

## Point by point response to Paulo Fernandes (Reviewer 1)

**R1.1: I have just one relevant concern: the locations of energy release and static probability of exceedance in fig. 5 and fig. 7. seem quite marked by specific fire events, e.g. the very large and severe fire in Arouca, Portugal, 2016. Isn't the validation period too short, and did this affect calibration and consequently the general applicability of the procedure?**

This point was raised by both reviewers (see R2.7) and is indeed a relevant concern. We therefore decided to assess the robustness of our approach by using all data currently available from the LSA SAF Fire Radiative Power (FRP) product. The study period was accordingly extended from January 2010 – August 2017 (almost 8 years) to January 2004 – September 2017 (almost 14 years). This implied redoing all the computations and changing Tables 1 and 2, and Figures 4 to 14 with the new results. As expected, extending the database of FRP has an impact on the distributions of energy released by wildfires, especially at the level of upper quartiles and extreme values (Figs. 4 and 6) as well as on the geographical distribution (Fig.5) where there is a better enhancement of regions affected by severe wildfires (namely Northern Portugal and Galicia, and Greece) and changes in the distributions of static probability (Figs. 8) are again noticeable in the upper quartiles and extremes.

When fitting a GP distribution to the extended database of daily released energy, the impact is nevertheless quite low. When comparing the old and new versions of Fig. 9, the fitting is still very good for values of exceedances below  $2 \times 10^4$  GJ; for values above this threshold, discrepancies between model and sampled quantiles are now more prominent but, as previously mentioned, besides representing only 1% of the sample, they are attributed to sensor saturation. The dependence of daily energy released on static probability and FWI anomaly is now clearer (Fig. 10) and the dependence of the scale parameter of the Pareto distribution on these two parameters (Fig. 11) presents a similar functional relationship, although with a steepest gradient in the region of high values of static probability and FWI anomaly. The quality of fitting of the final model (Fig. 12) is nevertheless virtually the same and changes in the partitioning of the domain of probability of exceedance versus the respective anomalies are minimal (Fig. 13). New results obtained are consistent with previous ones and, as shown in the updated Tables 1 and 2 the characteristics of the product are the same, in particular the ability to discriminate fire events in terms of released energy and an Extreme Class of fire danger containing a very large fraction of fires releasing very high values of daily energy (above 10 000 GJ).

**R1.2: P1, L19. Replace “that is more than the double of the” by “that more than doubles the”.**

The expression now reads “that is more than one and a half times the”.

**R1.3: P2, L7-9. I know this is a common assumption but I would prefer to see this sentence removed or toned down. Studies in Europe that examined this assumption by considering other variables in the analysis, namely confounding**

effects, could not find evidence that the assumption holds. Both ecophysiology and fire behaviour disprove the assumption. Plant productivity depends also of temperature and easily saturates under the influence of either higher temperatures or higher rainfall, and created biomass is different from fuel, or different from fuel available to burn in the same year. Additionally, this assumption is true in fuel-limited ecosystems or grass-dominated fuel complexes, and neither is the case in Mediterranean Europe.

This issue was raised by both reviewers (see R2.5) and therefore the sentence “A severe fire season is often triggered by a wetter-than usual winter that increases the amount of biomass, followed by a warmer and drier than average spring that leads to higher levels of vegetation stress (Pereira et al., 2013).” was removed.

**R1.4: P2, L9-10. “high temperature, strong wind, low fuel moisture and low relative humidity”. Temperature and RH have no direct effect on fire ignition and spread and are only relevant in their effect upon fuel moisture. To avoid redundancy and confusion between short- and mid-to-long-term processes I advise rephrasing as “strong wind and low fuel moisture” or as “high temperature, strong wind, low relative humidity and drought”.**

The authors agree with the suggested clarification and therefore the expression was replaced by “high temperature, strong wind, low relative humidity and drought”

**R1.5: P2, L30. Be clearer as this sentence can be interpreted in distinct ways. Fires are always dependent on fire weather, regardless of their size. In fact, because fire size is dependent on landscape properties, fire weather will be increasingly less relevant as minimum weather thresholds for attaining certain fire sizes are crossed.**

The sentence now reads: “The rationale is that fires are always dependent on fire weather and meteorological conditions become more relevant for large fires (Ruffault et al., 2016)”.

**R1.6: P3, L10. State up-front why this is information needed.**

The sentence now reads “Since fire intensity and behaviour depend on the vegetation type (e.g.: Moreira et al., 2011; Fernandes, 2013; DaCamara et al. 2014), the GLC2000 database (Hartley et al., 2006) was used as the source of information about vegetation cover/land use.”

**R1.7: P4, L7. “cumulated”, replace by “cumulative” or “accumulated”.**

The word was replaced by cumulative.

**R1.8: P4, L17. The equations have not changed but for ease of calculation see the current programming codes in Wang et al. (2015). Reference: Wang, Y., Anderson, K. R., & Suddaby, R. M. (2015). Updated source code for calculating fire**

**danger indices in the Canadian Forest Fire Weather Index System. Information Report NOR-X-424. Canadian Forest Service Northern Forestry Centre.**

Thanks for providing the reference to the current programming codes for the CFFWIS. The reference was updated to Wang et al. (2015).

**R1.9: P5, L13. If you are referring to forest, shrubland and agriculture it's land cover type rather than vegetation type.**

The text was changed accordingly.

**R1.10: P6, L26. A more accurate heading would be "Fire danger rating classes".**

The heading was changed accordingly.

**R1.11: P7, L1-8. Please explain the rationale for the partition criteria. How does it compare with other common criteria, e.g. Andrews et al. (2003)? Reference: Andrews, P. L., Loftsgaarden, D. O., & Bradshaw, L. S. (2003). Evaluation of fire danger rating indexes using logistic regression and percentile analysis. International Journal of Wildland Fire, 12(2), 213-226.**

An overview of calibration procedures is now provided in the Introduction (see answer R2.1). A brief explanation of the rationale was also included in the manuscript at the end of Section 3.5: "It may be noted that the adopted approach to calibration differs from other common methods like those based on logistic regression and threshold setting based on a geometric progression that were mentioned in the Introduction. The present approach based on a partitioning of the space of probability versus probability anomaly by exponential type functions was motivated by the distribution of the daily energy released of observed fire events in that space during the study period (Fig. 13)".

**R1.12: P8, L8. And yet what made the Pedrogão Grande event unique is that the fatalities and fast fire growth happened on the 1st day of the fire. I suggest a brief reference to this as well as discussion (advantages or disadvantages of the developed classification) of the fact that the atmospheric conditions responsible for the event (gust front from a thunderstorm and highly unstable atmosphere that jointly allowed PyroCb development) are not captured by the FWI.**

These aspects were pointed out by both reviewers (see R2.4). Therefore, the following paragraph was added before the last paragraph of the Conclusions:

It is worth noting that the proposed approach is based on FWI that is defined at the daily level. Classes of fire danger are accordingly computed on a daily basis, and the same happens in the cases of the LSA SAF and the EFFIS products that also depend on FWI. The daily scale of the classes of fire danger may sometimes constitute a shortcoming, namely because local atmospheric conditions of short time duration cannot be captured by FWI. This was indeed the case on the first day of the large

2017 fire event at Pedrógão Grande-Góis, when the unstable atmospheric conditions favoured the formation of thunderstorms and gust fronts that jointly allowed pyrocumulonimbus development and played a crucial role in the extremely fast initial-spread of the fire, causing a large number of fatalities. Inaccuracies in the forecasts of precipitation at the local level may constitute another shortcoming given that they may lead to incorrectly low values of FWI. These two limitations may be circumvented, at least partially, by means of intraday high-resolution fire weather forecasts combined with the use of ensemble forecasts that will allow a better assessment of the uncertainties of fire danger predictions. Both aspects are currently being studied and results are expected to bring developments of the current method to be operationally implemented in the future.

**R1.13: P8, L8. “extremely”, not “extreme”.**

The word was modified accordingly.

**R1.14: P8, L9. Use “at the nearest station”.**

The text was modified accordingly.

**R1.15: P19, L13-14. Replace “fire prevention” by “fire management”. Fire danger rating is important for a variety of activities, including prevention, preparedness and suppression planning.**

The text was modified accordingly.

**R1.16: P20, L23. There’s a 2017 paper in the IJWF that explicitly relates FRP with fireline intensity.**

Reference to Johnston et al. (2017) has been included.

Reference: Johnston, J. M., Wooster, M. J., Paugam, R., Wang, X., Lynham, T. J., and Johnston, L. M.: Direct estimation of Byram’s fire intensity from infrared remote sensing imagery. *International Journal of Wildland Fire*, 26(8), 668-684, 2017.

## Point by point response to Reviewer 2

**R2.1: My main concern is that, in its current state, the manuscript provides only limited general overview of the issues addressed. I think that the manuscript would gain from more detailed introduction and discussion sections and it would help to reach a broader readership. I would appreciate an introduction that provides more information about the methodologies that have been developed so far and the rationale behind the development of such hybrid methods as yours.**

We agree with the reviewer and the third paragraph (lines 11-20) was considerably expanded into three paragraphs. It now provides an overview of previous approaches as well as of the advantages brought by the rationale behind our approach.

