

Please find in this document our point-by-point response to the reviews and the changes that were made in the manuscript to answer these comments. Other minor changes were also made in the manuscript to improve the language and clarity. Please also note that the title also been slightly modified.

#### Reviewer # 1

I read with great interest the manuscript "Extreme Wildfire occurrence in response to Global Change type Droughts in the Northern Mediterranean". This study evaluates the climatology of extreme wildfires in Mediterranean France and identified the emergence of new generations of fires expected with global change type droughts. Overall, the paper is interesting and it is carefully and clearly written. The conclusions are significant and can sustain the interest of a broad audience. To sum up, the authors make a convincing analysis of the problem and their manuscript deserves publication in NHESS.

We thank the reviewer for the very positive appreciation of our manuscript.

#### Reviewer # 2

The manuscript examines extreme fire events in southern France in 2003 and 2016 and compare the fire weather conditions with those observed on average. They conclude that increased fuel dryness created somewhat novel combinations of conditions, respectively marked by pronounced fuel aridity combined with strong wind and "normal" wind combined with fuel aridity (to a lesser degree) and a heat wave. I find these conclusions sound and the ms. generally robust, although the discussion could be deeper given the wealth of information provided by the graphed results. My major concerns are some inaccuracies and errors in nomenclature (or understanding of fire dynamics?), namely: - Fuel aridity does not apply to dead fuel dryness induced by short-term atmospheric influences; - What the authors describe as "heat-driven" is in fact dryness-driven (not necessarily drought-driven, because drought implies a longer time scale).

We thank the reviewer for this positive appreciation and thorough review of our manuscript. Following the main recommendations, we paid particular attention to use more appropriate nomenclature when describing both fire weather types and drought features that were, when necessary, modified in the revised

text of the manuscript. We present hereafter our detailed responses to each of the comments raised by the reviewer.

**(#1)** P1, L24. Rephrase. The sentence suggests that spatially continuous fuels are expected to limit fire spread. Also simplify to “dead and live fuels”, as litter is only a factor in forests.

5 Yes, this sentence has been corrected and now reads: “*In a large number of ecosystems, anthropogenic ignitions are dominant and dead or live biomass are rarely limiting...*” (P1, L24)

**(#2)** P2, L15-16. Unclear sentence: “theirs impacts of fire behavior for vegetation communities”. Do you mean “their impacts on fire behavior”? Vegetation communities is not really needed in the sentence.

‘Vegetation communities’ has been removed

10 **(#3)** P2, L16. They burn woody vegetation, but are in fact “foliage-fueled”.

That is correct, though the expression sounds awkward. To avoid any ambiguity, the term “woody-fueled” has been removed.

**(#4)** P2, L16. FWT refer to fire weather types, not to fire types, so correct the sentence. Also, “heat-driven” doesn’t say anything and is incorrect to refer to this type of fires. “Plume-driven” is the right

15 designation and would be the preferred option to replace the less accurate “convective”; all fires are driven by convection as the prevailing heat transfer mechanism, irrespective of their nature or intensity. A second objection is that you have no data supporting the claim that these types of fires are convection/heat/plume driven, because that depends of atmosphere stability and stratification. All you can say is that those fires developed under weaker winds and dry conditions. Hence you should be  
20 conservative and describe them as fuel-driven or dryness-driven fires.

We agree about the reviewer’s main concern: “heat-driven fires” is a misleading classification, as fire are indeed not driven by heat. As the reviewer, correctly summarized hereafter (see comment **#18**), it is very likely that the impact of temperature on fire behavior is obtained indirectly through its effect on fuel dryness. Nevertheless, we believe that the fact that very large fires occur during very intense episodes of  
25 heat should be clearly mentioned. Thus, we have replaced the expression ‘heat-driven’ by ‘heat-induced’, a solution that actually enables to keep the reference to heat without misleading the readers about the main factors driving these fires. Accordingly, the paragraph describing these fire weather types has also been rewritten to frame these points clearly (P2, L18-L19).

(#5) P2, L21. Rephrase “that transport the flame closer to fresh fuel”. The flame is not transported by wind, and fuel is not “fresh”.

