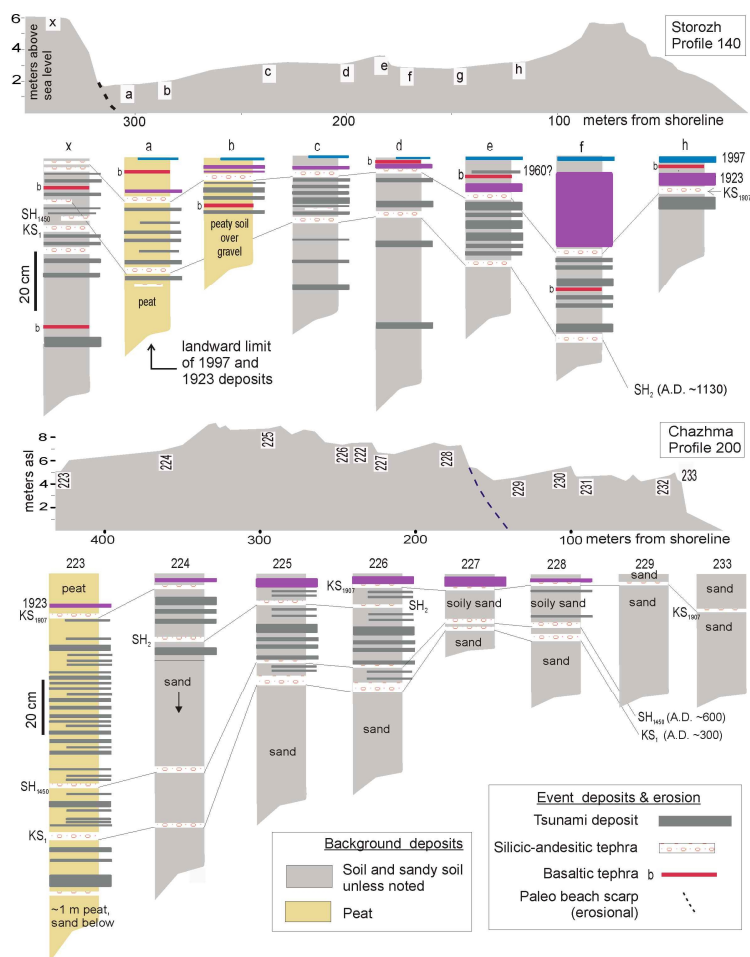

434
 435 **Figure 8.** Profile 110, Chazhma area (Fig. 1 location; more extensive key in Fig. 4). This profile has been uplifted
 436 through time – the landward part of the profile is higher. Exc. 45 contains many tsunami sand layers currently at
 437 high elevation, which when reconstructed were lower (Fig. S5). The profile shows the distribution of 20th century
 438 deposits, as well as a tsunami deposit very close below KS₁₉₀₇. The 1923 tsunami(s) reached the highest point
 439 shown on this profile, whereas 1997 and “below KS₁₉₀₇” were smaller. The deposit we tentatively assigned to Chile
 440 1960 on this profile is not included in Table 3 because the deposit was not well preserved; it is higher than any other
 441 excavation containing a deposit we attribute to Chile 1960.
 442

443
 444 **6 Tsunami deposits pre-20th century back to KS_I (~A.D. 300)**

445 Goals in reconstructing paleotsunami history include both scientific and practical objectives. Scientifically, southern
 446 Kamchatsky Bay paleotsunamis can help us see patterns of subduction zone behavior. Are the historical tsunamis
 447 (and their generating earthquakes) comparable to events in the past? What is the “typical” event and what are the
 448 rupture patterns of the northern Kamchatka subduction zone? Practically, these questions apply also to probabilistic
 449 hazard analysis – at what frequencies do tsunamis occur and what is their size-frequency relationship?
 450