The role played by meteorological factors in the occurrence of severe fire episodes is conveniently assessed by means of indices of meteorological fire danger that rate the likelihood of a fire event (Finney, 2005). Early examples include the Nesterov Index for use in the former Soviet Union (Nesterov 1949), the Forest Fire Danger Index (FFDI) for Eastern Australia (McArthur 1967) and the National Fire Danger Rating System for the USA (Deeming et al., 1977). One of the most reliable and globally applied fire rating methodologies is the Canadian Forest Fire Weather Index System (CFFWIS). The system consists of six components that account for the effects of fuel moisture and wind on fire behavior (Van Wagner 1974). The first five components are based on empirically derived relationships between meteorological variables and the stress of different components of typical fuels that are present in jack pine forests of Canada (Stocks et al. 1989). The last component, the Fire Weather Index (FWI), results from the combination of the preceding five and may be viewed as a general index of fire danger (Van Wagner 1987). FWI provides a numeric rating of fire intensity and is particularly suitable as a general index of meteorological fire danger, namely for the ecosystems of Mediterranean Europe (Viegas et al., 1999). Currently FWI is on the basis of the Fire Danger Forecast module of the European Forest Fire Information System (EFFIS) that is one of the components of the Emergency Management Services in the EU Copernicus program (San-Miguel-Ayanz et al., 2012) as well as of the Fire Risk Map (FRM) product disseminated by the Satellite Application Facility for Land Surface Analysis (LSA SAF) that is part of the EUMETSAT application ground segment (Trigo et al., 2011).

However, FWI was specifically designed for the Canadian forest and therefore should be calibrated to the vegetation cover and meteorological conditions over the Mediterranean region. The calibration process involves defining a set of break points in indices of fire danger that are in turn used to delimit classes of fire danger from low to extreme conditions. Several approaches have been proposed involving different techniques to rate indices of fire danger against fire history over a given period and study area. Examples of such techniques include logistic regression and percentile analysis (Andrews et al., 2003), cluster analysis (Dymond et al., 2005) and threshold setting based on a geometric progression (Van Wagner 1987) or on values of probability (DaCamara et al., 2014). Fire history traditionally consists of ground observations of fire occurrence (Anderson and Englefield 2001), fire load (Merrill and Alexander 1987), suppression difficulty (Kiil et al., 1977) and area burned (San-Miguel-Ayanz et al., 2012). The current availability of remote-sensed data of fire activity using information derived from instruments on-board geostationary satellites and polar orbiters has opened new perspectives for calibration procedures that

are consistent in space and time, continuously monitorable on a daily basis and easily tuned at the end of the fire season. Information about fire activity consists of location and time of detection of hot spots, which is accompanied by quality flags and confidence level, and, in certain cases, by the amount of energy released per unit time (fire radiative power). Data are either global or cover vast continental areas and time series usually span more than a decade. Examples of remote-sensed databases of fire activity include the World Along Track Scanning Radiometer (ATSR) Fire Atlas (Arino et al., 2001), the MODIS and the VIIRS Active Fire Products (Giglio et al., 2003) and the LSA SAF Fire Products (Trigo et al., 2011). The EFFIS product relies on a traditional calibration approach where the lower threshold of the class of highest fire danger is estimated from FWI values associated with burned areas of more than 500 ha and the subsequent thresholds are defined by a geometric progression (San-Miguel-Ayanz et al., 2012). In the case of the LSA SAF FRM product, calibration is performed by fitting a Generalized Pareto model to the duration of fire episodes derived from hot spot observations from space (DaCamara et al., 2014). When calibrating indices of fire danger over large areas such as the Mediterranean basin, the spatial and temporal consistency of historical records of fire activity derived from remote-sensed information provided by the same sensors present an important advantage over ground-based data where the data about time and location of the fire event and the associated burned area are usually obtained by visual inspection and the information recorded depends on policies that change from country to country as well as on criteria that may vary in time (Pereira et al., 2011). Use of data of fire radiative power derived from satellite measurements presents the additional advantage of calibrating the indices of fire danger against a physical quantity that is especially useful in fire management and firefighting (Roberts and Wooster, 2008).

**R2.2: For instance, the description for the need new estimations of fire danger (Page 2, 18-20) is quite brief.**

An overview of techniques for estimation of fire danger is now included in the Introduction and the added value of an approach such as the one proposed is also discussed (see answer R2.1).

**R2.3: Another example is that the description of the fire radiative power derive from remote sensing does not appear until discussion (P20, line 21-26).**

The authors acknowledge the existence of this caveat in the original manuscript. Fire radiative power is now briefly described in the Introduction and the advantages of this quantity for calibration of indices of fire danger are also indicated (see answer R2.1).

**R2.4: Similarly, the discussion would gain from a more thorough description of the limits and future developments of this method as well as its comparison with other methods.**

This point was also raised by the other reviewer (see answer R1.12).

**R2.5: Page 2 lines 7-9: I am not sure there is a consensus about this assertion, especially in the Mediterranean where recent studies tend to point out towards a drought-limited fire regime.**

This point was also raised by the other reviewer (see answer R1.3).

**R2.6: Page 3 line 9: What is the averaged size of these pixels over the Mediterranean?**

The average pixel size is about 15.7 km<sup>2</sup>. The sentence now reads: “Both satellite and meteorological data are gridded in the Normalized Geostationary Projection (NGP) of MSG (EUMETSAT, 1999) with an average pixel size of about 15.7 km<sup>2</sup> over the land regions in the study area.”

**R2.7: P6 line 15-21. I wonder how much does the results of the daily models depend on the estimations of P(E/0) and FWI\* that in turn depends on the calibration period This seems particularly the case for P(E/0) where the calibration period is relatively short.**

This is a very important point that was also raised by the other reviewer. We have fully addressed this issue by significantly extending the analysed period from January 2010 – August 2017 (almost 8 years) to January 2004 – September 2017 (almost 14 years). This implied redoing all the computations and changing Tables 1 and 2, and Figures 4 to 14 with the new results. (see answer R1.1).

**R2.8: Besides, It might be not relevant but I failed to understand the purpose of using the FWI anomalies instead of the raw FWI values (P4, lines 23-27). I agree that FWI is influenced by numerous factors (topography, distance to the sea...) but there are also large-scale patterns involved in these processes. For instance, a one Standard Deviation from the FWI mean in southern Greece is not equivalent in terms of fire danger to a one standard deviation in northern Spain.**

As stated in P4, lines 26-27, the main reason for the use of FWI anomalies is just to mitigate the delay in solar time that may introduce a zonal bias in the estimations of probability. The text was slightly changed as follows: “Use of anomalies instead of values of FWI aims at reducing all the above-mentioned factors that regionally affect FWI over Mediterranean Europe. Given that FWI is defined at 12 local standard time (LST) use of anomalies also mitigate the impacts associated to the delay in solar time (1 hour every 15° towards the east) given that all meteorological fields are defined at 12 UTC (DaCamara et al., 2014)”.

**R2.9: Fig 6 and Fig 8: maybe provide a statistical test to support your conclusions on these figures.**

The following sentences were added in P10, L4 and P11, L5:

“Differences among the distributions for the three land cover types were assessed by means of the two-samples Kolmogorov-Smirnov test (Massey, 1951); for each pair of the three considered distributions, the null hypothesis that the distributions are identical is rejected with a p-value lower than 0.0001.”

“As in the case of daily energy released by fires, the two-sample Kolmogorov-Smirnov test corroborates the significance of the results indicating that, for each pair of the three distributions, the null hypothesis that the distributions are identical is rejected with a p-value lower than 0.0001.”

Reference: Massey, F. J.: The Kolmogorov-Smirnov Test for Goodness of Fit, Journal of the American Statistical Association, Vol. 46, No. 253, pp. 68–78, 1951.

**R2.10: Figure 14: This figure is interesting and relevant for your study but not easy to follow because of the different sources of information provided. Maybe provide more details within the figure and subpanels descriptions.**

The following text was included at the beginning of the last paragraph of the Results section (P18, L18): “Results obtained for the two 2017 case studies of Pedrógão Grande-Góis (Portugal) and Marseille (France) are summarized in Fig. 14 that is subdivided into two main vertical panels, the left one respecting to Pedrógão Grande-Góis and the right one to Marseille. For each event a map covering the study area is presented on the top, showing the geographical distribution of values of  $P(2000|200)$  for Pedrógão-Góis and of anomaly values of  $P(2000|200)$  for Marseille. At the bottom of each panel, at the left hand side, a map is shown of the geographical distribution of classes of danger and active fires detected over the region affected by the fire event; finally, at the right hand side, there is a diagram showing the distribution of active fires detected in the domain  $G$  of  $P(2000|200)$  versus respective anomalies  $A$ .”

## List of relevant changes

1. The study period was extended from January 2010 – August 2017 (almost 8 years) to January 2004 – September 2017 (almost 14 years). This implied redoing all the computations and changing Tables 1 and 2, and Figures 4 to 14 with the new results (**see R1.1**).
2. The Introduction was considerably expanded and now provides an overview of previous approaches as well as of the advantages brought by the rationale behind our approach (**see R2.1**).
3. An overview of calibration procedures is now provided in the Introduction (**see R2.1**). A brief explanation of the rationale was also included in the manuscript at the end of Section 3.5 (**see R1.11**).
4. A detailed description of Fig. 14 is now included in the manuscript (**see R2.10**).
5. A brief reference to the advantages and shortcomings of the developed procedure is now included before the last paragraph of the Conclusions (**see R1.12**).
6. Acknowledgments were added after the Conclusions

All departures from the original manuscript **are marked in yellow** in the new version below.

