Abstract

Uncertainty in rainfall datasets and landslide inventories is known to have negative impacts on the assessment of landslide-triggering thresholds. In this paper, we perform a quantitative analysis of the impacts of uncertain knowledge of landslide initiation instants on the assessment of rainfall intensity-duration landslide early warning thresholds. The analysis is based on a synthetic database of rainfall and landslide information, generated by coupling a stochastic rainfall generator and a physically based hydrological and slope stability model, and therefore error-free in terms of knowledge of triggering rainfall instants. This dataset is then perturbed according to hypothetical “reporting scenarios”, that allow to simulate possible errors in landslide triggering instants as retrieved from historical archives. The impact of these errors is analysed jointly using different criteria to single-out rainfall events from a continuous series and two typical temporal aggregations of rainfall (hourly and daily). The analysis shows that the impacts of the above uncertainty sources can be significant, especially when errors exceed one day or the actual instants follow the erroneous ones. Errors generally lead to underestimated thresholds, i.e. lower than those that would be obtained from an error-free dataset. Potentially, the amount of the underestimation can be enough to induce an excessive number of false positives, hence limiting possible landslide mitigation benefits. Moreover, the uncertain knowledge of triggering rainfall, limits the possibility to set up links between thresholds and physio-geographical factors.

25

1. Introduction

Thresholds estimating rainfall conditions correlated to landslide occurrence are useful for landslide early warning systems (Guzzetti et al., 2007; Highland and Bobrowsky, 2008; Sidle and Ochiai, 2013). Commonly, thresholds are derived by empirical approaches based on the direct statistical analysis of historical rainfall series and landslide inventories, from which a line roughly separating triggering from non-triggering conditions is drawn. Among the various thresholds types, precipitation intensity-duration power law thresholds (hereafter referred to as ID thresholds), introduced by Caine (1980), have been derived for many regions of the Earth, and are still considered as a valid empirical model (Caracciolo et al., 2017; Gariano et al., 2015; Peruccacci et al., 2017; Vennari et al., 2014), though they are affected by several theoretical and practical limitations (Bogaard and Greco, 2018).

35 Thresholds derived for different geographical areas vary significantly, and some attempts have been made to find a rationale underlying this variability, by linking threshold parameters to physio-geographical and climatic features (Guzzetti et al., 2007, 2008). Nevertheless, rainfall and landslide data quality issues, reported in almost all of the papers on threshold determination, are known to potentially hamper the assessment of this link. As reported in many studies, the triggering instants available from real landslide inventories are imprecise. For instance, Guzzetti et al. (2007, 2008) reported that in a global database of 40 2626 landslides, the vast majority (68.2 %) had no explicit information on the date or the time of occurrence of slope failure; for most of the remaining events only the date of failure was known, and more precise information was available just for 5.1%

of landslides. These issues are confirmed with reference to an updated dataset of landslides occurred in Italy (Peruccacci et al., 2017). In their analysis, only information with an accuracy at least of one day was retained from the larger available dataset. Still for this trimmed dataset, triggering instants were available with high precision (minute or hour) only for the 37.3% of the data, being the day or part of it available for the majority (27.6% and 35.1%, respectively).

5

Other data artifacts include: *i*) rainfall measurement delays related to manual collection of data; *ii*) different criteria to identify rainfall events; *iii*) lack of completeness of landslide catalogues; *iv*) imprecise location of landslides, or precipitation measurements available at a significant distance apart from the location of failure. Though there is a general agreement that these factors affect the accuracy of rainfall thresholds, a quantification of the influence of these data quality issues on landslide triggering thresholds has been carried out in the literature only partially. In particular, to the authors knowledge, only the effect of rain gauge location and of the density of rainfall networks (point *iv*) has been analysed (Nikolopoulos et al., 2014), showing that the use of rainfall measured at some distance from debris flow location can lead to an underestimation of the triggering thresholds.

10

15

Quantitative assessments of the influence of the sources of errors listed above are difficult to be based on observational datasets, since it cannot be ensured that these are immune of errors. In this paper we capitalize on the synthetic rainfall-landslide data set of a preceding study (Peres and Cancelliere, 2014), to quantify the effects of the imprecise identification of triggering rainfall on the assessment and performances of landslide triggering thresholds. The dataset is in principle “error-free” in the sense that the instants of landslide triggering are exactly known, as well as the triggering rainfall time history. We then fictitiously introduce errors in the triggering instants and in the rainfall series based on hypothetical scenarios of landslide data retrieval and analysis, and analyse the implications on the accuracy of ID thresholds. Quality of information available in real datasets is generally intermediate of that corresponding to the hypothesized scenarios. These scenarios are combined with different criteria for event rainfall identification, and different aggregations of rainfall data (hourly and daily, and daily in the presence of a shift due to manual collection of data), so the effects of these other two sources of uncertainty are analysed as well (items *i*) and *ii*) of the above list). The synthetic data used for our analyses are based on characteristic for hillslopes in the landslide-prone region of Peloritani Mountains, in Northeastern Sicily, Southern Italy.