451 **6.1 Occurrence and Size**

452 For the record and analysis of tsunami deposits below KS₁₉₀₇, for each excavation we count the number of deposits
 453 between marker tephra and determine the approximate elevation above sea level and distance from shore of the
 454 excavation locale in that time (tephra) interval (Fig. S5). For some deposits, this excavation may be their limit and
 455 for others not (e.g., Fig. 9). We do not attempt to correlate sand layers from excavation to excavation (or profile to
 456 profile), though there are cases where it is possible. Rather, we count the maximum number of tsunami deposits
 457 between tephra, which is our indication of how many tsunami events have occurred.
 458

459
 460 **Figure 9.** Example of two profiles that illustrate paleotsunami deposits used in analyses. Also see Figs. 4, 7, 8)
 461 **Storozh Profile 140 (top).** Here we use this profile to illustrate an analysis of tsunami deposits between KS_{1907} and
 462 SH_2 ; note that the deposits thin landward, in general. In most excavations there are six tsunami deposits between
 463 KS_{1907} and SH_2 ; excavation “x” has only three. Thus all six tsunamis reached “a” but only three reached “x”; or,
 464 three of the six tsunamis only reached “a”. All six tsunamis had to exceed the height of the shoreward beach ridge.
 465 **Chazhma Profile 200 (bottom).** As in Profile 110 (Fig. 8) this profile has undergone uplift through time. For sub-
 466 SH_2 deposits, the profile was reconstructed to 4 m lower and 150 m narrower. Sites 229-233 are young; the profile
 467 from 228 landward is older than KS_1 (A.D. ~300). Site 223 is not far from the modern Chazhma River and in the
 468 past some tsunamis may have flooded this site via the river, when the profile was lower. Sites 226 and 225 both
 469 have six deposits between SH_2 and SH_{1450} ; no other excavation on this profile provides a good count in this interval,
 470 but these six deposits probably are in the record at 223, and 224 was simply too sandy to count all layers in this
 471 interval. SH_2 is not preserved (was not detected) in the peat excavation (223), but the 23 tsunami deposits in this
 472 excavation can be used in the overall count above KS_1 . Excavations 223, 225 and 226 all preserve tsunami deposits
 473 between SH_{1450} and KS_1 . In this interval the peat excavation (223) contains six deposits to the two in 225 and 226,
 474 for two possible reasons; first, peat is a better preserver/displayer of thin layers, and second, 223 is lower than 225
 475 and 226 and at this time all were closer to shore. For the latter reason, 223 may have received tsunamis and their
 476 deposits directly from the river rather than over the beach ridge(s).

477 In order to summarize paleotsunami sizes, we determine sediment runup--or the highest point seaward,
478 whichever is higher--and sediment inundation for tsunami deposits on each profile. For each tephra interval along
479 each profile, there will be deposits at maximum distances and maximum elevations; the two measures are treated
480 separately because tsunami deposits are not correlated (in fact, high runup is associated with shorter, steeper profiles
481 and long inundation with low-relief profiles). For example, for the historical deposits, two points are plotted (Fig.
482 10) – their point of maximum inundation and their point of maximum runup, which are on usually on separate
483 profiles.

484 A few of the paleo-events are comparable to Chile 1960 (Fig. 10), but most are likely from locally
485 generated tsunamis because Chile 1960 was an outsized event and its deposits is not well represented on the profiles.
486 The 1997 tsunami has dimensions similar to the majority of paleotsunamis as represented by sediment runup of on
487 the order of 5-7 m (Fig. 10). The “1923” deposit, for which we do not know if related to February or April or both,
488 is a “typical largest” event (Fig. 10). Recall that in these field sites there are few excavations at elevations of 10 m
489 or more (Fig. S6), and that these higher elevations are on uplifted profiles, so we do not have a record of older
490 paleotsunamis reaching such elevations, simply as an artefact of the data and analysis (Fig. S5). This issue is
491 present also for paleo- inundation on prograding profiles, but is not such a strong artefact in this dataset. Overall,
492 the number of deposits tends to decrease away from the coast and at higher elevations (density of points on Fig. 10),
493 although there is a lot of scatter in the data, likely due to preservation and identification differences (e.g., Fig. 9).