# Fire danger rating over Mediterranean Europe based on fire radiative power derived from Meteosat

10 **Abstract.** We present a procedure that allows the operational generation of daily forecasts of fire danger over Mediterranean Europe. The procedure combines historical information about radiative energy released by fire events with daily meteorological forecasts, as provided by the Satellite Application Facility for Land Surface Analysis (LSA SAF) and the European Centre for Medium-Range Weather Forecasts (ECMWF). Fire danger is estimated based on daily probabilities of exceedance of daily energy released by fires occurring at the pixel level. Daily probability considers meteorological factors by  
15 means of the Canadian Fire Weather Index (FWI) and is estimated using a Daily Model based on a Generalized Pareto distribution. Five classes of fire danger are then associated to daily probability estimated by the Daily Model. The model is calibrated using **thirteen** years of data (2004-2016) and validated against the period of January–**September** 2017. Results obtained show that about **72** % of events releasing daily energy above 10 000 GJ belong to the “Extreme” class of fire danger, a considerably high fraction that is more than **one and a half times** the values obtained when using the currently operational  
20 Fire Danger Forecast module of the European Forest Fire Information System (EFFIS) or the Fire Risk Map (FRM) product disseminated by the LSA SAF. Besides assisting in wildfire management, the procedure is expected to help in decision making on prescribed burning within the framework of agricultural and forest management practices.

## 1 Introduction

25 Wildfires have been identified as the most important threat to forests in Mediterranean Europe (Requardt et al., 2009) that is regularly affected by large and destructive events. These weather-related hazards represent a serious problem to modern societies, with great negative impacts at social, economic and ecological levels and causing significant human casualties (Amraoui et al., 2015). A striking illustration of the magnitude of the problem is provided by the recent tragic episode of June 17, 2017, that took place in central Portugal at Pedrógão Grande-Góis, with an official death toll of 64 people and by the fire

episodes of the last week of July 2017 near Marseille in southeastern France that led to the evacuation of more than 10 000 people in the French Riviera.

According to the last report issued by the European Commission (San-Miguel-Ayanz et al., 2016), during the period 1980-2015 the five Southern Member States (Portugal, Spain, France, Italy and Greece) were affected by a total of 1 751 067 fires that burned 16 121 036 ha, corresponding to a yearly average of 48 641 fires and a burned area average of 447 807 ha per year. This proneness of Mediterranean Europe to be affected by fire is linked to its climate characterized by rainy and mild winters followed by warm and dry summers (Pyne, 2009). Extreme weather conditions in summer (high temperature, strong wind, low relative humidity and drought) are a key factor in the ignition and spread of large wildfires (Amraoui et al., 2013; Pereira et al., 2013; Ruffault et al., 2016).

The role played by meteorological factors in the occurrence of severe fire episodes is conveniently assessed by means of indices of meteorological fire danger that rate the likelihood of a fire event (Finney, 2005). Early examples include the Nesterov Index for use in the former Soviet Union (Nesterov, 1949), the Forest Fire Danger Index (FFDI) for Eastern Australia (McArthur, 1967) and the National Fire Danger Rating System for the USA (Deeming et al., 1977). One of the most reliable and globally applied fire rating methodologies is the Canadian Forest Fire Weather Index System (CFFWIS). The system consists of six components that account for the effects of fuel moisture and wind on fire behavior (Van Wagner, 1974). The first five components are based on empirically derived relationships between meteorological variables and the stress of different components of typical fuels that are present in jack pine forests of Canada (Stocks et al., 1989). The last component, the Fire Weather Index (FWI), results from the combination of the preceding five (Van Wagner 1987). FWI provides a numeric rating of fire intensity and is particularly suitable as a general index of meteorological fire danger, namely for the ecosystems of Mediterranean Europe (Viegas et al., 1999). Currently FWI is on the basis of the Fire Danger Forecast module of the European Forest Fire Information System (EFFIS) that is one of the components of the Emergency Management Services in the EU Copernicus program (San-Miguel-Ayanz et al., 2012) as well as of the Fire Risk Map (FRM) product disseminated by the Satellite Application Facility for Land Surface Analysis (LSA SAF) that is part of the EUMETSAT application ground segment (Trigo et al., 2011).

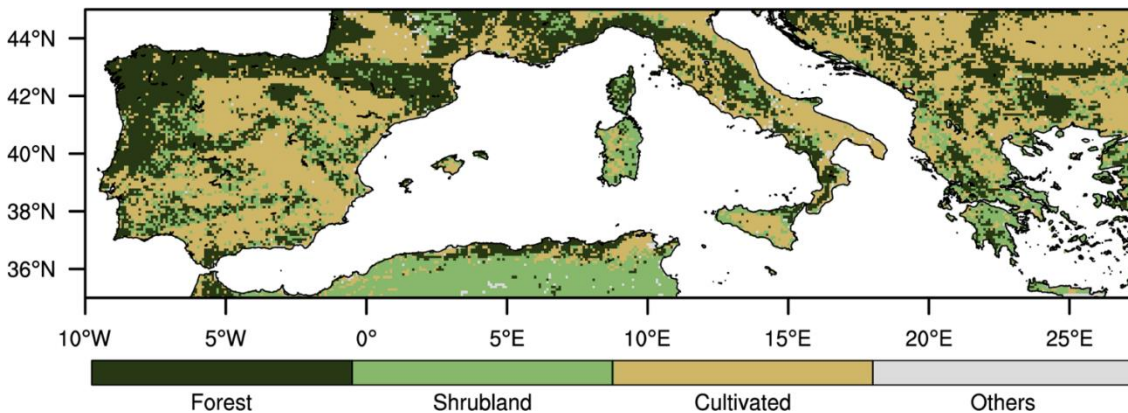

However, FWI was specifically designed for the Canadian forest and therefore should be calibrated to the vegetation cover and meteorological conditions over the Mediterranean region. The calibration process involves defining a set of break points in indices of fire danger that are in turn used to delimit classes of fire danger from low to extreme conditions. Several approaches have been proposed involving different techniques to rate indices of fire danger against fire history over a given period and study area. Examples of such techniques include logistic regression and percentile analysis (Andrews et al., 2003), cluster analysis (Dymond et al., 2005) and threshold setting based on a geometric progression (Van Wagner, 1987) or on values of probability (DaCamara et al., 2014). Fire history traditionally consists of ground observations of fire occurrence (Anderson and Englefield, 2001), fire load (Merrill and Alexander, 1987), suppression difficulty (Kiil et al., 1977) and area burned (San-Miguel-Ayanz et al., 2012). The current availability of remote-sensed data of fire activity using information derived from

instruments on-board geostationary satellites and polar orbiters has opened new perspectives for calibration procedures that are consistent in space and time, continuously monitorable on a daily basis and easily tuned at the end of the fire season. Information about fire activity consists of location and time of detection of hot spots, which is often accompanied by quality flags and confidence level, and, in certain cases, by the amount of energy released per unit time (fire radiative power). Data are either global or cover vast continental areas and time series usually span more than a decade. Examples of remote-sensed databases of fire activity include the World Along Track Scanning Radiometer (ATSR) Fire Atlas (Arino et al., 2001), the MODIS and the VIIRS Active Fire Products (Giglio et al., 2003) and the LSA SAF Fire Products (Trigo et al., 2011). The EFFIS product relies on a traditional calibration approach where the lower threshold of the class of highest fire danger is estimated from FWI values associated with burned areas of more than 500 ha and the subsequent thresholds are defined by a geometric progression (San-Miguel-Ayaz et al., 2012). In the case of the LSA SAF FRM product, calibration is performed by fitting a Generalized Pareto model to the duration of fire episodes derived from hot spot observations from space (DaCamara et al., 2014). When calibrating indices of fire danger over large areas such as the Mediterranean basin, the spatial and temporal consistency of historical records of fire activity derived from remote-sensed information provided by the same sensors present an important advantage over ground-based data where the time and location of the fire event and the associated burned area are usually obtained by visual inspection and the information recorded depends on policies that vary from country to country as well as on criteria that may change in time (Pereira et al., 2011). Use of data of fire radiative power derived from satellite measurements presents the additional advantage of calibrating the indices of fire danger against a physical quantity that is especially useful in fire management and firefighting (Roberts and Wooster, 2008).

We present a methodology to assess fire danger based on the estimation of the probability of exceedance of predefined thresholds of daily released energy by active fires as derived from satellite observations of fire radiative power. The procedure is applied to Mediterranean Europe and is calibrated with data covering the period 2004-2016. First, estimates of static probability (i.e. not depending on the day of the year) are obtained, for each location, by dividing the recorded number of fires exceeding a given threshold of energy and observed within a cell centered on each pixel by the total number of fires observed within the same cell. Then it is shown that statistical models based on Generalized Pareto (GP) distributions adequately fit to the upper tails of the observed distributions of released energy and that these models can be improved by integrating both the estimates of static probability and daily FWI as covariates of the scale parameter of the GP distributions. The rationale is that fires are always dependent on fire weather and meteorological conditions become more relevant for large fires (Ruffault et al., 2016). Five classes of fire danger are then attributed to each pixel on a daily basis, taking into account both the values of probability of exceedance and the respective deviations from a long-term mean. Performance of the methodology is assessed by comparing, for different ranges of daily released energy by fires, the distributions of observed events among the five classes of danger with the corresponding distributions when using the classes of fire danger from the above mentioned LSA SAF product and EFFIS module. Finally, the procedure is validated by applying it to the period January–September 2017 and by analyzing the two above mentioned extreme events that took place in Portugal and France, in June and July 2017, respectively.

