Abstract. Oman is located in an area of high seismicity, facing the Makran Subduction Zone, which is the major source of earthquakes in the eastern border of the Arabian plate. These earthquakes, as evidenced by several past events, may trigger a tsunami event. The aim of this work is to minimize the consequences that tsunami events may cause in coastal communities by integrating tsunami risk assessment and risk reduction measures as part of the risk-management preparedness strategy. An integrated risk assessment approach and the analysis of site-specific conditions permitted to propose target-oriented risk reduction measures. The process included a participatory approach, involving a panel of local stakeholders and international experts. One of the main concerns of this work was to obtain a useful outcome for the actual improvement of tsunami risk management in Oman. This goal was achieved through the development of comprehensive and functional management tools such as the Tsunami Hazard, Vulnerability and Risk Atlas and the Risk Reduction Measures Handbook, which will help to design and plan a roadmap towards risk reduction.

The integrated tsunami risk assessment performed showed that the northern area of Oman would be the most affected, considering both the hazard and vulnerability components. This area also concentrates nearly 50% of the hot spots identified throughout the country, 70% of them are located in areas with a very-high risk class, in which risk reduction measures were selected and prioritized.

1 Introduction

Tsunamis are low-frequency natural events but have a great destructive power when striking coasts around the world, involving loss of life and extensive damage to infrastructures and coastal communities worldwide. Between 1996 and 2015, estimated tsunami disaster losses reached 250,000 lives, more than 3,500,000 affected people and more than 220,000 million of USD (International Disaster Database, EM-DAT; UNISDR/CRED, 2016).

Oman is located in an area of high seismicity, facing the Makran Subduction Zone (MSZ), which is the major source of earthquakes in the eastern border of the Arabian plate (Al-Shaqsi, 2012). These earthquakes may trigger a tsunami event, as evidenced at least three times in the past (Heidarzadeh et al., 2008a,; Jordan, 2008). The high potential for tsunami generation of MSZ makes it one of the most tsunamigenic areas of the Indian Ocean. The most recent tsunami event of seismic origin was the 1945 Makran tsunami, which caused more than 4,000 fatalities and property losses in Iran, Pakistan, Oman and the United Arab Emirates (Heck, 1947; Heidarzadeh et al., 2008, 2009, 2011, 2014a, 2014b; Mokhtari, 2011, Latcharote et al., 2017). Similar episodes may occur again in this area.

In addition to the tsunami threat on the coast of Oman, the rapid development and industrialization of this area explains the need to develop specific studies on tsunami vulnerability and risk, especially in the northern low-lying coastal plain, which is the most densely populated and most exposed to the MSZ.

Suitable tsunami vulnerability and risk assessments are essential for the identification of the exposed areas and the most vulnerable communities and elements. They allow identifying appropriate site-specific risk management strategies and

40 measures, thus enabling to mainstream disaster risk reduction (DRR) into development policies, plans and programs at all

41 levels including prevention, mitigation, preparedness, and vulnerability reduction, considering its root causes.

42 Most methods for risk assessment are quantitative or semi quantitative (usually indicator-based). Quantitative risk assessments

43 are generally better related to the analysis of specific impacts, which require large scales and high resolution for all the

44 components contributing the risk. Results are usually expressed in terms of potential losses both economic (derived from

45 building damage or even infrastructure damage) and human (derived from mortality estimations). There are several works

46 following this approach, among others Tinti et al. (2011) and Valencia et al. (2011) within the frame of the European project

47 SCHEMA[1], Leone et al. (2011), Suppasri (2011), Mas et al. (2012), Suppasri et al. (2013), Sohi and Nakamura (2017), and

48 Suppasri et al. (2018), with a main focus on infrastructure and building damage. Sato et al. (2003), Sugimoto et al. (2003),

49 Koshimura et al. (2006), Jonkman et al. (2008) and Løvholt et al., 2014 focused on human damage and casualties whereas

50 Berryman et al. (2005) and Harbitz et al. (2016) dealt with both aspects.

51 Although not as common, quantitative risk assessments are sometimes applied at global scale such as the case of the GRM -

52 Global Risk Model (last version in GAR, 2017), which addresses a probabilistic risk model at a world scale to assess economic

53 losses based on buildings damage (Cardona et al., 2015).

54 However, when the scope requires a holistic and integrated approach in which several dimensions, criteria and variables with

55 different magnitudes and ranges of values have to be taken into consideration, such as the case of the present work, it is

56 necessary to apply an indicator-based method. Some works following this approach may be found in ESPON (2006), Dall'Osso

57 et al. (2009a, 2009b), Taubenböck et al. (2008), Jelínek (2009, 2012), Birkmann et al. (2010, 2013), Strunz et al. (2011),

58 Aguirre-Ayerbe (2011), Wegscheider, et al. (2011), González-Riancho et al. (2014), the European TRANSFER[2] project, the

59 Coasts at Risk report (2014), the World Risk Report (last version: Garschagen et al., 2016) and the INFORM Global Risk

60 Index (INFORM, 2017).

61 Nevertheless, very few of the previous works tackle with the direct link between integrated tsunami risk results and risk

62 reduction measures (RRM). González-Riancho et al., (2014) propose a translation of risk results into disaster risk management

63 options and Suppasri et al. (2017) describe some recommendations based on the lessons learned in recent tsunamis.

64 Therefore, it has been identified that there is not a clear applicability of science-based tsunami hazard and vulnerability tools

65 to improve actual DRR efforts, highlighting a general disconnection between technical and scientific studies and risk

66 management.

67 This work attempts to be complementary to preceding efforts and to fill the gap found in previous studies. The developed

68 methodology is based on the direct relationship found between risk components (hazard, exposure and vulnerability) and

69 specific DRR measures and integrates tsunami risk assessment and site-specific characteristics to select a suitable set of

70 tsunami countermeasures. The ultimate goal is the application of the method and the generation of useful management tools

71 to minimize the consequences that a potential tsunami could have on the coast of Oman.

72 **2 Methodology**

73 The methodology comprises two main phases: (i) the integrated tsunami risk assessment and (ii) the identification, selection

74 and prioritization of appropriate DRR measures. These two different but complementary tasks will guide the entire

75 methodology applied in this work.

[1] SCHEMA Project: Scenarios for Hazard-induced Emergencies Management. European 6th Framework Programme Project no. 030963, August 2007 - October 2010.

[2] TRANSFER project: Tsunami Risk and Strategies for the European Region. European 6th Framework Programme no. 37058, October 2006-September 2009.