20

25

2 Dataset: generation of synthetic rainfall and landslide data

We refer to the dataset developed in Peres and Cancelliere (2014). Here we provide a basic description of the methodology used for its generation, which includes the following steps:

30

- *Synthetic generation of hourly rainfall time series*: A seasonal Neyman-Scott Rectangular Pulses (NSRP) stochastic rainfall model (Cowpertwait et al., 1996; Rodríguez-Iturbe et al., 1987a, 1987b) is used for the generation of 1000-years of hourly rainfall data. The model is calibrated on approximately 9 years of hourly observations from the Fiumedinisi rain gauge located in the area (Fig. 1).

35

- *Computation of hillslope pressure-head response*: A two-state hydrological model is used for the computation of pressure head. State 1 and 2 are activated separately during rainfall events and during no-rain intervals, respectively. Rainfall events are defined as a section of the rainfall series preceded and followed by no rainfall for a minimum time interval of 24 hours. Within state 1 the TRIGRS-v2 model (Baum et al., 2010) is applied, which is based on the Richards’ equation for mono-dimensional vertical infiltration with a Gardner negative exponential soil water characteristic curve. This is the least simplified form of the Richards’ equation for which an analytical solution has been derived so far (Srivastava and Yeh, 1991). A leakage flux at the soil-bedrock interface is considered, assuming the vertical hydraulic conductivity of the bedrock strata $c_D = 0.1$ times the saturated

40

conductivity K_S of the pervious soil layer. Within state 2 a linear reservoir water table recession model is activated to simulate sub-horizontal drainage, and is used to compute water table height at the beginning of the next passage to state 1. A linear reservoir scheme computes a drainage flow that depends on the water table level, determining a negative-exponential decay of pressure head at the bottom of the regolith layer, with recession constant τ_M .

- *Derivation of virtual landslide occurrence times:* An infinite slope model to compute the factor of safety F_S for slope stability is applied. For this schematization, failure surface coincides with the regolith-bedrock interface. The time instants at which a downward crossing of $F_S = 1$ occurs are assumed to be the instants at which landslides are triggered.

The data set is generated considering soil hydraulic and geotechnical properties shown in Tab. 1 that can be considered representative of hillslopes in the Peloritani Mountains landslide-prone area (see Fig. 1). The application to a hillslope of definite characteristics enables us to isolate the impact of the uncertainty in triggering rainfall identification; regional determination of thresholds do contain also factors of uncertainty related to the heterogeneity of landslide characteristics; the assessment of this combined uncertainty is out of the scope of our present analysis. The Peloritani area has been affected several times by catastrophic shallow landslide phenomena in the past; including the 1 October 2009 disaster, which has been analysed and described in several studies (Cama et al., 2017; Schilirò et al., 2015a, 2015b, 2016; Stancanelli et al., 2017). A morphological analysis of the catastrophic landslides occurred on 1 October 2009, has shown that a reasonable value of the recession constant for the specific case study area is $\tau_M = 2.75$ days (Peres and Cancelliere, 2014). Nevertheless, for the purposes of this study, we focus our analysis mainly on the hypothetical case of no pressure head memory ($\tau_M = 0$), so that the main source of uncertainty considered in threshold determination is that related to identification of triggering rainfall events. In other words, in the “ideal” simulations described above, the only uncertainty present is that of rainfall intra-event intensity variability, which is relatively small, so that a landslide-triggering threshold expressed in terms of rainfall duration and intensity performs almost perfectly (Peres and Cancelliere, 2014). For completeness, we however present a secondary analysis including antecedent rainfall memory, for which $\tau_M = 2.75$ days – a value determined from the analysis observed landslides (see Peres and Cancelliere, 2014). Table 2 shows some characteristics of the 1000-year long synthetic databases, which do not change among the different scenarios illustrated in the following section.

3 Methodology

3.1 Simulation of uncertainty in triggering rainfall identification

As already mentioned, the available triggering instants from real landslide inventories are seldom precise. On the other hand, the instants at which landslides are triggered are known exactly (on hourly resolution) for the synthetic series illustrated in previous Sect. 2. We then introduce errors to this synthetic dataset by hypothesizing the way such an information may be retrieved from newspapers, and similar resources (blogs and fire brigades reports), which in fact are the main primary sources available to build landslide historical inventories (e.g., Guzzetti and Tonelli, 2004).