## 2 Data

The study area is defined by latitude circles of 35 and 45°N and meridians of 10°W and 27.5°E (Fig. 1) and the study period spans from January 2004 to September 2017. The sub-period from January 2004 to December 2016 is used to calibrate the models whereas the remaining sub-period from January to September 2017 is retained for validating results against independent data. The two sub-periods will be referred hereafter as calibration and validation periods. Both satellite and meteorological data are gridded in the Normalized Geostationary Projection (NGP) of MSG (EUMETSAT, 1999) with an average pixel size of about 15.7 km<sup>2</sup> over the land regions in the study area. Since fire intensity and behaviour depend on the vegetation type (e.g.: Moreira et al., 2011; Fernandes, 2013; DaCamara et al. 2014), the GLC2000 database (Hartley et al., 2006) was used as the source of information about vegetation cover/land use. Originally available at a 1 km resolution, vegetation/land use types were re-projected onto the MSG NGP grid. The 22 types of vegetation/land use were merged into the following three main land cover types: 1 to 10 – forest, 11 to 15 – shrubland and 16 to 18 – cultivated areas (Fig. 1).

**Figure 1: Geographical distribution of the types of vegetation cover/land use as derived from the GLC2000 database.**

15

Data of fire radiative power from January 2004 – September 2017 were obtained from the Fire Radiative Power (FRP) Product generated and disseminated by the LSA SAF (Trigo et al., 2011; Wooster et al., 2015). The FRP product consists of estimates of the radiative power emitted by landscape fires and is derived on a pixel-by-pixel basis from the Spinning Enhanced Visible and Infrared Imager (SEVIRI) instrument, which operates on-board the Meteosat Second Generation (MSG) series of EUMETSAT geostationary satellites (LSA SAF, 2015). The product is provided for the whole MSG disk (up to 72° view zenith angle) every 15-minutes and each active fire location in the study area is represented at the centre of the corresponding SEVIRI pixel. The database provides for each event the geographical coordinates, the date and time, the fire confidence and the fire radiative power (expressed in MW). A full description of the product and its validation is available in the on-line documentation provided at the LSA SAF site (<http://lsa-saf.eumetsat.int>).

Meteorological data covering the period from January 1979 to December 2016 were obtained from the ERA-Interim reanalysis dataset (Dee et al., 2011) generated by the European Centre for Medium-Range Weather Forecasts (ECMWF). With the aim of recreating the kind of information available when using the developed model in operational mode, data respecting to the validation period (from January to September 2017) consisted of ECMWF's operational 24-hour forecasts (Haiden et al., 2016). Both reanalysed and forecasted data fields consist of daily 12 UTC fields of 24h cumulative precipitation (from 12 UTC of the previous day to 12 UTC of the current day), 2m air temperature and dew point, 10m zonal and meridional wind components. Since the spatial resolution of the reanalysis is about 0.75°, data were re-projected onto the MSG NPP grid. In the case of 2m and dew point temperatures, a topographical correction was performed on the data by applying a constant lapse rate of -0.67°C/100m to the difference between the surface height of ECMWF model and that of SEVIRI nearest pixels, assuming a constant dew point depression. Relative humidity was computed based on values of temperature and dew point temperature at 2m, according to the Magnus expression (Lawrence, 2005).

### 3 Methods

#### 3.1 Fire Weather Index

Daily values of FWI covering the period from January 1979 to September 2017 were computed according to the procedure described by Wang et al. (2015). For each pixel, the grand average of FWI for all days of the period 1979–2016 hereby denoted  $\overline{FWI}$ , was also computed. The spatial distribution of  $\overline{FWI}$  (Fig. 2) shows a general tendency to decrease with increasing latitude that reflects the same behaviour of the surface temperature field. The spatial distribution is also consistent with the land cover (Fig. 1), the forested areas tending to be associated to lower values  $\overline{FWI}$ . Other factors such as topography and proximity to the sea are also relevant, the values of  $\overline{FWI}$  tending to be lower over the mountains and along the coast. For each pixel  $p$  of the MSG NPP grid and for each day  $d$  of the study period, the anomaly  $FWI_{pd}^*$  was defined as

$$FWI_{pd}^* = FWI_{pd} - \overline{FWI}_p, \quad (1)$$

where  $FWI_{pd}$  is the FWI value for pixel  $p$  and day  $d$  day and  $\overline{FWI}_p$  is the grand average of FWI for that pixel. Use of anomalies instead of values of FWI aims at reducing all the above-mentioned factors that regionally affect FWI over Mediterranean Europe. Given that FWI is defined at 12 local standard time (LST), use of anomalies also mitigates the impacts associated to the delay in solar time (1 hour every 15° towards the east) given that all meteorological fields are defined at 12 UTC (DaCamara et al., 2014).

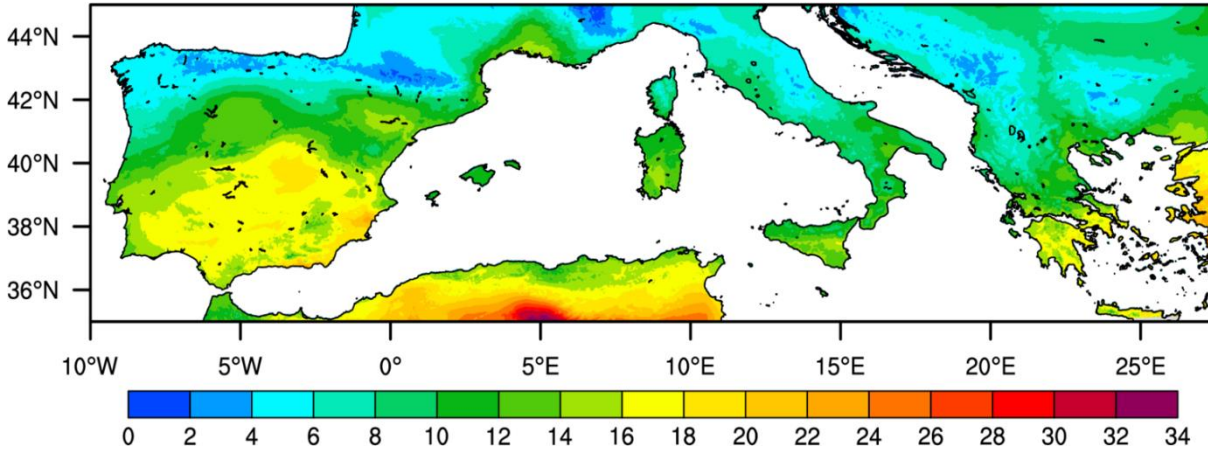

Figure 2: Spatial distribution of the FWI average over the 1979-2016 period.

### 3.2 Daily energy released by fires

Daily energy released by fire at a given pixel was computed by integrating the radiative power recorded by SEVIRI in that pixel along the considered day. Since the data are sampled every 15 minutes the daily energy,  $E$ , in GJ, for each pixel  $p$  and day  $d$  may be estimated as:

$$E_{pd} = 0.9 \times \left( \sum_{k=1}^{96} FRP_{kp} \right)_d \quad (2)$$

where index  $k$  indicates the sequence of 15-minute images for each day,  $FRP_{kp}$  is the fire radiative power (in MW) in pixel  $p$  of image  $k$  and the 0.9 factor converts the result into GJ.

### 10 3.3 Static probability of exceedance of energy released by fires

Considering the calibration period (2004–2016), the static probability of exceedance of a given threshold  $E$  of daily energy released by fires at each pixel  $p$  was estimated by counting the total number of daily fire occurrences in pixels with the same land cover type as  $p$  (Fig. 1) located inside a cell centred in the considered pixel with initial size  $\delta = 0.7^\circ$  in latitude and longitude. The size was then successively enlarged by increments of  $0.05^\circ$  until the maximum size of  $20^\circ$  is attained or the total number of events reaches 200. Denoting by  $S_p(\delta, E)$  the total number of daily fires inside cell of size  $\delta$  centred at  $p$  and with released energy exceeding  $E$ , the probability of exceedance  $x$  is estimated as:

$$P_p(E|0) = \frac{S_p(\delta, E)}{S_p(\delta, 0)} \quad (3)$$

where  $S_p(\delta, 0)$  is the number of all observed daily fire events (i.e. with energy exceeding zero). As suggested by the notation employed,  $P_p(E|0)$  may be viewed as a conditional probability, namely the probability that the daily energy released by fires at pixel  $p$  is greater than  $E$  provided that an ignition has occurred in that pixel. The rationale for this procedure is that the static

probability of exceedance is expected to present smooth spatial variability over pixels with the same **land cover** type, while steep changes are to be expected among the different **land cover** types.

### 3.4 Statistical models of exceedance of energy released by fires

Following DaCamara et al. (2014), the statistical distribution of daily released energy,  $E$ , is modelled using the ‘peaks over threshold’ (POT) approach (Pickands, 1975).

The POT approach uses the Generalized Pareto (GP) distribution as a model to assign probabilities to the exceedances of  $E$  over a predefined threshold, i.e. to values  $\Delta E = E - E_{min}$  (with  $E > E_{min}$ ) where  $E_{min}$  is a prescribed minimum value (de Zea Bermudez and Kotz, 2010). The GP cumulative distribution function of exceedances  $\Delta E$  is:

$$G(\Delta E|\alpha, \sigma) = 1 - \left(1 + \frac{\alpha}{\sigma} \Delta E\right)^{-\frac{1}{\alpha}} \quad (4)$$

where  $\alpha$  and  $\sigma$  are the shape and scale parameters. Value of minimum threshold  $E_{min}$  is obtained by plotting the sample mean of the values exceeding successive thresholds against the respective thresholds, the chosen value being such that the dependence becomes linear for values greater than the chosen one (Coles, 2001). The shape ( $\alpha$ ) and scale ( $\sigma$ ) parameters of the GP distribution are then estimated **using the maximum likelihood method (Grimshaw, 1993)**.