494

495 **Figure 10.** Three-dimensional diagram summarizing
496 sediment runup and inundation for tsunami deposits,
497 south Kamchatsky Bay, above KS_1 tephra (A.D. ~300, up
498 through A.D. 2000) (from data plotted in Figs. S7 and S8).
499 The three historical tsunami deposits are highlighted with
500 their two points of maximum runup and maximum
501 inundation, which do not coincide. For prehistoric events,
502 we calculated (sediment) runup and inundation per tephra
503 interval, with adjustments for changes through time in
504 shoreline location and excavation elevation (see text and
505 Fig. S5). The axis “average time between deposits” is
506 biased by deposit counts and short time intervals but is
507 shown here for general pattern.

508

509

510 6.2 Recurrence

511 To determine tsunami recurrence according to size, we consider all tsunami deposits above KS_1 (A.D.
512 ~300) (Fig. 11). There are intermediate Shiveluch tephra layers between KS_{1907} and KS_1 (Table 2), but their
513 presence is not consistent enough to break down recurrence statistics, and the time intervals are relatively short
514 relative to the number of events, so statistical analysis cannot be supported. For this exercise, we only use
515 excavations now at or reconstructed to be more than 5 m above sea level or landward of a beach ridge (reconstructed
516 to be) higher than 5 m. The grand total of the maximum number of events per each interval is 18 deposits, including

517 the historical cases. For each event, we determine a maximum sediment runup, that is, if there are four deposits
518 between two marker tephra on a given profile, we determine the four highest points those deposits reach; e.g., two
519 may reach 8.3 m and the other two only 7.2 m (all four reaching 7.2 m). We use reconstructed distances and
520 elevations for each time interval below KS_{1907} . The maximum elevation is either sediment runup, h , or maximum
521 elevation before sediment runup, H (as in Fig. 5), whichever is higher. Independent of the determined maximum
522 elevation, we determine a maximum sediment inundation for each deposit in each tephra interval.

523 All 18 deposits reached elevations of 5 m (smaller not considered) and inland distances of 100 m, each
524 factor with a recurrence interval of about 100 years (Fig. 11). Note again that runup and inundation are not paired;
525 high runup commonly occurs on shorter, steeper profiles and long inundation on lower profiles. Tsunamis reaching
526 an elevation of at least 7 m have a recurrence of ~200 years (Fig. 11). The largest reconstructed tsunamis as
527 recorded by tsunami deposits have runup of 10 m or more and occur on average every 425 yr. Tsunamis with
528 inundation of 600 m or more occur on average every ~570 yr.

529

530 **Figure 11.** Tsunami (>5 m) recurrence for
531 exceeded elevations (sediment runup) and
532 exceeded distances from shoreline (sediment
533 inundation) of tsunami deposits since KS_1 (A.D.
534 ~300) in south Kamchatsky Bay. (For runup,
535 integers of m are shown; for inundation,
536 multiples of 100 m.) For example, tsunamis
537 with runup of 8-9 m or more occur on average
538 every 283 years. Tsunamis exceeding
539 inundation of 500 m occur on average every
540 340 years. Recall that runup and inundation are
541 not paired (see text).