76 As regards the conceptual framework, the methodology applied is fundamentally adapted from the definitions of UNISDR

77 (2004, 2009), ISO/IEC Guide 73 (2009), UNESCO (2009b) and UN (2016). Accordingly, the sequence of the work is

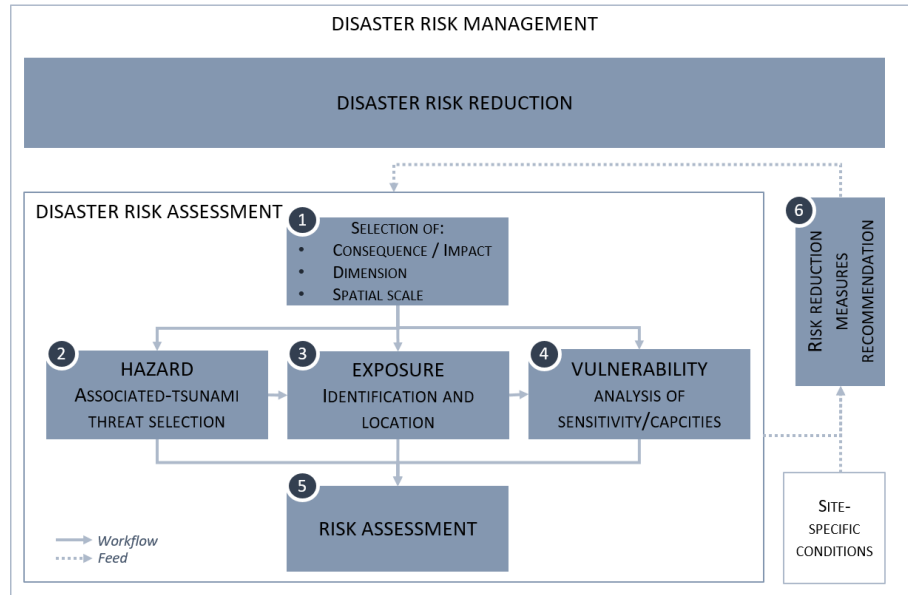
78 summarized schematically in Figure 1. Within the disaster risk assessment phase and prior to any risk study, it is necessary to

79 define the consequence to be analysed and the type of result pursued (for example, the estimation of buildings damages or the

80 community's affection from a holistic perspective, as the case presented in this article). The establishment of this main goal

81 determines the specific method, the dimensions to include in the study and the spatial and temporal scales (point 1 of Figure

82 1).

83


85 **Figure 1. Schematic workflow**

86 Next, the assessment of the hazard, explained in detail in section 2.1 Hazard Assessment, requires the selection of the variable

87 associated to the event (e.g. flow depth) mainly determined by the general goal defined in the first step. The hazard evaluation

88 drives to the analysis of the individuals and elements exposed (e.g. people, buildings and infrastructures located in a flooded

89 populated area) together with its vulnerability (e.g. sensitive age groups). The risk assessment is performed by the combination

90 of the vulnerability assessment -of what is exposed- and the hazard intensity (points 3, 4 and 5 of Figure 1, explained in detail

91 in sections 2.2 Vulnerability assessment and 2.3 Risk Assessment). Both, exposure, vulnerability and the integration of all risk

92 components, circumscribed to a given spatial, cultural and socioeconomic context, are necessary for the preliminary selection

93 of risk reduction strategies and measures. These countermeasures are essential to prevent new and reduce existing risk, as

94 stated by UN (2016), contributing to the strengthening of resilience and reduction of disaster losses (point 6 in Figure 1.

95 Schematic workflow, detailed in section 2.4 Risk reduction measures).

96 The determination of the efficiency of each proposed countermeasure is essential for the success of the risk reduction planning.

97 When an appropriate countermeasure is selected, the overall risk assessment must be conducted again to understand how and

98 to what extent it will actually reduce the risk.

99 DRR measures are framed in the disaster risk management cycle proposed below, which brings together four main strategies

100 for risk reduction (Figure 2): (i) prevention and (ii) preparedness strategies in the pre-event stage and (iii) emergency/response

101 and (iv) recovery in the post-event phase. Each of the strategies includes several actions that may be overlapped on time and

102 that may even belong to more than one strategy. At the centre of the figure, research is presented as an essential element to

103 improve disaster management enriching the process through the integration of various disciplines and studies. This particular

104 study focuses on the strategies related to the pre-event phase: the prevention and the preparedness, which are explained in

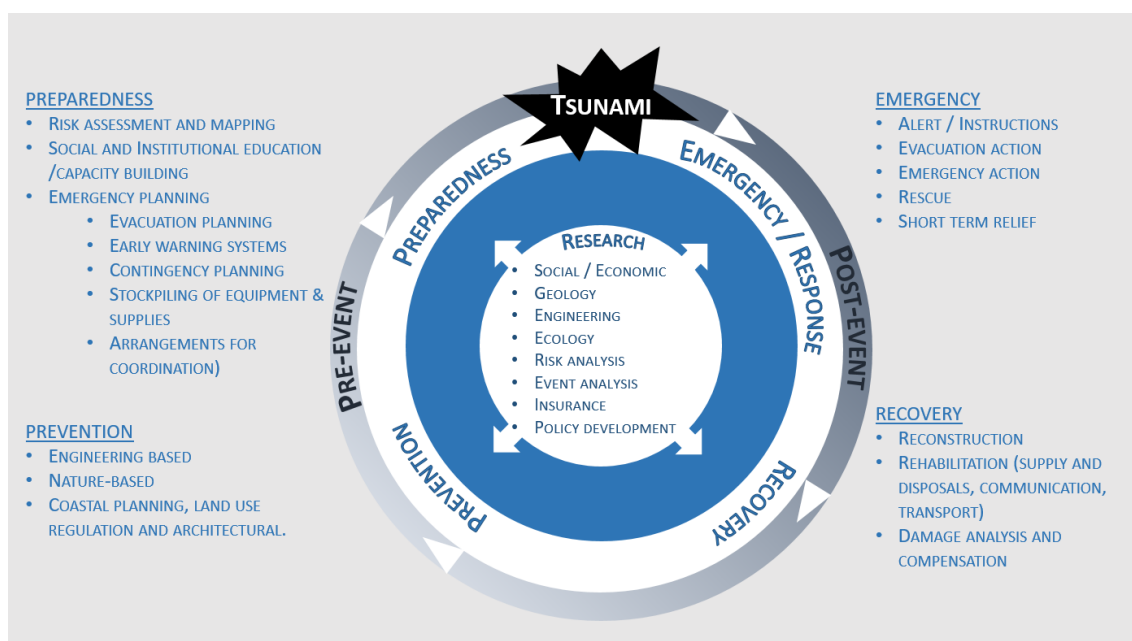
105 section 2.4 Risk reduction measures.


Figure 2. Disaster risk management cycle.