We suppose that only the date of the landslide is reported, with some delay (See Fig. 2). For a landslide to be reported on day D , it has to be spotted within a time interval we denote as the “observers’ day” D' . Then the user of the landslide archive (the analyser), makes an interpretation of the available information, i.e. chooses an instant of the reported day of landslide occurrence to seek backwards for the triggering rainfall. In particular, the i -th landslide observed at t_i within the observers’ day D' , i.e. hours $[T_O - 24 \text{ h}, T_O]$ of day D , is assumed by the analyser to be triggered T_A hours after the start of day D (civil day D starts at 00:00). The observer day is made of the hours in which observers can report a landslide on day D . We assume that the

observer day is given by hours going from 6 pm of day $D-1$ to 6 pm of day D ($T_O = 18$ h); this choice is an attempt to resemble usual working hours, and the fact landslides occurring by night may be reported the morning after. The analyser time is the instant of landslide triggering as considered by who analyses the data (the “analyser”) to derive landslide-triggering thresholds, counted from the beginning of day D . This way to process the data introduces a sampling error and a shift between the actual instant at which the generic landslide i is triggered, t_i , and that assumed by who analyses the data, t'_i . Hence the error for the i -th landslide is given by:

$$e_i = t'_i - t_i \quad (1)$$

These errors are implicitly random, since though t'_i are deterministically chosen, the actual instant t_i varies in an aleatory fashion according to rainfall time history.

A positive error can be in general considered as more likely than a negative, since landslides are typically reported after some time they have occurred (Guzzetti et al., 2007, 2008; Peres and Cancelliere, 2013). This, however, does not exclude the possibility of a significant number of negative errors, because of temporal shifts in rainfall data, as will be discussed later.

The two parameters, T_O and T_A , can be set to simulate a range of scenarios, for which real situations may represent intermediate cases. We perform our analysis based on four scenarios (which include the “ideal” one), hereafter referred to as landslide information “reporting scenarios” (RS), and illustrated in Fig. 2:

1. *Ideal scenario* RS0 ($T_O = 0$, $T_A = 0$; $e_i = 0$ for all landslides). This is the error-free scenario (described in Sect. 2), that is considered for definition of the actual instants of landslide triggering, t_i .
2. *Small delay reporting* RS1 ($T_O = 18$ h, $T_A = 24$ h; random in the range $0 \leq e_i \leq 30$ hours). A landslide occurring within the interval from night hours of $D - 1$ until the evening of day D (i.e. within the observers’ day D') will be reported at day D . Here we suppose that the analyst attributes the landslide *at the end* of day D ($T_A = 24$ hours), i.e. searches the triggering event backwards from that instant.
3. *Large delay reporting* RS2 ($T_O = 18$ h, $T_A = 48$ h; random in the range $0 \leq e_i \leq 54$ hours). This scenario is similar to the previous, but here larger errors are hypothesized. We suppose that the landslide occurring during the observers’ day D' is reported on day $D + 1$, which is also erroneously assumed by the analyser as the day at which the landslide was triggered. He then attributes the landslide at the end day $D + 1$ ($T_A = 48$ hours). These timing errors may also be likely when landslides occur on weekends.
4. *Anticipated reporting* RS3 ($T_O = 18$ h, $T_A = 0$ h; random in the range $-18 \leq e_i \leq 6$ hours): This case is the same of RS1, but here analyst searches the triggering event backwards *from the beginning* of day D , i.e. at 00:00 (instead that at 24:00).

Within the context of sampling errors, another point is related to the way *rainfall* data is collected, specifically for daily data manually measured until some decades ago. A significant amount of papers derive landslide triggering thresholds using daily rainfall data (Berti et al., 2012; Leonarduzzi et al., 2017; Li et al., 2011; Terlien, 1998). In an ideal situation rainfall intensity should be aggregated from 00:00 to 23:59, i.e. over a civil “calendar day”, as illustrated in Fig. 3. With reference to manual collection of rainfall data, this requires that rain gauge should be read at midnight of each day, which is an uncomfortable hour. Manual collection of daily data is usually carried out at easier hours. For instance, in Italy, where the widest source of information are the Hydrological Bulletins (locally known as *Annali Idrologici*), the operator would measure the rainfall collected in the rainfall bucket every day at 9 am. Thus, daily rainfall in a given day is the amount of rainfall occurred in the 24 hours preceding 9 am of the same day. As illustrated in Fig. 3, in this case the reported daily rainfall amounts can be dramatically different than actual (see also Caracciolo et al., 2017).

Identification of triggering rainfall is uncertain also because of the different criteria that one can apply to isolate rainfall events from a continuous time series – Tab. 3 lists a range of criteria adopted in the literature. Here we analyse how the different

criteria can impact the identification of triggering rainfall, both in the case that uncertainty in the triggering instants is present (datasets RS1-RS3) or not (dataset RS0).