Yes, corrected. It now reads: “*Wind-driven fires are dominated by strong winds that accelerate the rate of spread*” (P2, L18).

5 (#6) P2, L34. Correct “for to the”.

Corrected

(#7) P4, L5. I understand that these fires threatened valuable resources but find hard to accept that fires of ~300 ha are classified as extreme. The nature of the fire (i.e. extreme or not as determined by the fire environment) should not be mixed with its impact for the purpose of a study of this type. The single fact of being controlled at such size suggests they were not that extreme. Please justify better.

10 This is a relevant comment. It is our belief that the definition of Extreme Wildfire Events should not only be based on their final size but also on the direct (and indirect) economic, social and environmental impacts. Having said that, we understand that the reviewer might be surprised that a wildfire of 250 hectares could be considered as extreme while some wildfires can burn tens of thousands of hectares in some other areas, e.g. Portugal. However, in Mediterranean France where landscapes are highly fragmented and firefighting system strongly control fire size, most of the fires are small and only few fires reach extended surfaces. For instance, in Mediterranean France 43,436 fires occurred over the period 1996-2016 but only 145 were larger than 250 ha (less than 0.4%; source: [www.promethee.fr](http://www.promethee.fr)). We agree that such information should have been mentioned on the manuscript and is now included (P4, L24-L27).

20 The main reason why we chose to focus on 2003 and 2016 extreme wildfire events is indeed at the core of what motivated our study.

(#8) P4, L13. This is not true, i.e. extreme fires can spread for several days. I suggest you justify the option by stating that the main fire runs often occur on the first day.

Yes, we agree that stating that fires generally do not last more than one day in the Mediterranean is wrong.

25 Although this statement is true for the vast majority of large fires in southern France, it can be misleading when generalized to other Mediterranean countries. We are aware that fires in Portugal (e.g. 2003, 2005, 2017) and in Greece (e.g. 2007) can last several days. Accordingly, we followed the reviewer’s advice and rephrased this sentence that now reads: “*Only the weather and fuel conditions of the day of fire occurrence were analyzed because the main runs of large fires often occur on the first day in in this part of the Mediterranean*” (P4, L14-L16).

30

(#9) P4, L13-14. The concept of fuel aridity (check the original papers) is different from low fuel moisture contents attained on the short to mid-term so you should not use it in this context. Can an absence of rain for 4-6 weeks (drying time for the fuels represented by the DMC) be designated as “drought”?

5 That is true, we changed the term ‘aridity’ and adopted the more appropriate term ‘dryness’ throughout the manuscript, namely in section 2.3 (P4, L14) and in Figure 9.

(#10) P4, L16. Again, this is not correct, the fuel moisture content of surface fuels in the FWI system is expressed by the FFM. The DMC accounts for the part of the forest floor that produces flame plus more compacted layers that smoulder, i.e. it includes sub-surface fine and coarse fuels.

15 Also true. This sentence has been rephrased and now reads: “*The DMC is generally associated with the moisture content of slow drying surface fuels and is computed from daily rainfall, relative air humidity and air temperature during and prior to the fire day.*” (P4, L17-L19)

(#11) P4, L19. Make the sentence clearer, because the DC was not conceived to track the moisture content of live fuels.

20 Yes, this sentence has been rephrased to clarify the primary purpose of DC. It now reads “*The DC was initially developed to estimate the soil water content of relatively deep and compacted duff and is generally associated to very slow drying fuels. It is calculated from daily rainfall and air temperature during and prior to the fire day. In the Mediterranean, DC has also been related with the moisture content of living shoots of plants, although the responsiveness of living fuel to weather can greatly vary among species according to their ability to dynamically adjust their water status (Viegas et al., 2001).*” (P4, L19-L23)

(#12) P5, L1-2. You certainly do not need to include this explanation.

We agreed with this suggestion. This equation was removed from the manuscript.

(#13) P5, L10. This line is not understandable.

25 Yes, we apologize for this unclear sentence. It has been rephrased and now reads: “*Then, to assess whether and to what extent does the climatology of the large wildfires of 2003 and 2016 differ from that of other large wildfires, fire climatologies were compared between them and with the mean summer daily conditions for the period from 1996 to 2016.*” (P5, L7-L9)

(#14) P5, L16. Wildfire, not wildfires.