Risk and vulnerability assessments are performed both for a specific place and at a specific time. For this reason, both the analysis and the proposal of measures for risk reduction must be updated periodically, considering the changes that may occur over time and their influence on the results, such as a significant variation in population, land-use changes, new constructions or new lessons learnt.

The involvement of key local stakeholders and decision-makers in coastal risk management is essential throughout the entire process, both to include their knowledge and expertise and to enhance the usefulness of the results of the project throughout their encouragement. Thus, a stakeholder panel composed of local and international experts on coastal risks and risk management supported the entire process, driven to actively participate and collaborate to achieve the goal of DRR. Their main contribution focused on the validation of the methodological approach, the identification of hot spots and the analysis of the technical, institutional and financial capacities of the country for implementing each one of the countermeasures. In the last stage of the study, they prioritized each measure according to their knowledge and expertise.

2.1 Hazard Assessment

The hazard analysis allows determining the areas that would be affected due to the potential tsunamis that may strike the study area. The analysis is carried out considering the worst possible tsunami scenarios based on the seism-tectonic characterization of the area, so that the maximum impact that a tsunami would cause is calculated. Similar approaches may be found in Jelínek et al. (2009, 2012), Álvarez-Gómez et al. (2013) and Wijetunge (2014) among others. The deterministic tsunami hazard analysis allows identifying, locating and analysing the elements at risk in a conservative approach. It is worth considering this method when dealing with intensive risks, i.e. derived from low frequency but high severity hazards, such as tsunamis, where the catastrophic consequences of the impact are complex and difficult to estimate.

In this study, only potential earthquake sources were considered as the tsunami generation mechanism. A seism-tectonic analysis was performed to identify and characterise the major seismic structures with capacity to generate a tsunami affecting the coast of Oman (see Aniel-Quiroga et al., 2015). The study area was divided in three tectonically homogeneous zones including eleven main structures. The geometrical characterization of the fault planes (from the tectonics and the focal mechanisms analysis) allowed identifying 3181 focal mechanisms with a magnitude varying from Mw 6.5 to Mw 9.25.

Once these scenarios are established, the analysis includes the characterization of the quake (fault location, magnitude, length and width of the fault, fault dislocation angles, epicentre location and focal depth of the epicentre) and the sea level. The numerical modelling applied to conduct the simulations is COMCOT (Wang, 2009), which solves shallow water equations

135   using Okada model (Okada, 1985) model to generate the initial deformation of the sea surface. This model uses moving

136   boundary technique for land flooding. Based on the bathymetry, the propagation of each potential tsunami is modelled from

137   the source to the coast. Finally, according to the topography, the coastal area is flooded, with a final resolution (grid size) of

138   45 m onshore.

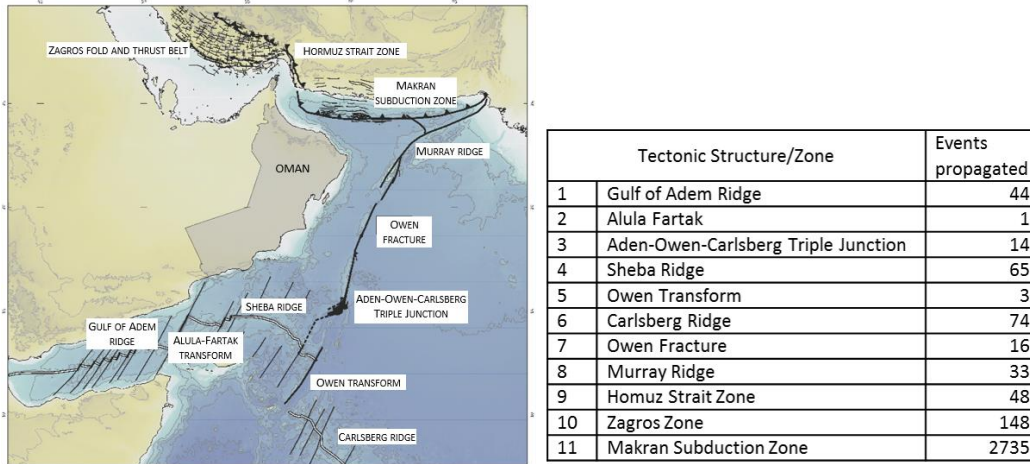
139   The approach is described in detail in Aniel-Quiroga et al. (2015) and is based on the works of Álvarez-Gómez et al. (2014)

140   and Gutiérrez et al. (2014).

141   Figure 3 shows the distribution of the major seismic structures and the number of events propagated for each of them. The

142   seism-tectonic study was particularly focused in the Makran subduction zone, since it is possibly the most active area in the

143   western Indian Ocean and located very near the north coast of Oman.

	Tectonic Structure/Zone	Events propagated
1	Gulf of Adem Ridge	44
2	Alula Fartak	1
3	Aden-Owen-Carlsberg Triple Junction	14
4	Sheba Ridge	65
5	Owen Transform	3
6	Carlsberg Ridge	74
7	Owen Fracture	16
8	Murray Ridge	33
9	Homuz Strait Zone	48
10	Zagros Zone	148
11	Makran Subduction Zone	2735


144

145   **Figure 3. Main seismic areas surrounding the study area and number of events propagated for each area**

146   On one side, the complete set of the 3181 scenarios were included in a tsunami-scenarios database, which is the basis of the

147   current early warning system in the country. On the other, seven scenarios were selected to perform the deterministic hazard

148   assessment, including the historical event of 1945, which took place in the Makran subduction zone (Heidarzadeh et al., 2008).

149   Hazard variables are calculated at each time step of every single simulation and then the maximum values are selected. These

150   scenarios were aggregated into a map that shows at each point of the study area the worst possible situation. This enveloping

151   map is the base for the risk assessment and includes the variables of flow depth (vertical distance between the water surface

152   and the ground, also called inundation depth by some authors, e.g., Aniel-Quiroga et al., 2015), water velocity, and a proxy

153   for the drag force, the depth-velocity product (drag level).

154   Hazard variables were finally classified into five levels of intensity to be subsequently combined with vulnerability, as

155   described in section 2.3 Risk Assessment Risk Assessment. Tsunami drag level classification is based on previous works

156   carried out by Xia et al. (2014), Jonkman et al. (2008), Karvonen et al. (2000), Abt et al. (1989), which establish different

157   thresholds related to the people stability. As for the flow depth variable, the classification is based on the work developed in

158   the SCHEMA project (Tinti et al., 2011) to establish building damage levels, based on empirical damage functions considering

159   building materials and water depth.

160   **2.2 Vulnerability assessment**

161   The method applied to assess the vulnerability relies on an indicator-based approach. The process include three main stages:

162   (a) the definition of criteria for selecting the dimensions and variables to be analysed for the exposed elements, (b)

163   establishment, calculation and classification of indicators and (c) the construction of vulnerability indexes and its classification.