542

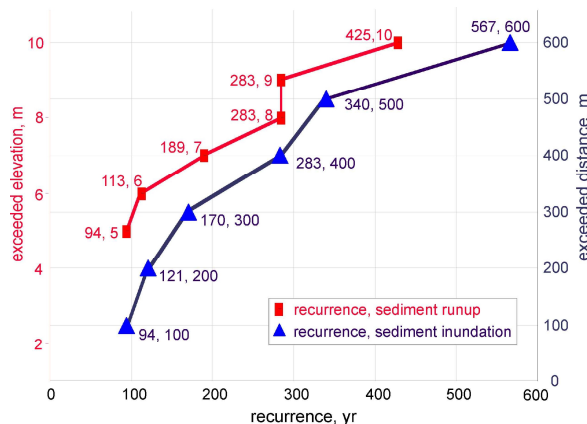

543

544 7 Discussion and conclusions

545 7.1 Historical tsunamis

546 This work adds to the tsunami catalogue for 1997 Kronotsky and 1960 Chile, but not February or April
547 1923 Kamchatka events because we cannot differentiate the (two) 1923 deposits. The nearfield nature of the 1997
548 Kronotsky tsunami is significantly revised by this study of coastal profiles north of the Kronotsky Peninsula, adding
549 substantial data to its catalogue. The 1997 tsunami reached runup heights of more than 9 m, averaging 6 m over
550 about 60 km of coastline. As would be expected, tsunami heights (as indicated by deposits) and inundation
551 distances are influenced by the coastal topography, with higher runups on steep profiles and higher inundation on
552 lower-relief profiles. Data catalogues do not commonly provide topographic profiles, yet this information can be
553 critical to understanding a tsunami and its generating source.

554 Based on deposits from 15 profiles and more than one hundred excavations, we conclude that the 1923
555 tsunami (February or April indeterminate) was larger than the December 1997 Kronotsky tsunami, but the summary
556 and tabulated data (Fig. 6, Table 3) are tricky to interpret, with sediment inundation (L) being more indicative of

557 tsunami size than runup (h) or highest point seaward of runup (H). On the basis of the total number of profiles
558 exhibiting a deposit, “1923” is more extensive, but its average sediment runup (h) value is lower because the farthest
559 point it reached on a number of profiles is actually lower than the points for 1997. Moreover, even though “1923”
560 exceeded more of the high beach ridges seaward of the (sediment) runup point (H), the average of those is almost
561 the same as for 1997 (Table 3). The most telling measurements distinguishing 1997 from “1923” are sediment
562 inundation distances, with the average for “1923” almost twice that for 1997.

563 The 1952 tsunami deposit in southern Kamchatka (and the northern Kuril Islands) (MacInnes et al., 2010)
564 reaches greater heights and inundation distances along its earthquake rupture zone than any of the historical tsunami
565 deposits along the northern part of the Kamchatka subduction zone (this study; Pinegina, 2014). While this
566 observation is not surprising given that 1952 was Mw 9.0 and the historical events to the north no larger than about
567 Mw 8.5, the question to address is, can (does) the northern part of the subduction zone produce Mw 9 events, or
568 does Kronotsky Cape represent an asperity that keeps ruptures shorter, as in 1923? For that, we must turn to the
569 prehistoric record.

570

571 **7.2 Implications for the 1997 Kronotsky earthquake rupture and the 1923 events**

572 The sediment runup and inundation data reported here require a reevaluation of rupture source models for
573 the 1997 Kronotsky earthquake; models which place most rupture energy to the south of or under the peninsula are
574 not consistent with the tsunami data. The tsunami, rather than being unusually small for its generating earthquake’s
575 moment magnitude (Sohn, 1998), generated runup averaging 6 m over about 60 km of coastline, and 30 cm
576 amplitude on the Hilo tide gage, requiring a “normal” offshore, subduction-zone rupture under a substantial depth of
577 water. Some significant portion of that rupture must be under substantial water depth to produce the indicated
578 tsunami north of Kronotsky Cape, while not generating as much runup on the Cape, or to the south. While part of
579 the rupture could well have been under the Kronotsky Peninsula and the relatively shallow region directly offshore,
580 deformation in deeper water east and north of the peninsula is needed.

581 We conclude that a rupture consistent with the mainshock and aftershock locations from Kamchatka’s
582 network are more reasonable than more westerly locations, e.g., in the ISC catalogue (Fig. 2, Table S2). This issue
583 is illustrated by Hayes (2017) inversion, which takes the NEIC hypocentral location (Table S2) to start and, while
584 his inversion results in most slip to the north (Fig. S9), locates that slip under the peninsula, where it cannot generate
585 a tsunami.