Corrected

(#15) P7, L12. "charactering".

Corrected

(#16) P7, L26. What about the fires of 2017 in southern France? You could discuss them in this framework.

5 That is a relevant suggestion. Several very large fires occurred during July 2017 in what is named eastern  
area in the present manuscript (Figure 1) During the 24<sup>th</sup> and 25<sup>th</sup> of July 3 wildfires burnt more than  
3,500 ha and about 10,000 residents and tourists were moved by local authorities. It seems that these fires  
were associated with strong winds and that the whole year 2017 was also particularly dry while spring  
and summer were anomalously warm (and 2017 follows an already anomalous dry and warm year in  
10 2016). We have therefore added a sentence in the discussion to mention these fires (P7, L24-L26).

(#17) P7, L28. Not clear what you mean with "some new generations of fires". Increase in the  
occurrence of hot droughts and press droughts simply imply that the distribution of fire behavior  
characteristics will change to include more extreme fires at higher frequency.

The reviewer is right. Two important conclusions should have been distinguished here. In one hand and  
15 as the reviewer suggested it, an increase in the occurrence of hot droughts and press droughts will lead to  
extreme fires at higher frequency. On the other hand, our results suggest that droughts are also becoming  
more extreme, thereby leading to fire weather conditions that have not been explored before. To clarify  
these points, the sentence has been rephrased and now reads "*Our study suggests that 'hot droughts' and  
'press droughts', both anticipated to occur more frequently throughout the XXI century according to the  
20 vast majority of models, can lead to a higher frequency of extremes wildfires and to fire weather  
conditions that have not been explored before*" (P7, L27-L29). A sentence in the abstract has also been  
rephrased (P1, L18-L19).

(#18) Figure 9 is nice, but again I have problems with the nomenclature adopted (see previous  
comments): the aridity concept does not apply to fast drying fuels, and "heat driven" is quite poor and  
25 inaccurate when in fact these fires are driven by fuel dryness, both on the short and long term. I suppose  
"heat" is used because of the high temperatures, but temperature in fire behavior only acts indirectly  
through its effect on live fuel desiccation and dead fuel moisture content.

Yes, according to the two main comments of the reviewer, Figure 9 has been modified. The expressions  
"Aridity" and "heat-driven" have been replaced by 'dryness' and 'heat-induced', respectively. Specific  
30 responses to can be found in our responses to comments #4 and #9

# Extreme Wildfire Events are linked to Global-Change-type Droughts in the Northern Mediterranean

**Abstract.** Increasing drought conditions under global warming are expected to alter the frequency and distribution of large, high intensity wildfires. Yet, little is known regarding how it will affect fire weather and translate into wildfire behavior. Here, we analyzed the climatology of extreme wildfires that occurred during the exceptionally dry summers of 2003 and 2016 in Mediterranean France. We identified two distinct shifts in fire climatology towards fire weather spaces that had not been explored before, and which result from specific interactions between the types of drought and the types of fire weather. In 2016, a long-lasting ‘press drought’ intensified wind-driven fires. In 2003, a ‘hot drought’ combining a heatwave with a press drought intensified heat-induced fires. Our findings highlight that increasing drought conditions projected by climate change scenarios might affect the dryness of fuel compartments and lead to a higher frequency of extremes wildfires.

## 1 Introduction

There is increasing evidence that global changes are altering the distribution and frequency of the largest, most destructive, extreme wildfires (EW) in different regions of the world (Trigo et al., 2006; Bowman et al., 2017) with ensuing economic, social and ecological impacts (Schoennagel et al., 2017). In a large number of ecosystems, anthropogenic ignitions are dominant and dead or live biomass are rarely limiting (Krawchuk et al., 2009; Pausas & Fernández-Muñoz, 2012). In these regions, fuel dryness therefore mainly regulates wildfires (Abatzoglou & Williams, 2016; Littell et al., 2016; Nolan et al., 2016; Fernandes et al., 2016; Turco et al., 2017). But while climate change is expected to increase the frequency and intensity of droughts in regions such as the Mediterranean (Hoerling et al., 2012), our understanding of the impact of increasing drought on EW remains incomplete, because of still unresolved uncertainties.