164   These steps are explained in the following paragraphs.

165   Two different dimensions are selected: human and infrastructures, with the aim of developing an analysis with a human-centred

166   perspective. On one side, the human dimension allows analysing the intrinsic characteristics of the population. On the other,

167   the infrastructure dimension allows the analysis of buildings and critical facilities, to consider their potential worsening

168   implications for the populations, following the rational described in González-Riancho et al. (2014). In this sense, it is

169   considered that an increase in the number of victims is likely to occur due to the loss or damage of emergency services, or the

170   recovery capacity may decrease due to the loss of strategic socioeconomic infrastructures such as ports.

171   The criteria to analyse the human dimension are the population capacities related to their mobility and evacuation speed, and

172   the ability to understand a warning message and an alert situation. The criteria determined to analyse the infrastructure

173   dimension are the critical buildings housing a large number of people (schools, hospitals, etc.), the emergency facilities and

174   infrastructures, the supply of basic needs, the building and infrastructures that could generate negative cascading effects, and

175   the economic consequences.

176   Consequently, a set of 11 indicators has been defined (see Table 1) to develop a framework that allows to encompass the major

177   issues related to the community's vulnerability This framework was developed in agreement with local stakeholders and

178   international experts through the participatory process.

179

Index		Indicator	Variable
Human Vulnerability Index	Human Exposure	H1 - Population	Number of persons exposed
	Human Sensitivity	H2 - Sensitive age groups	Number of persons <10 and > 65years
		H3 - Disability	Number of disabled persons (physical / intellectual)
		H4 - Illiteracy	Number of illiterate persons
		H5 - Expatriates	Number of expatriates
Infrastructure Vulnerability Index	Infrastructures Exposure	I1 - Buildings and infrastructures	Number of exposed buildings and infrastructures
	Infrastructures Sensitivity	I2 - Critical buildings	Number of critical buildings (health, educational, religious, cultural, governmental)
		I3 - Emergency	Number of emergency infrastructures (civil defence, police, firemen, military, royal guard)
		I4 - Supply	Number of water supply (desalination plants) and energy supply (power plants) infrastructures
		I5 - Dangerous	Number of dangerous/hazardous infrastructures
		I6 - Strategic	Number of strategic infrastructures (ports and airports)

180   **Table 1. Exposure and sensitivity indicators built for the tsunami vulnerability assessment in Oman.**

181   Indicators H1 and I1 identify and locate the number and type of exposed population and infrastructures respectively, i.e. the

182   number of people and buildings and infrastructures located in the flooded area. The human indicators H2-H5 are oriented to

183   measure weaknesses in terms of evacuation and reaction capacities of the exposed population. Specifically, H2 and H3 are

184   related to problems with mobility and evacuation velocity whereas H2, H3, H4 and H5 are related to difficulties in

185   understanding a warning message and an alert situation.

186   The infrastructure indicators I2-I6 measure the number of critical facilities and buildings that would be affected by

187   administrative area, bearing in mind the implications for the population. I2 provides the number of buildings that would require

188   a coordinated and previously planned evacuation due to the high number of people in them (in some cases sensitive population),

189   such as hospitals, schools, geriatrics, malls, stadiums, mosques, churches, etc. I3 calculates the loss of emergency services that

190   are essential during the event. I4 reports on the potential number of power plants and desalination plants affected, hindering

191   the long-term supply of electricity and water to local communities. I5 analyses the generation of cascading impacts that could

192   take place due to affected hazardous/dangerous industries. Finally, I6 considers the loss of strategic ports and/or airport

193   infrastructures, essential for the economy of the country and the local livelihoods (fishing ports).

194   The construction of vulnerability indexes is performed through the weighted aggregation of the previously normalized

195   indicators via the min-max method (OECD, 2008). Aggregated indexes are then classified considering the data distribution

196 via the natural breaks method (Jenks, 1967) and grouped in five classes, obtaining homogeneous vulnerability areas that are

197 expected to need similar DRR measures.

198 Indicators and indexes have been applied to every wilayat along the coast of Oman (wilayat is an administrative division in

199 Oman). Comparable results are obtained among all areas due to the methods of normalization and classification, which take

200 into account the values of the index for all areas when establishing classes' thresholds. This method depends on the distribution

201 of the data, therefore the study of any index evolution over time, for comparable purposes, must maintain the thresholds

202 established in the initial analysis. In the same way, if new study areas were added, they should be included and new thresholds

203 should be established.

204 **2.3 Risk Assessment**

205 Risk results are obtained by combining hazard and vulnerability components through a risk matrix (Greiving et al., 2006;

206 Jelínek et al., 2009; Aguirre-Ayerbe, 2011; González-Riancho et al., 2014; Schmidt-Thomé, 2006; ESPON, 2006; IH

207 Cantabria-MARN, 2010 and 2012 projects). Classes derived from the hazard assessment are blended with vulnerability classes

208 by means of a risk matrix, as shown in Figure 4, to obtain two types of results, partial risks for each dimension and a combined

209 risk result from the weighted aggregation of both dimensions. The results are finally classified into five risk classes.
211 **Figure 4. Risk matrix combining hazard and vulnerability classes.**

212 The hazard variable differs according to each dimension of the study to analyse specifically the potential impacts. The

213 combination of water depth and velocity, as a proxy for the drag force, which is related to the loss of people's stability (Jonkman

214 et al., 2008), is applied to the human dimension whereas the flow depth variable is applied to the infrastructure dimension.

215 The results obtained from the risk matrix reveal areas at high risk, which are expected to have serious negative consequences

216 due to the combination of hazard and vulnerability conditions. In-depth analysis of these areas allows to identify the causes of

217 these results and to propose adequate RRM according to each of the components, dimensions and variables considered to

218 perform the risk assessment.

2.4 Risk reduction measures

A method has been developed to identify, recommend and prioritize most-suitable alternatives for tsunami risk reduction based on the risk analysis and site-specific conditions. The very first step has been the development of a RRM catalogue, to finally obtain a set of site-specific and target-oriented countermeasures. This method facilitates the decision-making process by connecting scientific and technical results with risk management.