586 The northern part of the Kamchatka subduction zone ruptured in two large events in February 1923 and
587 April 1923 (Fig. 1), and our study requires that a substantial portion of the energy released by the 1997 Kronotsky
588 earthquake was generated in a seismic gap between those earthquakes (Fig. 1), as originally recognized by Fedotov
589 et al. (1998) and predicted by his group’s earlier work. The Kronotsky Peninsula lies landward of the (subducting)
590 Emperor Seamount chain, which has been postulated to generate an asperity and is characterized by a relatively
591 strong positive gravity anomaly (e.g., Bürgmann et al., 2005, Llenos and McGuire, 2007; Bassett and Watts, 2015)
592 (Fig. S9). That asperity may well keep the northern Kamchatka subduction zone from generating (Mw 9) 1952-
593 scale Kamchatka earthquakes, but it does rupture, as required by the tsunami data presented herein.

594 **7.3 Paleotsunami results – implications for tectonic studies and hazard analyses**

595 Southern Kamchatsky Bay has a relatively short but well-preserved record of paleotsunami deposits which
596 can be calibrated with the historical record. Combined with the record in north Kamchatsky Bay (Pinegina et al.,
597 2012) (the central bay is characterized by cliffs), the pattern of runup and inundation in the prehistoric record for the
598 last 1700 years does not diverge from the 20th century record. Compared with southern Kamchatka, the region
599 where Mw 9-scale events occurred in 1952 and 1737, the northern subduction zone has generated smaller and less
600 extensive tsunamis, in agreement with analyses of Bürgmann et al. (2005) for the modern and Pinegina (2014) for
601 the prehistoric record.

602 A robust, 1700-year-long record may be sufficient to generate a probabilistic hazard analysis that can be
603 used for both local and far-field hazard studies, and not only for tsunami recurrence statistics, but also for recurrence
604 statistics that include tsunami size. Reconstructing paleo- runup and paleo- inundation requires, and is thus limited
605 by, accurate reconstructions of past shoreline locations and past (relative) sea levels. Coastlines with well-
606 established marker tephra enable such reconstructions.

607 As are seismologists, paleoseismologists are cautioned by the lessons of the 11 March 2011 Tohoku
608 earthquake and tsunami to qualify our generalizations. Characterizing subduction-zone behavior and quantifying its
609 hazards are goals which we will only ever accomplish imperfectly.

610 **Supplement link (will be included by Copernicus)** – see supplemental material

611 **Author contribution** – we contributed equally and together

612 **Competing interests** -- none

613 **Acknowledgments**

614 Field research was supported by grants from the Russian Foundation for Fundamental Research (00-05-
615 64697- to T.K. Pinegina), the National Geographic Foundation to Vera Ponomareva, and the U.S. National Science
616 Foundation (EAR 9903341 to J. Bourgeois). Research and manuscript preparation were supported by RFBR grant
617 15-05-02651- to T. Pinegina and a U.S. Fulbright Foundation award to J. Bourgeois, which supported her visit to the
618 Institute of Volcanology and Seismology, winter/spring of 2017.

619 We thank Vera Ponomareva for field advice and discussions regarding tephra stratigraphy and analysis;
620 Alexander Lander for discussions concerning the nature of the 1997 Kronotsky earthquake; Alexander Gusev for
621 discussions regarding the 1997 and earlier large earthquakes on Kamchatka; Vasily Titov for insights into the 1997
622 Kronotsky tsunami; and Vadim Saltykov for his helpful recommendations about statistical analyses of tsunami
623 recurrence. We are grateful to Alexander Storcheus (deceased), Leonid Kotenko, Ivan Storcheus and Edward
624 Cranswick for their field assistance. Roland Bürgmann, Andrea Llenos and Gavin Hayes offered helpful insights
625 into their source models for 1997 Kronotsky.