The automatic procedure we adopt for isolating events is as follows (see sketch on Fig. 4). First, a minimum rainfall threshold s_{\min} is applied to all rainfall pulses at the fixed temporal aggregation. This means that from the original series a new one is obtained, where precipitation pulses less than s_{\min} are replaced by zeros. In the sketch, these pulses are colored in light gray. Afterwards, rainfall events are singled-out when separated by zero-rain intervals longer than u_{\min} . This parameter is the most important parameter for the identification of rainfall events. With the aim of quantifying how the impact of the errors implied by the different reporting scenarios changes with rainfall identification criteria, various pairs of s_{\min} and u_{\min} have been set (see Sect. 3.3). The described algorithm defines the rainfall event regardless it is associated or not to a landslide. For attributing a rainfall event to a landslide, the cases where the triggering instant is within a dry or a wet period should be analysed separately. In the first case, the landslide is associated to the whole closest event occurring before the landslide, in the other case it is to the part of rainfall event occurring before the triggering instant. Automatic procedures have the advantage of being objective and reproducible, and thus more scientifically sound than subjective judgment (Melillo et al., 2015; Vessia et al., 2014); nevertheless, algorithms are suitable to reproduce the latter with a certain level of fidelity (Berti et al., 2012).

Finally, triggering rainfall identification uncertainty is simulated by combining the reporting scenarios, different parameters of the rainfall event identification algorithm, and three rainfall aggregation schemes (hourly, daily correct and daily shifted). This results in twenty-eight combinations for each recession constant value τ_M (see Tab. 4).

3.2 Threshold definition, calibration and testing performance

Seventeen different landslide-triggering threshold types based on rainfall characteristics have been proposed in the literature in the period 1970-2006 (according to the list reported at rainfallthresholds.irpi.cnr.it, last date accessed 15 Jan. 2018). In spite of this variety, the most widely used is the rainfall intensity-duration (ID) threshold, as 96 out of 125 (about 77 %) are of this type, if one includes equivalent rainfall depth-duration (ED) thresholds. Therefore, our analysis adopts this threshold type, which may be defined as follows:

$$I = \alpha D^{-\beta} \quad (2)$$

where I [L/T] is the mean rainfall event intensity, D [L] is the rainfall event duration (both defined according to scheme of Fig. 4); $\alpha, \beta > 0$ are respectively the intercept and slope parameters of the threshold. ED thresholds are equivalent to IDs, since rainfall intensity I is the ratio between event rainfall E (the total depth of a rainfall event) and its duration D ; so they can be converted in the ID type just by subtracting 1 to the exponent of duration.

The procedures for the identification of best threshold parameters have historically increased their complexity through time. Early works have considered lower boundary curves of the triggering events traced with subjective criteria (Caine, 1980). Then more objective procedures have been then proposed, still based on the triggering events only, such as the so-called “frequentist” method (e.g., Brunetti et al., 2010). More advanced approaches are currently used, and are derived from the analysis of both triggering and non-triggering events. These procedures are more transparent than methods based on triggering events only, as the uncertainty of the thresholds can be assessed through indices based on the confusion matrix or the Receiver-operating characteristics (ROC), that is, in terms of the count of true positives (TP), true negatives (TN), false positives (FP) and false negatives (FN) (Tab. 5). More importantly, these methods are also more robust, since the presence of non-triggering data points makes the choice of the threshold less sensitive to possible errors in the attribution of triggering rainfall event duration and intensity. Here we use these methods of recent application, implicitly assuming that the impact of the uncertainty under analysis is likely to be higher on thresholds derived from procedures based on triggering rainfall only.

Best-thresholds can be calibrated by maximizing their performances expressed in terms of suitable metrics. One widely used metric is the True Skill Statistics (Ciavolella et al., 2016; Peres and Cancelliere, 2014; Staley et al., 2013) originally proposed by Peirce (1884) :

$$TSS = \frac{TP}{TP+FN} - \frac{FP}{TN+FP} \quad (3)$$

5 An apparently alternative approach is given by Bayesian analysis (Berti et al., 2012). Indeed, this approach can be interpreted as a special case of the ROC analysis, since Bayesian a-posteriori probability is equivalent to the ROC-based Precision (PRE):

$$P(L|R) = \frac{P(R|L)P(L)}{P(R)} = \frac{\frac{TP}{TP+FN} \frac{TP+FN}{N_T}}{\frac{TP+FP}{N_T}} = \frac{TP}{TP+FP} = PRE \quad (4)$$

where:

$P(L|R)$ = probability of landslide occurrence given rainfall exceeding the threshold (*a posteriori* probability),

10 N_T = total number of rainfall events (triggering and non-triggering),

$P(R) = (TP + FP)/N_T$ = probability of rainfall events exceeding the threshold,

$P(L) = (TP + FN)/N_T = (a priori)$ probability of landslide occurrence,

$P(R|L) = TP/(TP+FN)$ = probability of rainfall event exceeding the threshold, given that a landslide has occurred (known as the *likelihood*).