First, meteorological drought is a complex phenomenon whose magnitude, length and timing depends on multiscale spatial and temporal interactions between evapotranspiration and precipitation (Ruffault et al., 2013). Several types of droughts can

Supprimé: occurrence in response to

Supprimé:

Supprimé:

Supprimé:

Supprimé: .

Supprimé: driven

Supprimé:

Supprimé: spatially continuous areas of surface litter and

be defined, depending on their characteristics (Hoover et al., 2015; Hoover & Rogers, 2016). “Press droughts” are subtle but chronic reductions in water availability, driven by long-term (month to seasons) reductions in precipitation and/or warmer temperatures, which increase potential evapotranspiration and reduce soil moisture (Hoover & Rogers, 2016). By contrast, “pulse-droughts” (or “flash droughts”; Mo & Lettenmaier, 2016) are short in duration (days to weeks) but extreme in magnitude. When combined, press and pulse droughts may yield ‘hot droughts’ (Overpeck, 2013).

Second, translating drought characteristics into fuel moisture content is not straightforward, because fire-prone ecosystems consist of several fuel compartments that respond to drought on different timescales (Pyne, 1996; Nolan et al., 2016). Fuel moisture of trees and shrubs live foliage responds to mid-term to long-term droughts because of the control of vegetation over water fluxes (Ruffault et al., 2013). By contrast, the fuel moisture of fine, dead fuels and surface litter responds to short term (hours to days) atmospheric dry conditions (e.g. Resco de Dios et al., 2015).

Third, large fire climatology itself (i.e. typical local-scale weather conditions associated with fires) might not be unique within a homogeneous biogeographic area. Indeed, after observing that the weather conditions associated to large fire occurrence may be different in Mediterranean ecosystems, Ruffault et al. (2016) proposed a new hypothesis wherein large fire climatology was described as the coexistent combination of a limited number multi-scalar weather conditions called Fire Weather Types (FWTs). The FWTs are the result of the linkage between instantaneous and antecedent regional weather patterns and their impacts on fire behavior. For instance, two main FWTs are generally observed in crown fires in forests and shrublands: wind-driven and heat-induced (Rothermel, 1991; Flannigan & Wotton, 2001; Jin et al., 2015; Duane et al., 2015; Ruffault et al., 2016, 2017; Cardil et al., 2017). Wind-driven fires are dominated by strong winds that accelerate the rate of spread. By contrast, heat induced fires are linked to anomalously warm conditions that increase fuel dryness (Jin et al. 2015, Ruffault et al. 2016).

During the summers of 2003 and 2016, Mediterranean France (see Figure 1) experienced several extreme wildfires that raised issues regarding how increasing drought conditions might affect fire activity. Indeed, despite growing efforts in fire management and suppression capacities implemented since the beginning of the 90’s (Fox et al., 2015; Ruffault and Mouillot, 2015; Curt and Fréjaville, 2017), several fires became particularly large and devastating during these two years. Besides, the 2003 and 2016 summers are also known to be particularly dry in Mediterranean France, although they did not share similar climatic characteristics. Summer 2003 combined a long drought and a summer heat-wave (Trigo et al., 2005) resulting in a ‘hot drought’. Summer 2016 was marked by a long-lasting ‘press drought’ (French national meteorological institute; Météo-France, 2017; Figure 2) while the anomalously warm temperatures were less extreme than in 2003. Interestingly, these two events closely reflect the expected impacts of climate change on drought that are projected in the Mediterranean (Sousa et al., 2011; Hoerling et al., 2012) and in other regions of the world (e.g. Mazdiyasi & Aghakouchak, 2015).