The obtained model, hereafter referred to as the null model, may be improved by incorporating daily anomalies,  $FWI^*$ , and static probabilities,  $P(E|0)$ , as covariates of the scale parameter in the GP distribution using a feed forward artificial neural network. The network is trained using the Levenberg-Marquardt algorithm (Hagan and Menhaj, 1994). Daily probabilities are then given by:

$$G(\Delta E|\alpha, \sigma_N) = 1 - \left(1 + \frac{\alpha}{\sigma_N} \Delta E\right)^{-\frac{1}{\alpha}} \quad (5)$$

where  $\sigma_N = \sigma_N[FWI^*, P(E|0)]$  is the neural network trained model using  $FWI^*$  and  $P(E|0)$  as inputs and providing the corresponding scale parameter  $\sigma$ , as output.

Performance of the new alternative model, hereafter referred to as the Daily Model because of its dependence on daily values of  $FWI^*$ , is compared against the respective null models by using the standard likelihood ratio test (Neyman and Pearson, 1933) which is based on statistic  $\Lambda$  defined as:

$$\Lambda = 2(\ln L' - \ln L) \quad (6)$$

where  $L$  and  $L'$  are the likelihood functions of the null and the Daily Models, respectively.

### 3.5 **Fire danger rating classes**

Classes of fire danger are defined, based on values of probability of exceedance and of the respective deviations from the expected value. The rationale is that large fires tend to occur in pixels of high probability of exceedance or of high positive deviation from the expected value for a given day of the year and location. For each pixel  $p$  and day  $d$ , the probability of

exceedance  $G$  is evaluated using Eq. (5) and the respective anomaly  $A$  is computed by subtracting the average of all values of probability of exceedance for that pixel and day of the year over the period 1979–2016. As shown in Fig. 3, five classes of fire danger (conventionally named “Low”, “Moderate”, “High”, “Very High” and “Extreme”) are then defined by setting five partitions in the domain  $G$  versus  $A$  (delimited by dashed lines) by means of four curves ( $\gamma_0, \gamma_1, \gamma_2, \gamma_3$ ) defined as follows:

$$5 \quad \gamma_0: A \equiv 0, 0 \leq P \leq 1 \quad \text{and} \quad \gamma_i (i = 1, 2, 3): A = e^{\frac{\ln(P_n)}{P_n} P}, P_n \leq P \leq 1 \quad (7)$$

where  $P_n$  are break points estimated from fire events according to the following criteria: 1) the first break point is set to 0 so that the “Low” class of fire danger encompasses all cases where the probability of exceedance is below average ( $A < 0$ ); 2) the four breakpoints are equally spaced; and 3) the classes “Very High” and “Extreme” should have about the same number of fire events.

- 10 **It may be noted that the adopted approach to calibration differs from other common methods like those based on logistic regression and threshold setting that were mentioned in the Introduction. The present approach based on a partitioning of the space of probability versus probability anomaly by exponential type functions was motivated by the distribution of the daily energy released by observed fire events in that space during the study period (Fig. 13).**

15

**Figure 3: Partitioning of the domain of probability of exceedance,  $G$ , versus the respective anomalies,  $A$ , into five classes of fire danger named “Low”, “Moderate”, “High”, “Very High” and “Extreme”. The partitions are delimited by curves  $\gamma_0, \gamma_1, \gamma_2$  and  $\gamma_3$ .**

### 3.6 Model performance and validation

Assessment of performance of the Daily Model is based on a systematic comparison of the distributions of events among classes of fire danger for different ranges of energy released by fire with the corresponding distributions when using classes produced by other products, namely those from EFFIS and the LSA SAF. In the case of EFFIS, six classes are defined by means of a set of breakpoints in FWI that are set up using historical records of large fire events of more than 500 ha of burned area (San-Miguel-Ayanz et al., 2012). The six EFFIS classes are here reduced to five by combining the “Very Low” and the “Low” classes. In the case of the LSA SAF product, the definition of the five classes is based on breakpoints in FWI anomalies that are defined based on information of a probabilistic model of exceedances of active fire duration (DaCamara et al., 2014). Given that classes from the Daily Model are based on probabilistic information about exceedances of energy released by fires, when comparing against EFFIS and LSA SAF products, the Daily Model is expected to provide a better discrimination of events among classes from the point of view of energy released particularly for the most severe classes.

The validation of the Daily Model is performed for the January–September 2017 (validation) period, by comparing the distributions of daily fire events among classes of fire danger with those obtained for the calibration period (2004 – 2016). Two severe events that took place during the validation period are also examined, namely the fires at Pedrógão Grande-Góis and near Marseille in south-eastern France, which were already mentioned in the introductory section. The study of the Pedrógão Grande-Góis event focuses on the second day of the event (June 18, 2017) because no satellite measurements are available at the starting day due to the presence of clouds and thick smoke. The event took place within a context of extremely high temperatures, with values of up to 40°C registered at the nearest station, and relative humidity as low as 20 %. Besides killing 64 people, the fire involved more than 1 000 fire fighters, destroyed almost 500 buildings and a continuous patch of more than 42 000 ha burned in one week. In the case of the fire episodes near Marseille, two large fires that started on July 24, 2017 and burned more than 3 000 ha are analyzed, the study focusing on the day after the onset because of the recorded high values of released energy during that day. As mentioned in the Introduction several other episodes occurred in the area during that week, more than 2 000 fire fighters were deployed, and more than 10 000 people had to be evacuated.

## 4 Results

### 4.1 General features of energy released by fires

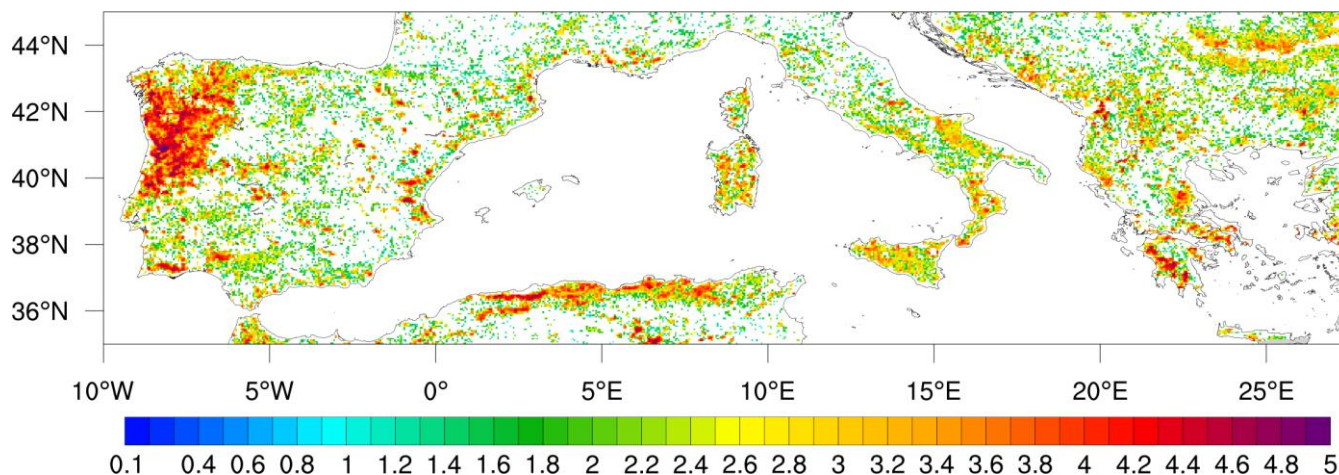

Figure 4 shows the monthly median values of daily energy released by fires at each pixel. The distributions represent the whole calibration period (2004 – 2016), and reveal an absolute maximum of 114 GJ in August and an absolute minimum of 52 GJ in May. All monthly distributions are positively skewed and the annual cycle of interquartile range presents a very similar behavior to that of the median, with the monthly values of the former presenting an absolute maximum of 309 GJ in August and an absolute minimum of 117 GJ in May. This behavior is to be expected since fire events with low values of released energy are less conditioned by meteorological factors and are therefore likely to occur all over the year whereas fire events

releasing high values of energy depend on favorable weather conditions that are more frequent in the summer months. It is also worth noting that monthly values of the median for the validation period (January–September 2017) are larger than the corresponding values for the calibration period in all months thus stressing the fire-prone year of 2017.

5 **Figure 4:** Monthly distributions of daily energy (GJ) released per pixel during the calibration period (2004–2016). Monthly values of the median are indicated by the horizontal line inside each box, the first and third quartiles are indicated by the bottom and top sides of the box and the maximum and minimum values by the whiskers. The superimposed grey curve shows the values of the monthly medians during the validation period (January–September 2017).

The spatial distribution of energy released by wildfires was analyzed by adding up for every pixel in the study area the daily values of released energy recorded during the calibration period (2004–2016). As shown in Fig. 5, a large patch of high values of total released energy may be identified over the northwest of the Iberian Peninsula with the highest values located in the forested lands of Central Portugal. An elongated patch of high values may be also identified along the Mediterranean coast of Africa, the highest values occurring in the forested areas of Morocco, Algeria and northern Tunisia. A patch of high values is also noticeable in Greece. Other patches albeit reaching less high values of total released energy may be identified in Central Europe, in Bulgaria and Romania, in Southern Italy as well as in Sicily and Sardinia.