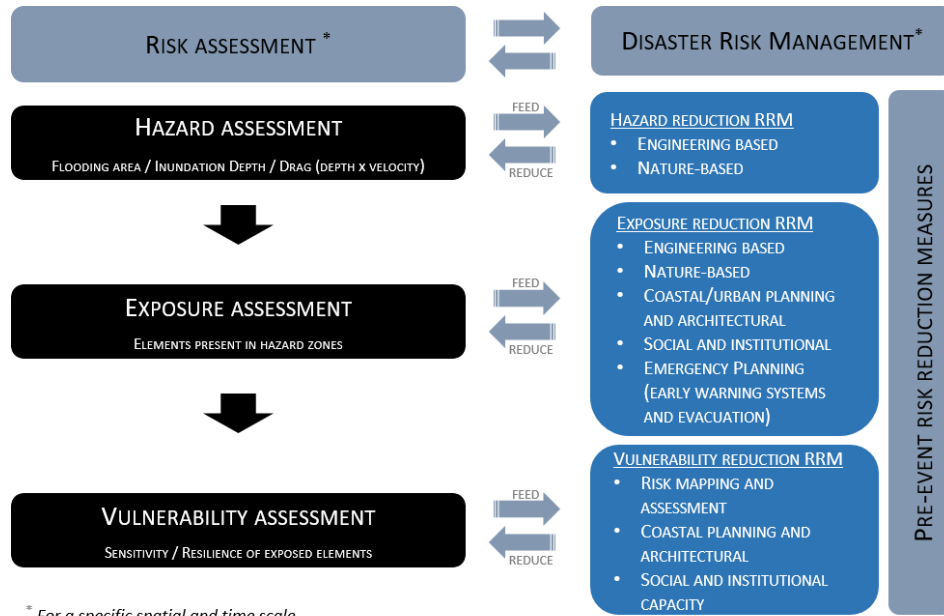
The work focuses on the straightforward feeding/reduction relation among the different risk components (i.e. hazard, exposure and vulnerability) and the risk reduction measures focused on the pre-event stage (see Figure 5).


Figure 5. Interactions between the different components of risk assessment and the pre-event approaches of risk reduction measures

Accordingly, two main strategies are identified to achieve a long-term coastal flooding risk reduction: preparedness and prevention, which are based on the concepts defined by UN (2016) and UNISDR (2009).

Preparedness actions focus on the knowledge, capacities and skills developed to anticipate and respond to the impacts of the event, and include the following: (i) risk assessment and mapping, (ii) social and institutional awareness, educational and capacity building measures, and (iii) emergency measures. The risk assessment and planning is the first step of the risk management cycle, providing essential guidance within the decision-making process. The social and institutional measures enhance the knowledge and capacities developed by communities and individuals to effectively anticipate and respond to the impacts of likely, imminent or current hazard events, as stated by UN (2016). The emergency measures ensure public safety by issuing alerts and planning evacuation of people and certain goods (e.g. vessels) at risk, to safe areas or shelters when a tsunami is detected. There are some other preparedness measures, which are oriented to the post-event phase of the disaster management, such as contingency planning, stockpiling of equipment and supplies and arrangement for coordination.

Prevention refers to actions that aim at shielding or protecting from the hazard through activities taken in advance, by reducing the hazard itself, the exposure to that hazard or the vulnerability of the exposed people or goods. These include (i) engineering-based measures, (ii) nature-based measures, and (iii) coastal planning and architectural measures. The engineering-based measures, i.e., controlled disruption of natural processes by using long term man-made structures (hard engineering solution) help to reduce the intensity of the hazard. The nature-based measures, i.e., the use of ecological principles and practices (soft engineering solution) help to reduce the intensity of the hazard and to enhance coastal areas safety while boosting ecological wealth, improving aesthetics, and saving money. The coastal planning and architectural measures, i.e. regulations and good practices, reduce the exposure and vulnerability mainly related to the infrastructure dimension.

Table 2 shows the set of RRM developed (based on UNFCC, 1999; Nicholls et al., 2007; UNESCO, 2009a, Linham et al., 2010), organised by strategies, approaches and specific goals.

Strategy	Approach	Code	Mitigation measure	Specific Goal
Preparedness	Risk Mapping and Assessment	RA. 1	Hazard, Vulnerability and Risk	V
	Social and institutional capacity	PR. 1	Raising awareness	
		PR. 2	Capacity building	E_t and V

249 **Table 2. Strategies, approaches, measures and specific goals for risk reduction derived from coastal risk due to tsunami hazard (H:**
250 **hazard, E_p: permanent exposure, E_t: temporary exposure, V: vulnerability).**

251 The catalogue has been developed following this concepts and structure. Each measure is analysed and characterised by means
252 of individual RRM-cards that include the specific objective pursued and description of the measure in several sections:
253 rationale, preliminary requirements, supplementary measures, efficiency, durability and initial cost analysis. Each card
254 includes a list of stakeholders involved in the implementation of the specific RRM in Oman, and the estimation of the current
255 capacity for implementation, based on the information provided by the stakeholder panel of experts. Each card also contains a
256 scheme, several figures and a suitability analysis, which is performed through a SWOT analysis. Finally, it is incorporated a
257 specific bibliographic reference list that permits a deeper study of each measure.

258 This RRM catalogue is the basis for the next step, the selection and prioritization of the specific set of countermeasures for
259 each area. It is also worth to mention that a combination of measures from different approaches often offers an effective risk
260 reduction strategy, even enhancing the performance of the individual measures when implemented at the same time.

261

262 The methodology for the selection and prioritization of the RRM has been designed to ensure its adequacy to site-specific
263 conditions at local scale among those proposed in the catalogue. It is summarized in three main steps (see Figure 6): (i)
264 determination of the hotspots, (ii) selection of the recommended RRM through a decision matrix and (iii) the prioritization of
265 RRM.