Following these considerations, the overarching goal of this study is to determine whether the increasing drought conditions observed during the years 2003 and 2016 are responsible for the occurrence of extreme wildfires in Mediterranean France. Specifically, we aimed at understanding how the weather conditions observed during these summers, although different, led to extreme wildfire occurrence. Our hypothesis is that fire weather types have been affected by these two droughts. To answer

## 2. Material and Methods

### 2.1 Study area

5 The study area includes two French administrative districts (Figure 1, total area of 11,157 km<sup>2</sup>) recognized as two of the most fire-prone regions in France (Lahaye et al., 2014). The climate is Mediterranean with hot and dry summers, cool and wet winters and high inter-annual variability. Although these two districts share a large number of common climatic characteristics, interannual variations in the amount of precipitation can differ greatly between them because of the existence of a west-east gradient in precipitation variability over southeastern France (Figure 2, see also Ruffault et al., 2017). Therefore, two distinct  
10 areas were considered in the following analyses (hereafter called the Western and Eastern area; Figure 1) based on the administrative borders of these districts. Fuels are similar in these two areas, consisting mostly of shrublands, pine forests, oak forests, and mixed pine oak forests (Curt et al., 2013) but the western area, which includes the Aix-Marseille Metropole urban area, is more urbanized (average population density of 394 inhabitants.km<sup>-2</sup>) than the eastern area (174 inhabitants.km<sup>-2</sup>) (French National Institute of Geographic and Forest Information; IGN, 2016). The average yearly burnt area during the summer  
15 season (June to September – JJAS–) from 1996 to 2016 is 1,393 ha.y<sup>-1</sup> and 1,389 ha.y<sup>-1</sup> in the western and the eastern area, respectively. Fire activity is highly variable from year to year and reached its highest level in 2003 (18,763 ha) and 2016 (4,825 ha) in the eastern and western area, respectively (Figure 3).

### 2.2 Fire data

Fire data for the summer season (June to September) were extracted from the PROMETHEE fire database ([www.promethee.fr](http://www.promethee.fr))  
20 for the period from 1996 to 2016. This database is managed by French forest services and provides reliable fire statistics with no major inconsistencies over the period examined (Ruffault and Mouillot, 2015, 2017). For each fire, PROMETHEE provides its ignition date, size and location of fires on a 2x2 km grid. In this study, large fires were defined as fires greater than 250 ha in order to match the minimum size of extreme wildfires (EW) that occurred during the 2003 and 2016 fire seasons (see below).

This size is rather small compared to other regions and ecosystems with relatively similar Mediterranean climate conditions, as seen in recent mega-fires in 2017 in Portugal or California. However, in Mediterranean France where landscapes are highly fragmented, only few fires reach extended surface and less than 0.4 % of fires exceed this 250 ha threshold for the period from 1996 to 2016 ([www.promethee.fr](http://www.promethee.fr)).

Wildfire events were then classified into three distinct groups: (i) extreme wildfires (EW) that occurred during the summer of 2003 in the eastern area (hereafter EW2003), (ii) EW that occurred during the summer of 2016 in the western area (hereafter  
30 EW2016) and (iii) other large summer wildfires that occurred between 1996 and 2016 (hereafter OLW).

EW were defined here as fires that caused or threatened to cause some economic, social, or ecological damages. Because of the absence of a national, comprehensive and quantitative dataset on the vulnerability of landscapes to wildfires, EW identification was based on a systematic literature review of scientific papers, governmental reports, newspaper articles or feedbacks from firefighters. We acknowledge that some subjectivity was unavoidable in this exercise, but as only few ignitions turn into large fires in Mediterranean France, large fires are systematically covered and well documented. In line with the detailed description of the 2003 summer fire season performed by Favre & Schaller (2004), six large wildfire events were particularly harmful and classified as EW for the year 2003 (Table 1). For the year 2016, three wildfires were classified as EW. These wildfires were extensively reported in the media and discussed by experts across the country, in part due to their large size but also because they threatened either industrial, socio-economical or ecological values (see Table 1). In fact, the occurrence of these three wildfires is one of the main reasons why we initiated our study. Finally, the OLW group consisted of all large wildfires that were not classified in either of the two previous groups (n=29; median size = 520 ha).