15

Different papers discuss advantages and disadvantages of various indices proposed in natural-hazard forecasting, as one single index is not sufficient to fully describe the confusion matrix (Frattini et al., 2010; Murphy, 1996; Stephenson, 2000). Nevertheless, the choice of a single index is essential to keep the calibration procedure simple, i.e. a single-objective optimization problem. Hence, here we calibrate thresholds by maximizing the TSS. One advantage of the TSS is that it includes
 20 all the entries of the confusion matrix, and thus its maximization yields thresholds that result in a good trade-off between correct and wrong warnings/non-warnings.

Once thresholds for each RS scenario are derived, the TSS and the confusion matrix provide a measure of the uncertainty inherent the data, as assessable by who derives the threshold and is not aware of the errors. On the other hand, it is also of interest to test how a threshold derived from erroneous data may perform when, after its determination, it is applied to precise
 25 monitored data, and thus potentially free of the errors present in the threshold calibration data set. To do so, the calibrated thresholds are applied to the error-free synthetic data set (Sect. 5). The performances in this test are indicative of the impacts of errors when thresholds are actually used.

4 Impact of uncertain identification of triggering rainfall on threshold calibration

30 4.1 Hourly data

Results relative to the use of hourly data are shown in Fig. 5, for a given separation algorithm ($s_{min} = 0.2$ mm, $u_{min} = 24$ h).

For the reference dataset RS0, there is a negligible overlapping between triggering and non-triggering events (Fig. 5a), due to intra-event rainfall intensity variability. In fact in this case the best ID threshold ($I = 101 D^{-0.80}$) performs almost perfectly, with a TSS of 0.99 (for $u_{min} = 24$ h). The presence of small delay reporting errors (RS1), has little impacts on the position of
 35 triggering rainfall points (Fig. 5b), which in general are shifted slightly down along the intensity axis; this is related to the higher durations produced by positive errors in triggering instants, combined with an induced decrease of mean rainfall event intensities – a general behavior exhibited by extreme events (cf. the negative slope of well-known rainfall intensity-duration-frequency curves, see Bogaard and Greco, 2018). Only two rainfall events (the 2.5 % of triggering events) are highly-impacted, being moved to a duration of 1 hour. The latter and mainly the former effect, contribute to slightly flatten the threshold for
 40 TSS maximization (decrease of β to 0.7). When high delay sampling errors are present (RS2), the effects may not be negligible

as in the previous case, as more highly-impacted rainfall events are present, now also for significant durations (up to 24 h in the plot, Fig. 5c). These erroneous data points are difficult to be identified by an analyser, and thus their impact on threshold determination can be significant, and lead to a lower slope and intercept, i.e. an underestimation of the threshold, which changes to $I = 19 D^{-0.50}$ (reference is $I = 101 D^{-0.80}$). The impact of these errors may be more dramatic when thresholds are assessed making use of triggering rainfall events only, following “traditional”, less robust, approaches.

Negative errors, introduced by an anticipation of the real landslide instant (RS3), can have very high impacts, as can be seen from the relative plot in Fig. 5d, and the loss of the correct position of many of the triggering points. The best threshold corresponds to $TSS = 0.49$, which reflects the high degree of uncertainty implied by this kind of data errors.

4.2 Daily data

Shallow landslides can be triggered by rainfall events that are only few hours long (Bogaard and Greco, 2016; Highland and Bobrowsky, 2008; Sidle and Ochiai, 2013), and various studies have shown that the impact of small scale intra-event rainfall intensity variability can have a significant effect on landslide triggering (D’Odorico et al., 2005; Peres and Cancelliere, 2014, 2016). Hence, apart from the errors in the dataset, it is of interest to see how the change from hourly to daily data may affect threshold determination. This can be done by comparing thresholds determined from the hourly and daily datasets.

Figure 6 shows the results of calibration obtained with correctly-aggregated daily rainfall data and $s_{\min} = 0$ and $u_{\min} = 1$ day. As can be seen from the plots, the impact of delayed reporting of landslides (errors RS1 and RS2) is less significant than with hourly data. In fact, though α and β are lower than those determined from hourly data, the threshold determined from daily data passes more or less in the same zone for durations in their range of validity, $D > 1$ day. This is because the smaller slope β in the log-log plane compensates the smaller intercept α . The effect of anticipating landslide time location (RS3) has also here high impacts on the thresholds, Fig. 6d.