**Figure 5:** Geographical distribution of total energy released by fire recorded during the calibration period (2004–2016). The colour bar indicates the values of the decimal logarithm of the total energy ( $\log_{10} E$ , with E in GJ).

- 5 The distributions of daily released energy per pixel for the three considered types of vegetation cover/land use (Fig. 6) show that pixels covered by forests have the largest values of both the median and the interquartile range, followed by shrubland and cultivated areas. Differences among the distributions for the three land cover types were assessed by means of the two-samples Kolmogorov-Smirnov test (Massey, 1951); for each pair of the three considered distributions, the null hypothesis that the distributions are identical is rejected with a p-value lower than 0.0001. These results are in agreement with the findings by
- 10 Moreira et al. (2011), Fernandes (2013) and DaCamara et al. (2014) pointing out that within the Mediterranean basin long-lasting and intense fire episodes are more frequent in forests and shrubland than in cultivated areas.

**Figure 6:** As in Fig. 4 but for the distribution of daily energy (GJ) released per pixel stratified by type of vegetation cover/ land use.

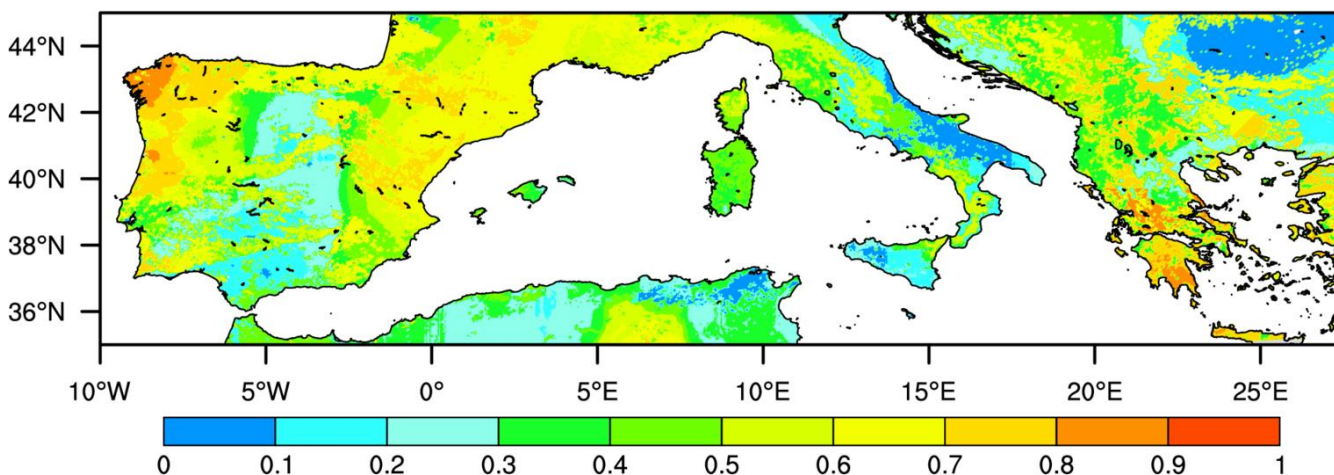

## 4.2 Statistical models of exceedance of energy released by fires

Probability of exceedance of daily energy per pixel released by fires was computed over the study area according to the procedure described in Sect. 3.3. Statistical models of exceedance were then built as described in Sect. 3.4, starting by adjusting a GP model to the sample of daily values of energy exceeding a prescribed threshold (null model) and then improving the null model by using static probability and FWI anomaly as covariates of the scale parameter (Daily Model). In order to reduce false alarms, the computation of daily energy per pixel (which characterizes each fire event) was restricted to days where the maximum value of confidence of FRP was at least 99 %.

### 4.2.1 Static probability

Values of static probability were computed over the study area for 20 thresholds ranging from 100 up to 2000 GJ with steps of 100 GJ. The geographical distribution of values of probability of exceedance for the threshold of 2000 GJ and the respective distributions by type of vegetation cover/land use are shown in Fig. 7 and in Fig. 8, respectively. Most spatial discontinuities in the field of  $P(2000|0)$  reflect changes in vegetation cover (Fig. 1) but there are some areas, e.g. in North Africa, that although belonging to the same type of vegetation cover/land use present changes in static probability which are associated to the spatial variability of the energy released by recorded fire events (Fig. 5).

Regarding the distribution of  $P(2000|0)$  for the three considered types of vegetation cover/land use (Fig. 8), it is seen that, as expected, there is a close agreement between the distributions of static probability of exceedance and that of daily released energy per pixel (Fig. 6). Again,  $P(2000|0)$  shows a clear distinction among the three types of vegetation, forests with the highest values of the three quartiles and cultivated areas with the lowest. As in the case of daily energy released by fires, the two-sample Kolmogorov-Smirnov test corroborates the significance of the results indicating that, for each pair of the three distributions, the null hypothesis that the distributions are identical is rejected with a p-value lower than 0.0001.

**Figure 7:** Geographical distribution of the static probability of exceedance for the threshold of 2000 GJ.

**Figure 8:** As in Fig. 6 but for the distribution of static probability of exceedance of the threshold of 2000 GJ.

#### 4.2.2 Null model

- 5 As described in Sect. 3.4, the choice of  $E_{min}$  threshold to be used in the GP distributions of daily released energy per pixel was based on the visual inspection of a plot of the sample mean of the values exceeding successive thresholds as a function of the respective threshold. Tested values of thresholds ranged from 0 to 1000 GJ with steps of 100 GJ. The chosen value  $E_{min} = 200$  GJ is such that above that value the dependence of exceeding means on thresholds becomes linear. The size of the sample obtained using this threshold is 14 782, representing 94 % of the original sample of recorded daily values of energy per pixel.
- 10 Maximum likelihood estimates of the shape ( $\alpha$ ) and scale ( $\sigma$ ) parameters of the GP distribution exceedances of energy (over 200 J) lead to the values of  $\alpha = 0.31$  and  $\sigma = 2470$  with corresponding 95 % confidence intervals of [0.29, 0.33] and [2403, 2540], respectively. The goodness of fit was visually confirmed by plotting sample quantiles against GP quantiles (Fig. 9). For values of exceedance greater than  $2 \times 10^4$  GJ a progressive departure from the 1:1 line is observed in the quantile-quantile plot, however, these values represent only 1 % of the sample size and are likely due to the saturation of the SEVIRI
- 15 sensor that occurs at about 1000 MW per pixel (Wooster et al., 2005).

**Figure 9:** Quantile-quantile plot for the fitted GP distribution. The dashed segment represents the 1:1 line. The square frame at the bottom left that delimits exceedances below  $2 \times 10^4$  GJ contains 99% of the sample.

### 5 4.2.3 Daily Model

Occurrence of large fires releasing large amounts of energy is expected to be more frequent in regions with high values of static probability. Large events are also likely to be steered by meteorological conditions favouring the ignition and propagation of fire, i.e. associated to large positive values of FWI anomalies. This is shown in Fig. 10, where the daily energy per pixel released by recorded fire events during 2004–2016 is plotted as a function of  $FWI^*$  and  $P(2000|0)$ . As expected, events releasing very high values of energy are mostly preferably associated to high positive values of  $FWI^*$  and/or  $P(2000|0)$ .

**Figure 10:** Daily energy per pixel released by fires as a function of  $FWI^*$  and  $P(2000|0)$ . Circles are coloured according to the released energy (GJ).

These results suggest improving the performance of the null model by incorporating  $FWI^*$  and  $P(2000|0)$  as covariates of the scale ( $\sigma$ ) parameter of the GP distribution. Using a procedure similar to the one proposed by DaCamara et al. (2014), the dataset of energy exceedances was stratified into  $51 \times 51$  cells by scrolling the domain  $FWI^* \times P(2000|0)$  by a sliding window successively defined by values of  $FWI^*$  and  $P(2000|0)$  ranging between corresponding minimum and 50<sup>th</sup> percentile, 1<sup>st</sup> and 51<sup>st</sup> percentiles, and so on up to between 51<sup>st</sup> percentile and the maximum with steps of 1 %, leading to a total amount of 2601 cells. Each cell was characterized by the respective mean values of  $FWI^*$  and  $P(2000|0)$  of its sides. GP distributions were then adjusted to each cell and estimated values of the scale parameter ( $\sigma$ ) were assigned to the respective cell. The two following boundary conditions were also defined in the domain translating the fact that no fires are expected at the lower bounds of both  $FWI^*$  and  $P(2000|0)$ :  $\sigma \equiv 1$  along  $FWI^* = -15$  (the minimum value observed) and along  $P(2000|0) = 0$ .

The behaviour of  $\sigma$  as a function of  $FWI^*$  and  $P(2000|0)$  was then modelled by means of a feed forward artificial neural network with one hidden layer with 3 neurons and the sigmoid function for activation (Haykin, 2009). The number of neurons was set by subdividing the data into a training set and a test set, and successfully trying different number of neurons so that both underfitting and overfitting of the model to the dataset is avoided. Results are shown in Fig. 11 and, as expected,  $\sigma$  monotonically increases with covariates  $FWI^*$  and  $P(2000|0)$ . It may be also noted that the larger the values of the covariates the closer is  $\sigma$  to a linear dependence.

**Figure 11:** Dependence of scale parameter  $\sigma$  of the GP distribution on covariates  $FWI^*$  and  $P(2000|0)$  as modelled by the neural network.