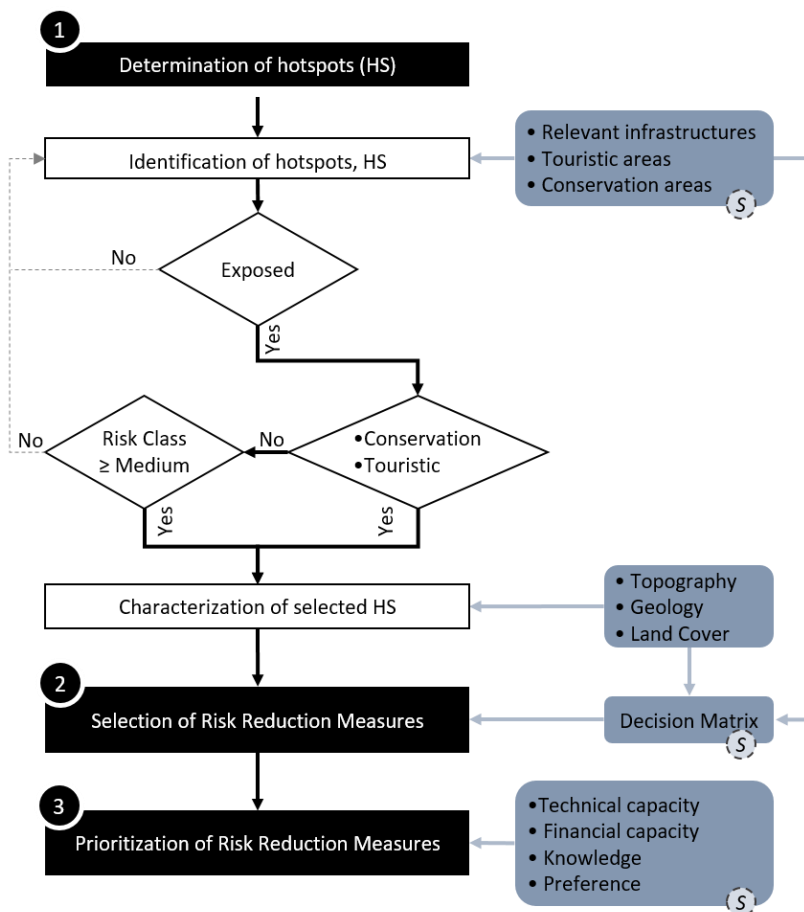
266


Figure 6. Scheme of the methodology for the prioritization of recommended tsunami risk reduction measures (S: participation of stakeholder panel of local and international experts on coastal and risk management).

2.4.1 Determination of hotspots

The first step is the determination of hotspots, which are the zones in which RRM will be further proposed. Coastal hotspots (HS) are identified in consensus with the stakeholder panel, including built-up populated areas and the following areas of special interest: (i) relevant infrastructures such as transport and communications infrastructures (airports and sea-ports), supply infrastructures (power and water) and dangerous infrastructures (refineries, dangerous industries areas and military bases); (ii) touristic regions, where there is significant seasonal variation in the population and (iii) environmental conservation areas, to consider the fragile and complex systems where the coastal ecosystems converge with the marine dynamics and the human activities, which include lagoons, mangroves and turtle nesting areas.

After the identification of the HS, it is evaluated whether they are exposed to tsunami hazard (i.e. located in the flooded area) and if they exceed the risk class threshold as shown in Figure 6, in order to determine the units that will feed the decision matrix into the second phase. Because of their significance, the scarcity of data when performing the vulnerability assessment and the relevance given by local stakeholders, touristic regions and environmental conservation areas will move to the next step if the HS is exposed, regardless the risk level. In all other cases, for those HS under very low, low risk or not expose, no countermeasures will be assigned. The HS characterization is carried out by assigning elevation characteristics (highlighting low-lying areas and wadis), a geology categorization (bare consolidated or non-consolidated substratum) and the land cover (cropland, built-up areas and vegetation-covered areas).

2.4.2 Selection of risk reduction measures

The second stage consists in the preliminary assignment of RRM to each HS according to the decision matrix. The matrix, which was validated by the stakeholder panel, is fed by the specific characteristics of each HS and by type of HS, as described

previously. Table 3 shows the decision matrix, already sorted by the ratings of the stakeholder panel of experts on coastal risk management in Oman, as explained in section 2.4.3.

The assignment of each recommended measure (highly recommended, recommended or not recommended) is based on the information described in each of the RRM-cards and depends on the characteristics that have determined the type HS. On one hand, the topography of the area, with a focus on the low-lying areas and wadis, where coastal and pluvial flooding occurs on a regular basis, at least annually. Likewise, the geology and land cover is analysed to consider the bedrock and type of land use, that condition the suitability of one or another measure. Finally, as shown in the decision matrix, the type of hotspot also conditions the suitability of the RRM preliminarily selection. The sets of RRM obtained according to the decision matrix for each of the determinants are merged, and finally the most restricted recommendation is considered.

RRM Code	Risk Reduction Measure	Topography	Geology		Land cover			Types of HS				Prioritization Stakeholders ranking

Table 3. Decision matrix for the selection of recommended RRM (++: highly recommended; +: recommended; -: not recommended). Last column: prioritization of RRM according to the stakeholder panel ratings on Oman risk management. The matrix is presented ordered by these prioritization results.

300 **2.4.3 Prioritization of risk reduction measures**

301 Finally, in the third phase, the prioritization analysis considers the characteristics of each measure, its technical and economic

302 requirements, efficiency and durability, the SWOT analysis and the capacity of the country to implement them. In addition to

303 technical criteria, there are subjective aspects, including local knowledge and expertise, which should be taken into account

304 when selecting certain recommended RRM as preferred over others. Results of this preferences, shown in figure Figure 7, are

305 also reflected in the sorting of Table 3, based on the last column.
306

307 **Figure 7. Scoring of the RRM according to the stakeholder panel ratings (1: the least preferred; 5: most preferred)**

308 **3 Results**

309 This section presents two types of results. First, sections 3.1 Tsunami risk assessmentand 3.2 Tsunami risk reduction in

310 Omandeal with technical results obtained from the application of the methodology to the Sultanate of Oman. Section 3.1

311 Tsunami risk assessmentdescribe the most relevant results of the tsunami risk assessment and 3.2 one example regarding the

312 risk reduction measures selected and prioritized for a specific site. Finally, section 3.3 Science-based support for the tsunami

313 DRR decision making process describe the management tools developed and its usefulness for the tsunami DRR decision-

314 making process.

315 **3.1 Tsunami risk assessment**

316 The tsunami hazard analysis indicates that the greater flooded area is located in the northern plain and in one section of the

317 eastern face of the country, as shown in figure Figure 8a (country's wilayats are sorted from north to south in this and following

318 graphs). However, the greatest flooded area does not necessarily yield the greatest the impact. In fact, the vulnerability analysis

319 show that the elements at risk are not homogenously distributed along these flooded areas. The greatest values for the exposure

320 are on the northern plain, especially between Shinas and Bawshar Wilayats (see figure Figure 8b and Figure 8c). Saham,

321 Suwayq, Al Musanaah, Barka and As Seeb Wilayats have the highest percentage of exposed population, all above 10%, the

322 latter two more than 15%, whereas there is almost no exposure in the coastline from Sur to Dalkut Wilayats, with most of

323 relative values below 1%. The Wilayat Al Jazir, even if having a low absolute number of exposed population, represents about

324 8% of the total, ranking on the side of the most exposed in relative terms. Regarding the exposure of buildings and

325 infrastructures, the pattern is very similar. The highest rates of exposure take place in the northern area, especially from Sinas

326 to As Seeb Wilayats (with exposure values over 40%), with the exception of Liwa. In the rest of the country, Jaalan Bani Bu

327 Ali and Al Jazir have the highest values, with 45% (about 8,300 items) and 25% (about 750 elements) respectively.

328 The vulnerability assessment reveals the different characteristics of each wilayat in terms of both population and infrastructure,

329 being the highest values correlated to the highest exposure values. In general, the most representative variables of the human

330 vulnerability assessment along the entire coast are the "expatriates" and the "sensitive age groups", both around the 30% of

331 the total population exposed (Figure 8b). The variable that contributes less to the human vulnerability is "disable", but even if

332 not very representative in relative values (about 2% of total exposure), it was maintained in the analysis because of its relevance

333 and importance within the risk assessment.