Figure 7 plots the results relative to daily rainfall data affected by a delay in the aggregation interval, as present for instance in Italian datasets, and related to availability of data from non-automatic rain gauges. The impacts of this systematic rainfall error can be high (Fig. 7a, b, and d). There is, however, the possibility that the errors due to rainfall aggregation and reporting landslide time interval compensate for each other, as in the case of scenario RS2 (delayed reporting of landslides), Fig. 7c (notice that this plot is similar to Fig. 6b). If the analyser is aware of the rainfall-aggregation shift, then he should correct as much as possible for this error – in this specific case, by shifting the entire daily rainfall dataset one day forward.

4.3 Possible effects of rainfall separation criteria and antecedent rainfall

Table 6 shows the results obtained by setting the parameters of rainfall event separation algorithms, in the hourly, daily correct, and daily shifted aggregation cases. From the TSS values obtained for hourly data, it can be seen that the impact of RS1 and RS2 increases with decreasing minimum interarrival value u_{\min} . For RS3, differences obtained with different u_{\min} are not relevant, since the performances are poor in general (TSS about 0.5). In the case of daily data, the importance of different criteria for separating events (values of the minimum daily rainfall threshold s_{\min}), are relatively lower than in the hourly data case. Though differences in the TSS are not significant, this may not be true for the thresholds parameters, which can vary significantly. In fact, higher thresholds are obtained from an increase of s_{\min} , because of the decrease of the number of days counted as rainy.

The behaviour related to hourly data, is related to the fact that, by choosing lower u_{\min} , events get generally shorter, and thus it is more likely that a landslide event is attributed to only a part of the actual triggering event. In this case the effect of preceding rainfall events cannot be neglected in general. In other words, our analysis suggests that the choice of the u_{\min} is crucial, and must be based on the timescales of the hydrological processes governing landslide triggering, in terms of long and short term responses (Iverson, 2000). This means that the effect of different criteria for rainfall separation is somehow related

to that of antecedent precipitation. The effects of antecedent precipitation is specifically taken into account performing Monte Carlo simulations with $\tau_M = 2.75$ days (results shown in Tab. 9). For this simulation, regardless of the rainfall separation time interval, the initial water table height measured from the bottom of the soil column is in general greater than zero, becoming negligible after a dry interval of $3\tau_M = 3 \times 2.75 = 8.5$ days (exponential decay). As can be seen, the results are qualitatively similar to the no-memory case; the main difference is that lower TSS are obtained for the added uncertainty due to antecedent conditions, and the thresholds are lower, since less event rainfall is needed in average to trigger a landslide because of non-zero initial wetness conditions.

5 Impact of uncertain identification of triggering rainfall on threshold use

Thresholds determined based on historical datasets are then meant to be used for early warning systems, when, consequently, more detailed meteorological and landslide monitoring is set up. This means that it is reasonable to hypothesize that after thresholds are determined, they are subsequently applied to high quality datasets, which suffer less of the limitations and errors present in datasets used for threshold calibration, generally not conceived for that specific purpose. This might induce to modify the thresholds in view of the new data, but this is a process whose implementation may take several years. Hence, with the aim of determining which would be the consequences of building an early warning system with thresholds derived from historical data with errors, Fig. 8 shows a visual comparison between the thresholds determined in the various numerical experiments and the ideal hourly dataset, for results related to the hourly (Fig. 8a) and daily data sets (Fig. 8b). For sake of clarity, it may be worthwhile to remember that the dataset of triggering and non-triggering points has been used in calibrating the thresholds only for the RS0 scenario, with hourly data and $u_{min} = 24$ h and $s_{min} = 0.2$ mm (the related threshold is shown on Fig. 8 as a thick black line). Thus the other thresholds are tested against this ideal dataset, which differs from the one used for their calibration.

The plots show that the presence of errors can induce a significant variability of thresholds which is totally unrelated to the different characteristics of a site (i.e. the geomorphological, hydraulic, geotechnical and land use characteristics). This allows to speculate that a significant part of the variability of landslide triggering-thresholds reported in literature (cf., Guzzetti et al., 2007) may be due to the sources of uncertainty here discussed. As a consequence, it is challenging to seek for links between the variability of physio-geographical characteristics and those of thresholds, as determined from different sites. The presence of errors in the landslide dataset yields thresholds that are in general underestimated, i.e. lower than the correct ones. Many thresholds on Fig. 8 are significantly lower than the correct ones, and the number of false positives can be relatively high, and not balanced by true positives. A good trade-off between correct and wrong predictions is essential for the success of an early warning system, since with an high number of false alarms the so-called cry-wolf effect may take place, inducing the populations not to take precautionary actions when warnings are issued (Barnes et al., 2007).