A new model (Daily Model) was then set up by replacing the constant scale parameter of the null model by a spatially and temporally variable one, as determined by covariates  $FWI^*$  and  $P(2000|0)$ . The null hypothesis of similar performance of both null and Daily Models was rejected by the likelihood ratio test given that the obtained p-value was lower than 0.0001. Goodness of fit of the Daily Model was then visually assessed by comparing probabilities  $P(2000|200)$  computed with the Daily Model using Eq. (5) against empirical probabilities estimated from observations. For this purpose, the dataset of daily

values of  $P(2000|200)$  over the study area during the calibration period was stratified into intervals of probability by means of a sliding window of probability successively ranging from 0 to 0.2, 0.05 to 0.25, and so on up to from 0.8 to 1, with a range of 0.2 and increments of 0.05. At each step, fire events in pixels associated to selected probabilities were counted, namely the numbers  $N_{200}$  and  $N_{2000}$  of fires occurrences with energy release above 200 and 2000 GJ. In order to have sufficiently large samples, retained steps were restricted to those containing more than 200 fire events releasing more than 200 GJ (i.e.  $N_{200} > 200$ ). The empirical probability of each step was accordingly computed as the ratio  $N_{2000}/N_{200}$  and this value compared to the mid-range of  $P(2000|200)$  associated to the sliding window at that step. As shown in Fig. 12 when empirical values of probability are plotted against respective mid-range values of  $P(2000|200)$ , a good fit is achieved between points and the 1:1 line.

10 **Figure 12:** Empirical values of probability computed from observations of fire events as a function of  $P(2000|200)$  derived from the Daily Model during the calibration period (2004–2016).

### 4.3 Classes of fire danger and model performance

Classes of fire danger were defined following the procedure described in Sect. 3.5, i.e. by plotting, for the whole study area during the calibration period, each value of daily energy  $E_{pd}$  released in day  $d$  at pixel  $p$  (Fig. 13). As expected, there is an increase in occurrence of higher values of released energy with increasing probability of exceedance  $G$  and anomaly  $A$ . The horizontal line  $\gamma_0$  separates the “Low” class from the remaining ones. This class contains 1269 events that represent only 8 % of the total amount of 15 752 events. The remaining classes are delimited by curves,  $(\gamma_1, \gamma_2, \gamma_3)$  defined by break points  $(P_1, P_2, P_3) \equiv (0.103, 0.206, 0.309)$ . As prescribed in the procedure, break points are equally spaced by steps of 0.103 and the

“Very High” and “Extreme” classes contain about the same number of events, i.e. 5408 and 5443, representing 34 and 35 % of the total amount, respectively.

A better insight into the characteristics of the Daily Model’s five classes of danger may be obtained by stratifying the occurrences into three ranges of energy released by the fire events, namely below 2000 GJ, between 2000 and 10 000 GJ and above 10 000 GJ. As shown in Table 1 (‘Daily Model’ sub-table), within the cases of the lowest range (< 2000 GJ), 59 % are distributed between the “High” (26 %) and “Very High” (33 %) classes, while the intermediate range (2000–10 000 GJ) presents a steep increase in frequency from “Low” to “Extreme”. An even steeper increase is observed for the upper range (> 10 000 GJ), for which the “Low” and “Moderate” classes contain 1 % of the cases and the “Extreme” one concentrating 72 % of the events in that layer.

10

**Figure 13:** As in Fig. 3 but respecting to results for the calibration period (2004–2016) based on values of  $P(2000|200)$  and respective anomalies  $A$ . Fire events during the period are superimposed, being represented by circles coloured according to the daily released energy (GJ).

15

**Table 1:** Distributions during the calibration period (2004–2016) of fire events among classes of fire danger for three ranges of daily energy released by fires when classes are obtained from the Daily Model, the LSA SAF product and the EFFIS module. Each cell contains the number of observed events and [in brackets] the corresponding fraction (%) of the total number of events belonging to the same energy layer.

	Energy [GJ]	Low	Moderate	High	Very High	Extreme	Total
Daily Model	< 2000	984 [12]	732 [9]	2146 [26]	2723 [33]	1652 [20]	8237 [100]
	2000–10000	272 [4]	58 [1]	685 [11]	2367 [38]	2893 [46]	6275 [100]
	> 10000	13 [1]	1 [0]	10 [1]	318 [26]	898 [72]	1240 [100]
LSA-SAF	< 2000	180 [2]	589 [7]	3319 [40]	2950 [36]	1199 [15]	8237 [100]

5

As mentioned in Sect. 3.6, the performance of the Daily Model is assessed by comparing the distributions of events among the classes of fire danger for the three ranges of energy with those obtained when using the LSA SAF and the EFFIS products (Table 1, ‘LSA SAF’ and ‘EFFIS’ subtables). Differences are particularly notable in the upper energy range (>10 000 GJ), especially for EFFIS classes where events spread in all classes and the “Very High” and “Extreme” classes only contain 70 % of the cases whereas for the Daily Model and the LSA SAF they contain 98 and 85 %, respectively. However, in the case of LSA SAF classes, the modal class is the “Very High” and not the “Extreme” as in the Daily Model. Similar differences, although less prominent, may be observed among the three products in the intermediate energy range (2000–10 000 GJ). The modal classes are the “Extreme” for the Daily Model and the “Very High” for the LSA SAF and EFFIS, the modal frequency being the highest (46 %) for the Daily Model, followed by the LSA SAF (45 %) and EFFIS where the frequency (33 %) is quite low and equal to that of the next class below. Finally, the lower energy range (< 2000 GJ) also presents differences among the three products, namely in the frequency of events in the “Low” and “Moderate” classes, that represent 21 % of the events in the Daily Model and only 9 and 7 % for the LSA SAF and EFFIS. The different features of the classes from the three products ultimately translate into different values of probability of a fire event releasing a given amount of energy in case of a given class danger. For instance, using results presented in Table 1, the conditional probability of having a large release of energy (> 10 000 GJ) given “Extreme” danger is  $898/5443 = 16.5\%$  and  $481/3066 = 15.7\%$  for the Daily Model and the LSA SAF, respectively, and is only  $511/4384 = 11.7\%$  for EFFIS. Similar features are presented by the conditional probability of having a small release of energy (< 2000 GJ) given “Low” danger, with values of  $984/1269 = 77.5\%$  and  $180/217 = 82.9\%$  for the Daily Model and the LSA SAF, respectively, and only of  $135/207 = 65.2\%$  for EFFIS.

Differences obtained among the three products point out the better performance of the Daily Model if the aim is to have information about the probability of occurrence of an event releasing a large amount of energy. This result is not surprising

25

since the Daily Model was specifically designed for such purpose. Estimates of probability by the LSA SAF product are closer to those by the Daily Model than the ones by EFFIS because the LSA SAF relies on duration of active fires inside each pixel and day that is a better proxy of energy released by fires than records of fire events with more than 500 ha of burned area. We nevertheless acknowledge that it is not a straightforward exercise to translate the 6 danger classes defined by EFFIS into a 5 class scheme such as those of the LSA SAF and Daily Model approaches.

#### 4.4 Model validation

As described in Sect. 3.6, model validation involves applying the Daily Model to the validation period (January–September 2017) and analysing results obtained for the two severe events of Pedrógão Grande-Góis (Portugal) and Provence (France). It is important to note that, contrasting to the calibration period where meteorological data were obtained from ERA-Interim reanalysis, ECMWF’s operational 24-hour forecasts are used during the validation period. The overall coherence of reanalysis data makes them especially appropriate to calibrate the Daily Model but forecast information has to be used for operational application. Results obtained in the validation period therefore reflect the effects of applying the procedure to an independent dataset as well as those due to using forecast information instead of reanalyses.

As shown in Table 2, during the validation period, the obtained distributions of events among classes of fire danger are similar to those obtained in the calibration (Table 1, ‘Daily Model’ subtable). The distribution of events for the lowest range (< 2000 GJ) is shifted toward the more severe classes of fire danger, the modal class being the “Very High” one, with 42 % of the events and the “Extreme” class containing 39 % of the cases. The intermediate range (2000–10 000 GJ) is slightly shifted towards the more severe classes of fire danger, the modal class being the “Extreme” with 57 % of the events and the “Very High” class containing 37 % of the cases, a figure very close to the one obtained in the calibration period (38 %); likewise, as gotten in calibration, the highest jump in relative frequency is from the “High” to the “Very High” class (5 to 37 %). In the highest range (>10 000 GJ) no cases are observed in the “Low” and “Moderate” classes and, as found in calibration, the modal class is the “Extreme” containing 76 % of the events (72 % in calibration), the remaining 24 % (26 % in calibration) belonging to the “Very High” class.

The percentage of fires for the “Very High” and “Extreme” classes is shifted toward the more severe classes (38.6 % and 48.7 %), a feature that may be attributed to the fact that up to September, according to information at the EFFIS site, the accumulated burned area in 2017 is more than 600 000 ha, more than two and half times the 2008–2016 average of about 224 000 ha. This may also explain the virtual absence of episodes in the “Low” class (8 events in a total of 1972).