334 As for the infrastructure dimension (Figure 8c and Figure 8d), the vulnerability analysis highlights that "critical buildings"

335 category are the most affected, being around 96% of all sensitive and exposed buildings. The 70% of the buildings within this

336 class are religious, being the wilayats Saham and As Suwayq the most affected. Despite their lower absolute number, it is

337 necessary to consider the other variables that feed the infrastructure vulnerability analysis due to their significant relevance in

338 case of an emergency (emergency, supply, dangerous and strategic), as described in the risk assessment section. In this sense,

339 Figure 8d shows their distribution along the coastal wilayats, highlighting Sohar, where ten petrochemical industries, three

340 container terminals, two bulk liquid terminals, one general cargo terminal and a sugar refinery could be affected. All of these

341 industries are located within the area and surroundings of the Port of Sohar.

342

343 Integrated vulnerability results are shown in Figure 9a for both human and infrastructure dimensions. According to the

344 vulnerability classification, the colour ramp varies from green to red, being the green the lowest value of the index and red the

345 highest. Note that, for a better understanding, the representation is at the wilayat level, while the vulnerability analysis is

346 performed exclusively for the potentially inundated area due to the tsunami hazard considered. The highest vulnerability scores

347 mainly corresponds with the wilayats located in the northern plain area. Analysing the differences among them, it may be

348 concluded that the most vulnerable wilayats (sorted from north to south) are Sohar, Saham (highest IVI score), As Suwayq,

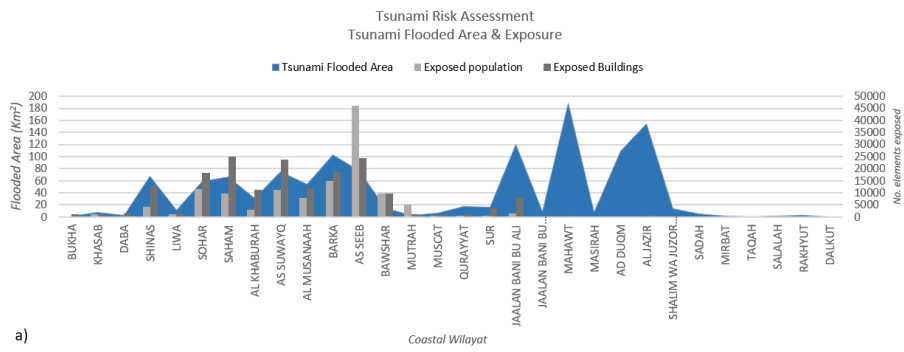
349 Barka, As Seeb (highest HVI score) and Bawshar.


Figure 8. Tsunami Risk assessment: (a) Tsunami flooded area and exposure, (b) Human exposure and vulnerability variables, (c) and (d) Infrastructures exposure and vulnerability variables.

Finally, Figure 9b shows the integrated risk map as a synthesis, indicating the amount of area disaggregated by each risk level and wilayat, which permits to know the amount of population and infrastructures per level. Therefore, it is shown that the northern area of the country would be the most affected by the tsunami scenario modelled in this work, both because of the greater impact of the hazard and the higher degree of exposure and vulnerability.

357
Figure 9. (a) IVI and HVI: Infrastructure and human vulnerability indexes; (b) Integrated tsunami risk assessment

359   Summarizing tsunami risk results, Figure 10a shows the distribution of the exposed population by risk level and wilayat, the
360   greater consequences being on As Seeb and Barka wilayats. Almost 55% of the exposed population is located in very high-
361   risk areas and around 25% in high-risk areas. Regarding the infrastructure dimension, most of the exposed built-up area is
362   located in medium risk zones (about 60%), and around a 25% in high-risk zones. Less than 1% of the built up area result in
363   very high infrastructure risk areas. Built-up area by risk level and wilayat is presented in Figure 10b, showing that Sohar and
364   As Seeb are the most affected wilayats both in terms of built-up area exposure and risk level.
365

366   **Figure 10. People and built up area by risk level**

367   **3.2 Tsunami risk reduction in Oman**

368   The methodology applied for the selection and prioritization of optimal RRM, resulted in the identification of 89 hot spots
369   (HS) along the entire coast of the country, half of them located on the north coast, mainly from Liwa to Sur wilayats. About
370   25% of them are concentrated in the southeast area of the country, especially in wilayats Salalah (12) and Sadah (9). Mashira
371   and Ad Duqm concentrates 10 and 5 HS respectively. According to the method followed, 79 out of the initial 89 were assigned
372   with a set of RRM.

373   Next, an example is included to show the whole procedure, focused on the wilayat As Seeb. This wilayat concentrates the
374   largest amount of population exposed to the highest level of risk and is the second wilayat with the greatest infrastructures risk
375   level. The target area (the HS) is the Muscat International Airport and surroundings where, in addition to the airport itself the
376   building of the Public Authority for Civil Aviation of Oman (PACA) that houses the Multi Hazard Early Warning System and
377   the National Tsunami Warning Centre is located.

378   Figure 11 shows the selected HS, a simple view of the risk assessment results, a summary of the characterization, and the
379   preliminary set of RRM recommended resulting from the decision matrix. The list is shorted (most preferred on top) according
380   to the prioritization made by the stakeholder panel, based on their knowledge and expertise on the feasibility and the
381   institutional, economic and technological capacity of the country for their implementation.

Figure 11. RRM preliminary proposal for Wilayat As Seeb relevant infrastructure area

The first six recommended RRM are related to the preparedness strategy. Based on this result, the implementation of these measures require specific supplementary studies at a greater resolution. These may be: high-resolution data collection for the risk analysis (topo-bathymetry, tsunamigenic sources characterization, and vulnerability), in-depth numerical modelling of the flooding physical process, development of a strategy for education of critical groups (most vulnerable members, leaders, institutions, government, educators, etc.), and the cooperation between the government, relief agencies and local communities to enhance the early warning systems and the evacuation planning process.