6 Conclusions

We have analysed and discussed the possible effects of uncertain triggering rainfall identification on the assessment of empirical landslide early warning ID thresholds, capitalizing on a synthetic rainfall-landslide dataset generated by Monte Carlo simulation. To this aim, we have investigated the effect of a set of hypothesized scenarios of landslide information retrieval and interpretation which can induce errors in the identification of instants of landslide occurrence. Moreover, we have analysed how the impact of reasonable scenarios may vary in dependence of rainfall aggregation (hourly or daily), and of rainfall event identification criteria. Real situations may be a mixture of the considered scenarios, and thus the impacts are presumably intermediate between the ones hypothesized.

The errors in the time instants can be, in an algebraic sense, positive or negative, according to whether a landslide is reported after its actual occurrence or before, respectively. Following literature, positive errors are more likely than negative,

since typically a landslide is reported some time after its actual occurrence. Our analyses have shown that if such errors are limited to less than 30 h (about one day), their impacts on the threshold may be relatively low; yet if the delay is higher, impacts can be significant. Negative errors, though less probable, can also exist, based on how an analyst interprets the information retrieved from landslide historical archives. The impact of these errors can be dramatic, as the location of triggering events in the $\log D - \log I$ plane can be completely altered. Errors in landslide triggering instants lead to triggering events that are shorter than the actual ones, so that their effect is to induce an incorrect identification of triggering rainfall for short durations. For higher durations (>1 day), the location of triggering events seems to be more robust, except when negative errors are present. This behavior induces a flattening of the ID thresholds (i.e. a lower slope β) and an underestimation of the position parameter of the threshold (i.e. a lower intercept α).

The impact of reporting errors can change significantly in dependence of the algorithm adopted for rainfall event identification. Specifically, a shorter “maximum dryness” interval for event separation induces an increase of the impacts of all reporting scenarios.

From our analysis no significant impacts seem to be induced by the use of daily data; however, it is of fundamental importance to check, and correct where possible, for the presence of delays in the rainfall accumulation interval, that is if precipitation reported for a given day is the total amount occurred in a shifted period (e.g., within the 24 hours preceding 9 am of that day rather than before midnight). Such a kind of shift affects, for instance, the Italian Hydrological Annual Reports, which constitute the largest rainfall data collection in Italy. The impacts of these shifts are potentially dramatic.

Overall, the presence of reporting errors in landslide triggering instants brings to lower thresholds, making them less suitable to set up of landslide early warning systems, as they can lead to a high number of false alarms, generating a misbelief by populations that are expected to benefit from their implementation. Similar effects have been found as a consequence of rainfall measurement uncertainty on thresholds (Nikolopoulos et al., 2014). These two sources of errors— always present in observed datasets – are alone enough to generate an uncertainty in thresholds assessment that is of significant magnitude. These results bring to the conclusion that the uncertainty inherent the available data can jeopardize the possibility to find a physically based rationale underlying the variability of empirical landslide-triggering thresholds across different sites. In other words, with the quality of current available data, attempts of relating thresholds to climate and other regional characteristics can be very difficult. An improvement of landslide and rainfall monitoring – e.g. rainfall, soil moisture and landslide satellite data, as well as landslide data crowd-sourcing (Guzzetti et al., 2012; Strozzi et al., 2013; Wan et al., 2014) – may be a step forward for overcoming these problems. Once accurate rainfall-landslide data are available, standardized methodologies have to be implemented to derive the thresholds, in order to allow their comparisons and to link their variability to site-specific landslide susceptibility factors.

Acknowledgements. *DJP was supported by post-doctoral contract on “Studio dei processi idrologici relative a frane superficiali in un contesto di cambiamenti climatici” (Analysis of landslide hydrological processes in a changing climate), at University of Catania. Part of the work was developed during his three-month stay as a visiting researcher at the Water Resources Section of TUDelft. The authors thank the comments by two anonymous reviewers, which helped to considerably improve the paper.*

List of figures

Figure 1: Location of the Peloritani Mountains area in Sicily, Italy, and of the Fiumedinisi rain gauge.

5 Figure 2: Sketch illustrating simulation of uncertainty in triggering instants likely present in landslide inventories built from newspapers or similar sources. The black numbered circles indicate one of the reporting scenarios (RS), which may induce a random error $e = t' - t$ in landslide triggering instants. In particular, a landslide that occurs within the observers' day, is reported at day D and attributed to the end of the same day (small delay reporting scenario, RS1) or to its beginning (anticipated reporting scenario, RS3). It can be reported also at day $D+1$ and then attributed to the end of it (large delay reporting scenario RS2). These scenarios can be described in terms of two parameters: T_O = the ending hour of observers' day, and T_A = the triggering instant, referred to hours 00:00 of day D , assumed by an analyser who interprets the newspaper-like information.

10 Figure 3: Aggregation of rainfall data from hourly to daily time scale: daily rainfall depths on the top row result from correct aggregation; those on the bottom row from shifted aggregation, as occurs for the Italian Hydrological Bulletins (Annali Idrologici). The shift is due to manual collection of data in early decades of operation of the monitoring network; the presence of the shift is still continued, in spite of installation of automatic rain gauges, to preserve homogeneity of the entire historical time series.