### 2.3 Data analysis

The climatology of large fires was characterized by using the five following daily variables: temperature, wind speed, relative humidity and two proxies of fuel dryness on the medium (days to weeks) and long term (weeks to months). Only the weather and fuel conditions of the day of fire occurrence were analyzed because the main runs of large fires often occur on the first day in this part of the Mediterranean. The drought code (DC) and the duff moisture code (DMC) of the widespread Canadian fire weather danger rating system (CFFDRS, Van Wagner, 1987) were used as proxies of fuel dryness. The DMC is generally associated with the moisture content of slow drying surface fuels and is computed from daily rainfall, relative air humidity and air temperature during and prior to the fire day. The DC was initially developed to estimate the soil water content of relatively deep and compact duff and is generally associated to very slow drying fuels. It is calculated from daily rainfall and air temperature during and prior to the fire day. In the Mediterranean, DC has also been related with the moisture content of living shoots of plants, although the responsiveness of living fuel to weather can greatly vary among species according to their ability to dynamically adjust their water status (Viegas et al., 2001).

Daily climate records for precipitation, wind speed, temperature and relative humidity for the period 1996-2016 were obtained from climate stations. The two weather datasets were obtained from the Marignane (43.436°N; 5.215°E, altitude 5 m a.s.l.) and Le Luc (43.381°N; 6.385°E, altitude 80 m a.s.l.) meteorological stations for the Western and Eastern Area, respectively (Figure 1, source Météo France). Both stations are located close to the center of their respective area and 75% of fires are within a 35-km perimeter of the station (Figure 4).

In addition to the five above-mentioned drought proxies and weather variables, we also examined the seasonal and inter-annual variations in live fuel moisture content (LFMC) for distinct Mediterranean shrubs species sampled from nearby wildfire locations. Historical observations of LFMC for the 1996-2016 period were obtained from the “Réseau Hydrique” dataset, fully available in a *Zenodo repository* (Cabane et al., 2017). It provides weekly measurements of LFMC during the fire season (generally from May to September depending on the level of fire danger) for various species and sites of the French

Supprimé: The DMC is an indicator of droughts of short duration (from days to weeks) and is generally associated with the moisture content of surface dead fuels in the Mediterranean. DMC is computed from daily rainfall, relative air humidity and air temperature during and prior to the fire day. The DC is an indicator of longer, deeper droughts (from weeks to months). It is computed from daily rainfall, relative air humidity and air temperature during and prior to the fire day. The DC is generally associated with the moisture content of slowly drying fuels such as living shoots of plants, although the responsiveness of living fuel to weather can greatly vary among species according to their ability to dynamically adjust their water status (Viegas et al., 2001).

Mediterranean area. For each area, we extracted the closest site from the barycenter of the fires under study: “Le Romaron” (43.354°N, 5.166°E, altitude 152 m a.s.l) and “Le Haras du Rastéou” (43.477°N, 6.483°E, altitude 147 m a.s.l) for the Western and Eastern areas, respectively (Figure 1, Figure 4). For each site, LFMC was examined for two species with distinct [post-fire](#) regeneration strategies (seeder and resprouter) as they generally display some distinct functional responses to drought (Vilagrosa et al., 2014).

#### 2.4 Statistical analysis

Daily weather conditions were computed for each large wildfire and averaged for each fire group. Then, to assess whether and to what extent does the climatology of the large wildfires of 2003 and 2016 differ from that of other large wildfires, fire climatologies [were compared](#), between them [and with the](#) mean summer daily conditions for the period from 1996 to 2016. For each weather variable, the significance of the difference between these groups was tested using the Welch’s modified t-test, [which](#) is more reliable than the student t-test when the two samples have unequal variances and unequal sample sizes (Welch, 1947). [Besides](#), the daily and seasonal variations in weather conditions and fuel moisture content for the year 2003 and 2016 were also examined and compared to the mean climatic conditions.

#### 3. Results

The climatology of the three [wildfire groups](#) exhibited [distinct patterns](#) (Figure 5). Wildfires belonging to OLW were associated with significantly higher daily wind speed (Welch’s two sample t-test,  $p < 0.001$ ), lower relative humidity ( $p < 0.001$ ) as well as both higher DC ( $p < 0.001$ ) and DMC ( $p < 0.001$ ) than the mean summer daily conditions for both areas (Figure 5a, 5f and 5e). This is in accordance with the dominant wind-driven fire FWT observed in Mediterranean France (Ruffault *et al.*, 2016, 2017). By contrast, we did not observe a significant difference between the temperatures associated to OLW and the mean summer daily conditions ( $p > 0.1$ , Figure 5a).