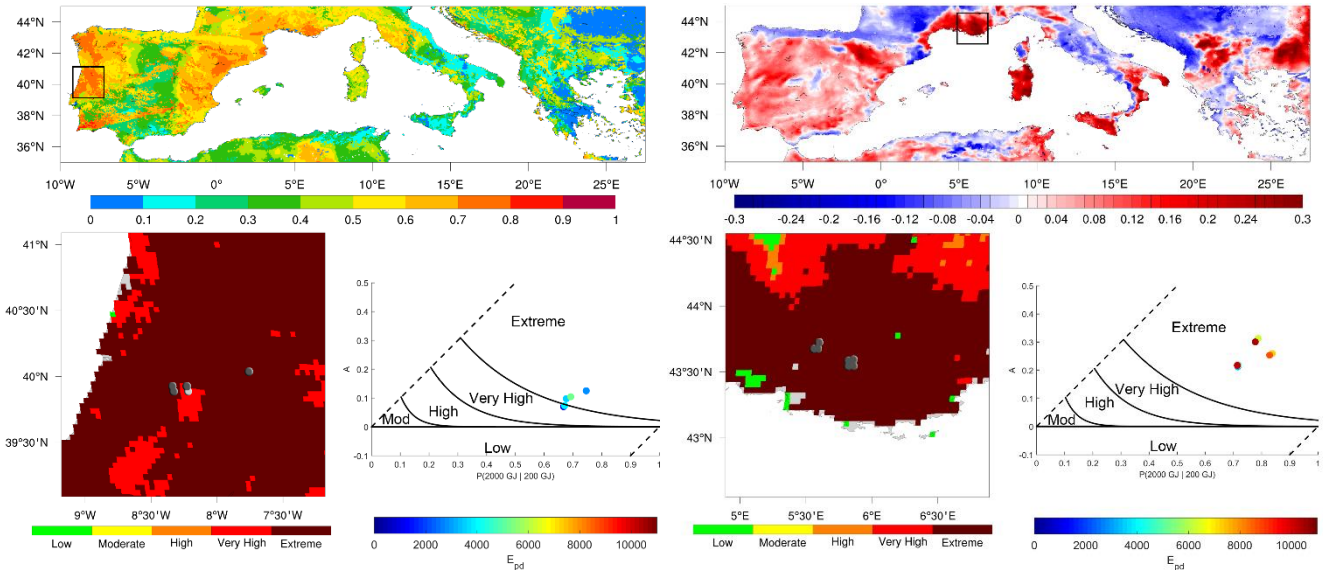

**Table 2:** As in Table 1 but for distributions obtained in the validation period (January–September 2017) of fire events among classes of fire danger as obtained from the Daily Model.

		Energy [GJ]	Low	Moderate	High	Very High	Extreme	Total
Daily Model	< 2000	2 [0]	45 [4]	154 [15]	429 [42]	395 [39]	1025 [100]	
	2000–10000	6 [1]	1 [0]	41 [5]	296 [37]	450 [57]	794 [100]	
	> 10000	0 [0]	0 [0]	0 [0]	37 [24]	116 [76]	153 [100]	

Results obtained for the two 2017 case studies of Pedrógão Grande-Góis (Portugal) and Marseille (France) are summarized in Fig. 14. The figure is subdivided into two main vertical panels, the left one respecting to Pedrógão Grande-Góis and the right one to Marseille. For each event a map covering the study area is presented on the top, showing the geographical distribution of values of  $P(2000|200)$  for Pedrógão-Góis and of anomaly values of  $P(2000|200)$  for Marseille. At the bottom of each panel, on the left hand side, there is a map showing the geographical distribution of classes of danger and the location of active fires detected over the region affected by the fire event; finally, on the right hand side, there is a diagram presenting the distribution of active fires detected in the domain  $G$  of  $P(2000|200)$  versus respective anomalies  $A$ . In the case of the Pedrógão Grande-Góis, it is worth noting that on June 18, 2017 the area surrounding the fire events is covered by a patch of values of  $P(2000|200)$  exceeding 0.7 (top frame) over a background of lower values covering most of the Mediterranean basin. Pixels inside the area of interest (black boxes) are mostly classified as “Extreme” danger of fire (lower left frame) and active fires detected (reaching up to 5000 GJ of released energy) are within or very close to the border of the partition classified as “Extreme” fire danger in the domain of  $P(2000|200)$  versus anomaly  $A$  (lower right frame). The fire episodes near Marseille Fig. 14 (right panel) took place within an area conspicuously characterized by values of anomalies  $A$  as high as 0.3, which are higher than the surrounding values and much higher than the values observed in the majority of pixels over the Mediterranean basin. As in the case of Pedrógão Grande-Góis, the fire events near Marseille (reaching up to 10 000 GJ of released energy) are located within an area classified as of “Extreme” danger of fire or near the border between the “Extreme” and “Very High” classes (lower left frame) There is however a difference between the two events that is worth mentioning. In the case of Pedrógão Grande-Góis, pixels where active fires were observed are classified as or near “Extreme” fire danger because of the high values of  $P(2000|200)$ , whereas in the case of Marseille that is mostly because of the high values of anomaly  $A$ . These two examples justify the adopted rationale of defining the classes of fire danger in the space  $P(2000|200)$  versus anomalies  $A$ .

## 5 Conclusions

The Mediterranean is one of the regions of the world most affected by large wildfires and fire prevention is therefore of crucial importance. Fire management requires adequate knowledge about wildfire potential assessment that is usually based on fire danger rating systems providing indices to be used on an operational and tactical basis in decision support systems.

**Figure 14:** Results obtained for the 2017 fire events at Pedrógão Grande-Góis (Portugal) on June 18 (left panel) and near Marseille (France) on July 25 (right panel). The geographical distributions over the Mediterranean basin of  $P(2000|200)$  for Pedrógão Grande-Góis and of anomaly  $A$  for Provence are shown in the upper frames of the respective panels and the areas of interest are represented by the two corresponding black boxes. Classes of fire danger for the areas of interest are shown in the colorbar of the lower left frames, together with the observed active fire events (dark grey circles). Locations of fire events (colored circles) in the space of  $P(2000|200)$  versus anomaly  $A$  are shown in the lower right frames, the colors indicating the amount of the daily released energy  $E_{pd}$  (in GJ).

5 The aim of the present work is to lay the grounds towards the development of an operational product that will be able to provide the user community with daily information on meteorological danger that will allow adopting the adequate measures to mitigate fire damage. The proposed product consists of forecasts of fire danger over Mediterranean Europe based on a statistical procedure that combines information about fire history derived from the Fire Radiative Power (FRP) product by the Satellite Application Facility for Land Surface Analysis (LSA SAF) with daily meteorological forecasts provided by the European  
 10 Centre for Medium-Range Weather Forecasts (ECMWF).

The procedure involves estimating static and daily probabilities of exceedance of daily energy released by fires occurring at the pixel level. Static probability at a given pixel is estimated by the ratio of the number of daily fire occurrences releasing energy above a given threshold to the total number of occurrences inside a cell centered at the point. Daily probability takes into account meteorological factors by means of the Canadian Fire Weather Index (FWI) and is estimated using a Daily Model  
 20 based on a Generalized Pareto distribution with static probability and FWI as covariates of the scale parameter. Five classes of fire danger are then associated to daily probability estimated by the Daily Model.

During the calibration period (2004–2016), it is shown that about 72 % of events releasing daily energy above 10 000 GJ belong to the “Extreme” class of fire danger from the Daily Model, a figure that is more than one and a half times the values

obtained when using EFFIS (41 %) or the LSA SAF (39 %). It is also shown that the “Low” class from the Daily Model contains 12 % of events with released daily energy lower than 2000 GJ, whereas this percentage is only 2 % when classes from LSA SAF or EFFIS are used. Classes of fire danger from the Daily Model are therefore more suitable to discriminate fire events in terms of released energy. When the Daily Model is applied to the independent dataset of January–September 2017, results are consistent with those obtained in calibration.

The product derived from the proposed Daily Model mainly differs from LSA SAF and EFFIS products in that the indices of meteorological fire danger are calibrated based on thirteen years of information about fire radiative power, with a temporal resolution of 15 minutes as derived from the SEVIRI instrument on-board MSG satellites. Besides providing a solid physical meaning to the approach since energy is a measurable physical property, fire radiative power is also directly related to the amount of fuel burned and smoke production (e.g. Wooster et al., 2005). Fire radiative power is also useful in fire management and firefighting because it can be used as a proxy of fire line intensity (Smith and Wooster, 2005; Johnston et al., 2017).

It is worth noting that the proposed approach is based on FWI that is defined at the daily level. Classes of fire danger are accordingly computed on a daily basis, and the same happens in the cases of the LSA SAF and the EFFIS products that also depend on FWI. The daily scale of the classes of fire danger may sometimes constitute a shortcoming, namely because local atmospheric conditions of short time duration cannot be captured by FWI. This was indeed the case on the first day of the large 2017 fire event at Pedrógão Grande-Góis, when the unstable atmospheric conditions favoured the formation of thunderstorms and gust fronts that jointly allowed pyrocumulonimbus development and played a crucial role in the extremely fast initial-spread of the fire, causing a large number of fatalities. Inaccuracies in the forecasts of precipitation at the local level may constitute another shortcoming given that they may lead to incorrectly low values of FWI. These two limitations may be circumvented, at least partially, by means of intraday high-resolution fire weather forecasts combined with the use of ensemble forecasts that will allow a better assessment of the uncertainties of fire danger predictions. Both aspects are currently being studied and results are expected to bring developments of the current method to be operationally implemented in the future.

A prototype of the proposed procedure is running since April 2017 at Instituto Dom Luiz, Faculty of Sciences, University of Lisbon (<http://idlcc.fc.ul.pt/CeaseFire/>). Besides assisting in wildfire management, information provided about the statistical distributions of exceedances in fire radiative power, as well as of meteorological parameters and derived indices of fire danger is expected to represent an added value in decision making on prescribed burning within the framework of agricultural and forest management practices, a very delicate activity since wrong or uninformed decisions may trigger severe events associated to large damages.