15 Figure 4: Sketch illustrating the algorithm for the identification of triggering and non-triggering rainfall events, and relative parameters s_{\min} and u_{\min} . When a landslide is triggered in a dry period, it is attributed to the whole event preceding it; otherwise, only the part of the event preceding the landslide triggering instant is considered. For non-triggering rainfall (the first one in the sketch), duration and intensity are computed considering the entire rainfall event.

20 Figure 5: Scatter plot, in the double-logarithmic rainfall duration-intensity plane, of triggering and non-triggering events for *hourly* data and separation algorithm parameters $u_{\min} = 24$ h, $s_{\min} = 0.2$ mm. Thresholds correspond to the maximum performance in terms of True Skill Statistic. The plots show outcomes relative to a) reference RS0, and b-d) various erroneous reporting scenarios (RS1, RS2, RS3).

25 Figure 6: Scatter plot, in the double-logarithmic rainfall duration-intensity plane, of triggering and non-triggering events for *daily* data and separation algorithm parameters $u_{\min} = 1$ day, $s_{\min} = 0$. Thresholds correspond to the maximum performance in terms of True Skill Statistic. The plots show outcomes relative to a) reference RS0, and b-d) various erroneous reporting scenarios (RS1, RS2, RS3).

30 Figure 7: Scatter plot, on the double-logarithmic rainfall duration-intensity plane, of triggering and non-triggering events for daily data with aggregation shift as in the Italian rainfall databases. Separation algorithm parameters are: $u_{\min} = 1$ day, $s_{\min} = 0$ mm. Thresholds correspond to the maximum performance in terms of True Skill Statistic. The plots show outcomes relative to a) reference RS0, and b-d) various erroneous reporting scenarios (RS1, RS2, RS3).

35 Figure 8: Comparison of thresholds, calibrated in the various scenarios and event identification parameters, with the correct hourly dataset. Thresholds determined with a) hourly and b) daily data (both correct and with aggregation shift), are distinguished. Correct thresholds are relative to the following event identification parameters: $u_{\min} = 24$ h, $s_{\min} = 0.2$ mm, and $u_{\min} = 1$ da, $s_{\min} = 0$ mm, for hourly and daily data respectively. These plots are representative of how thresholds calibrated with uncertain information of triggering rainfall data may perform in early warning systems that use high quality rainfall and landslide monitoring.

Nikolopoulos et al., 2014	hourly	0.2 mm	24 h

(*) More precisely “the algorithm scans a rainfall time series and detect the rainfall events using a moving-window technique: a new event starts when the precipitation cumulated over D_T days exceeds a certain threshold E_T , and ends when it goes below this threshold. For instance, if $D_T = 3$ days and $E_T = 2$ mm, the rainfall event starts when the cumulative rainfall exceeds 2 mm in 1, 2, or 3 days (that is if 2 mm are exceeded on the first day, the rainfall starts at day 1). Then, the rainfall event stops when it rains less than 2 mm in 3 days; the end of the event is defined as the last of the three days in which the rainfall is greater than zero”. $D_T = 3$ days and $E_T = 5$ mm were chosen.

(**) The algorithm can be only approximately expressed in terms of s_{\min} and u_{\min} . In particular, the algorithm additionally excludes “sub-events” having a total event rainfall below a seasonally variable threshold

Table 4: Set-up of the numerical experiments. Each set of algorithm parameters is considered for the four hypothesized landslide reporting-scenarios.

Aggregation	Event identification algorithm parameters
Hourly	$u_{min} = 24 \text{ h}, s_{min} = 0.2 \text{ mm}$
	$u_{min} = 12 \text{ h}, s_{min} = 0.2 \text{ mm}$
	$u_{min} = 6 \text{ h}, s_{min} = 0.2 \text{ mm}$
Daily correct and daily shifted (Italian database)	$u_{min} = 1 \text{ day}, s_{min} = 0 \text{ mm/day}$
	$u_{min} = 1 \text{ day}, s_{min} = 5 \text{ mm/day}$

Table 5: Confusion matrix for evaluation of landslide-triggering thresholds (assumed here to be of the ID type: $I = f(D)$).

		Actual	
		Landslide (POS = TP + FN)	No landslide (NEG) (NEG = FP + TN)
Predicted	Landslide (POS'): $I \geq f(D)$ (POS' = TP + FP)	true positives, TP	false positives, FP
	No landslide (NEG'): $I < f(D)$ (NEG' = FN + TN)	false negatives, FN	true negatives, TN

Table 6: Threshold calibration results for all simulations, in the case of nulled effects of antecedent precipitation ($\tau_M = 0$).