The climatology of EW2003 considerably differed from that of OLW. On average, EW2003 was characterized by warmer ( $p < 0.001$ , Figure 6) and drier (DC and DMC,  $p < 0.01$ , Figure 6) conditions than those of OLW (Figure 5a, 5e and 5f). Conversely, wind speeds associated to EW2003 were, on average, not different from the summer daily mean ( $p > 0.1$ ) but significantly lower than that of OLW (Figure 6).

The climatology of EW2016 was very similar to that of OLW. Indeed, as OLW, EW2016 climatology was also characterized by lower relative humidity ( $p < 0.001$ ), higher wind speed ( $p < 0.001$ ), DMC ( $p < 0.001$ ) and DC ( $p < 0.001$ ) than the mean summer climatology (Figure 5d, 5e, 5f and Figure 6). However, EW2016 was associated with significantly higher values of DC than OLW and also than EW2003 (Figure 5c, Figure 6). Besides, it is worth noting here that the “Calanque” fire (‘Cal.’ on Figure 5d) exhibited both windy and quite hot conditions (Figure 5c). This association is relatively unusual in Mediterranean France, where strong synoptic winds, [usually](#) blowing from the north, are generally associated with lower temperatures than usual (Figure 5c, see also Ruffault *et al.*, 2017).

**Supprimé:** LFMC is given on dry mass basis of vegetation tissue:  
$$LFMC = \frac{W_f - W_d}{W_d} \times 100 \quad (1)$$
where  $W_f$  and  $W_d$  are the fresh and dry weights the sampled fuel material, respectively.

Weather conditions and live fuel moisture content exhibited strong anomalies in the month before and during the summer of 2003 and 2016 (Figure 7). These anomalies are in line with the exceptional weather conditions associated to EW2003 and EW2016 that were described above (see Figure 5).

During the year 2016, DC was higher than usual in the western area (Figure 7a) because drought onset conditions occurred earlier this year and precipitations during spring and winter were anomalously dry (Figure 7g). The DC values observed during the summer 2016 were also the highest ever recorded over the period examined (not shown). Accordingly, the fuel moisture content of living vegetation was very low during that year, for both seeders and resprouters type of shrubs (Figure 8a and 8c). By contrast, DMC and daily temperature were both close to the mean summer conditions (Figure 7c and 7e). It is worth noting that these Exceptional DC values were not observed in the eastern area (Figure 7d), which indicates the local nature of this climatic event.

During the summer of the year 2003, temperatures were particularly warm from about July 15 to August 15 (Figure 7e and 7f). Accordingly, DMC was also very high during this period and until the first half of September, especially in the eastern area (Figure 7d). In addition, due to precipitation deficits during spring and summer (Figure 7g and 7h), DC was also above the average conditions (Figure 7c and 7d) but did not reach the levels observed in the Western area during the summer 2016.

Interestingly, LFMC was generally lower than normal for both seeders and resprouters during the summer of 2003 (Figure 8a-d) but remained also higher than the levels reached in 2016 over the Western area.

#### 4 Discussion

Over the next century, climate projections for the Mediterranean basin converge towards an increased severity of droughts and heatwaves, along with an elevated frequency of co-occurrence of these events (Sousa et al. 2011, 2015; Bador et al., 2017).

While it is generally accepted that this warmer and drier climate will alter the frequency, intensity or severity of extreme wildfires (EW), major uncertainties remain about how it will translate into wildfire behavior and fire weather. In this paper, we analyzed the weather conditions associated with the EWs that occurred during the 2003 and 2016 exceptional summer droughts in the northern Mediterranean. On the basis of this analysis, we introduce a novel conceptual scheme summarizing the response of EW to climate-change droughts, which combines the fire weather type (FWT) framework adapted from Ruffault et al. (2016) and the drought classification from Hoover et al. (2016), which is depicted in Figure 9. According to this framework, we propose that the exceptional drought of 2003 and 2016 induced two major shifts in the meteorological “fire niche”, that are expressed through some modifications of FWTs.

The first shift within the meteorological fire niche is expressed through the modification of the wind-driven FWT by press droughts, as illustrated by the 2016 fire season (Figure 9). Drought was longer and more intense than usual in 2016, due to an earlier accumulation of water deficits (since previous winter, Figure 7a and 7g). Thus, although the 2016 EWs were clearly associated with the wind-driven FWT (the dominant pattern in Mediterranean France; Ruffault et al., 2016, 2017), they were equally characterized by significantly drier-than-usual conditions. Taken together, the weather conditions associated to the

Supprimé: ‘

Supprimé: ’

2016 EWs appear to represent a new configuration within the fire weather space (Figure 5d), in which the probability of EW occurrence might be increased. Indeed, such long and intense drought periods can lead to the substantial level of desiccation in the living vegetation compartments, as evidenced by the significantly lower LFMCI during this year (Figure 5a). This could lead to an increase in fire intensity, rate of spread and thereby reduce suppression opportunities.

5 The second shift within the meteorological fire niche is expressed through the modification of the heat-induced FWT by hot droughts (Figure 9), as illustrated by the 2003 fire season. Our results showed that a long-term water deficit (press drought, Figures 7b) and a heat wave (pulse drought, Figure 7f) occurred simultaneously during the summer of 2003. Several studies documented the exceptional nature of this climatic event that occurred over central and southern Europe (e.g. Trigo et al., 2005; Ciais et al., 2005). Consistent with these observations, the 2003 EWs in Mediterranean France were associated with very

10 hot and dry conditions but low wind speeds, which are typical of heat-induced FWT. However, the magnitude in temperature anomaly and short-term drought anomaly (illustrated here by DMC) observed in 2003 had never been observed before in the fire-weather space (Figure 5b). Mechanisms underlying this heat-induced FWT are still unclear but could be linked to the fast desiccation of plant during hot droughts (Williams et al., 2012; Allen et al., 2015), which can increase fire intensity and overwhelm fire suppression policies.

15 Alongside these shifts within the meteorological fire niche induced by increasing droughts, consideration should also be given to the possibility of climate change causing the emergence of new FWTs. In particular, some modifications in the interaction between large-scale atmospheric processes and regional-scale physiographic features can lead to the alteration of the relationships between the major instantaneous weather parameters for fire spread: temperature, humidity and wind. For instance, the association of hot, windy and dry conditions is relatively unusual in Mediterranean France because strong synoptic

20 winds, blowing from the north, are generally associated with lower temperatures than usual (Ruffault et al., 2017) (see also Figure 2c). So far, this constraint avoided the occurrence of “mixed FWT fires”, combining strong winds and hot temperatures, and that are considered as one of the most critical FWT in southern latitude countries (Pereira et al., 2005; Koutsias et al., 2012; Fernandes et al., 2016). But the weather conditions associated to the “Calanques” fire in the northern Mediterranean (Figure 5c) suggest that this type of fire should be considered as an option in the near future. In this context, the large wildfires

25 that occurred in 2017 in the Eastern area should also be considered but additional analysis might help to provide further evidence for the emergence of new FWTs.

Our study suggests that ‘hot droughts’ and ‘press droughts’, both anticipated to occur more frequently throughout the XXI century according to the vast majority of models, can lead to a higher frequency of extremes wildfires and to fire weather conditions that have not been explored before. Our results underline that the dryness of fuel is pivotal in the occurrence of

30 EW and therefore urges modelers to improve our estimations of fuel moisture dynamics (see for instance Nolan et al., 2016) and mortality events. Whether some possible changes in fire management could compensate for increasing droughts and its impact on wildfire behavior remains an open and important question.

However, such the intensity magnitude in temperatures anomaly and short-term drought anomaly (illustrated here by DMC) observed in 2003, that have never been observed before in the fire-weather space (Figure 5b). Mechanisms underpinning this heat-induced FWT is still unclear but could be linked to the fast desiccation of plant during heat waves. Such hot droughts have been identified as a trigger for to the fast desiccation of living shrubs and trees leading to massive forest dieback (Williams et al., 2012; Allen et al., 2015), which can increase fire intensity and overwhelm fire suppression policies.