Regarding the prevention strategy, the first recommended countermeasure is the construction of breakwaters (EN. 2 in Figure 11). Tsunami breakwaters are usually constructed in the mouth of a bay or estuary, not in open coasts. However, according to the general workflow developed and presented in Figure 1 (point 6) a detached breakwater has been modelled to understand the efficiency of the measure. The model resulted in a local increase in the elevation of the waves in the study area due to the transformation that the breakwater generates in the tsunami waves. The waves overtop the structure generating an acceleration of the flow that penetrates inland, thus increasing the flooded area (see Figure 12 Figure 12b and Figure 12c). Therefore, although more detailed studies would be necessary, this prevention measure should be discarded at this site. The second recommended prevention measure is the "artificial sand dunes and dune restoration". Accordingly, a more detailed study has been done in a subset of the area by means of modelling an artificial sand dune with a crest height of 3 metres, showing an efficient reduction of the flooded area, as shown in Figure 12d.

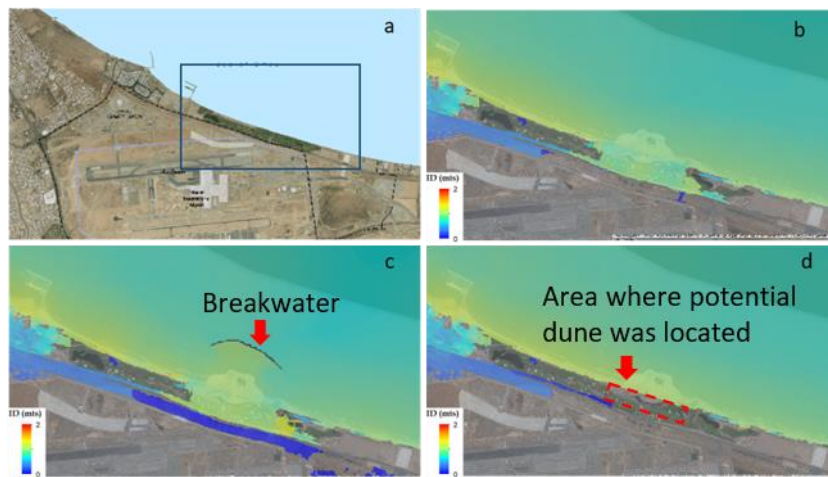
401


Figure 12 . Detailed analysis of preliminary engineering RRM: a) Zoomed sample area; b) Modelled flooded area; c) with the breakwater option; d) with artificial sand dune option.

404 Similar procedures for obtaining a preliminary set of RRM have been developed for all the hotspots and for some local areas.

405 In-depth studies should be made to perform a second stage analysis of the recommended countermeasures, considering higher

406 resolution of the hazard analysis and detailed information provided by the vulnerability variables and indicators.

407 **3.3 Science-based support for the tsunami DRR decision making process**

408 One of the main objectives of the study is to improve tsunami risk management through the effective use of the results

409 obtained. In this sense, science and technical results are translated into two risk management tools: (i) the Tsunami Hazard,

410 Vulnerability and Risk Atlas, and (ii) the Risk Reduction Measures Handbook. These tools have been implemented and

411 activated by the Directorate General of Meteorology of Oman (DGMET). In addition, a knowledge and technology transfer

412 strategy has been carried out to ensure adequate long-term management.

413 The "Tsunami Hazard, Vulnerability and Risk Atlas", contains a comprehensive description of the methodology applied to

414 assess the risk and all maps from the hazard analysis and vulnerability variables and indices to the final risk results. It is

415 expected to be used as the main source for awareness and education regarding tsunamis and as the basis for further local and

416 detailed studies. In this regards, DGMET efforts are focused in distributing and conducting follow-up meetings to all

417 involved stakeholders, including Supreme Council for Planning, Ministry of Education, The Public Authority Of Radio And

418 Television, National Committee for Civil Defence (NCCD), Public Authority for Civil Defence and Ambulance and Royal

419 Oman Police-Operation. Follow up meetings are also included in the general strategy to explain the atlas information and

420 discuss the best approaches to utilize such information for the planning and implementing policies and strategies.

421 The "Tsunami Risk Reduction Measures Handbook" is a useful manual to help in the decision-making process related with

422 the tsunami prevention and preparedness. It includes a brief explanation of the methodology developed to select and

423 recommend each set of measures, the catalogue of RRM, containing individual RRM-cards for each countermeasure and the

424 results obtained for each area along the coast of Oman, including the set of recommended RRM for each specific location.

425 Similar to the hazard, vulnerability and risk atlas, DGMET has forwarded the handbook to the government cabinet to

426 distribute among all stakeholders, especially to the Supreme Council for Planning.

427 Finally, as an additional result of this study, a web based tool to support the tsunami early warning system (called MHRAS)

428 was also developed, implemented and linked to the DGMET Decision Support System.

429 These tools are the necessary starting point for the development of a strategy for education, raising awareness and capacity

430 building of emergency management authorities and society in general.

431

4 Conclusions

Integrated risk assessments are essential for identifying the most vulnerable communities and worst expected consequences, as well as for designing and planning a roadmap towards risk reduction. For this reason, they should be the basis to link scientific and technical advances with appropriate decision-making and effective risk management.

The methodology presented was developed to build an effective connection between tsunami risk assessment and tsunami risk reduction, with the objective of supporting risk managers by facilitating science-based decision-making in the phases of prevention and preparedness, before an event occurs.

The tsunami hazard modelling, based on potential earthquake sources, permitted to perform an analysis to identify the worst possible scenario, considering the low frequency/high severity nature of the hazard. Thus, it permitted to estimate the worst negative consequences as the main outcome of the risk assessment. The potentially most affected areas in Oman, in terms of tsunami-prone flooded areas, are the northern plain of the country especially Barka and As Seeb as well as Mahawt and Al Jazir wilayats on the eastern area.

The semi quantitative indicator-based approach for the vulnerability and risk assessment, which integrates risk components (hazard, exposure and vulnerability) and the human and infrastructure dimensions, has been proved useful to discern the more sensitive areas from a human-centred perspective. The indicators system is helpful for the decision-making process in two ways. First, the information at the index and indicator level allows a broad insight of where the exposed elements are and which are more susceptible to suffering the impact of the hazard, i.e., where to focus the efforts towards risk reduction. Second, the approach permits to easily track back to the variables. This information is essential to understand the precise root causes of vulnerability and risk results, to be tackled by adequate and specific DRR measures. In Oman, the most vulnerable areas are located in the northern plain of Oman, highlighting wilayat As Seeb, both in the human and infrastructure dimension and wilayats Saham and Suwayq in the infrastructure dimension. The eastern part, although affected by the inundation, is not so vulnerable. The combination of hazard and vulnerability assessments reveals that the worst expected consequences are for As Seeb and Barka wilayats in terms of human risk and for Sohar and As Seeb in terms of infrastructure risk, according to the tsunami modelled in this work.

As for the connection between risk assessment results and risk management, for each defined tsunami-risk management area, the methodology allows identifying, selecting and prioritizing a preliminary set of suitable and site-specific RRM. This analysis discards non-suitable measures and allows a more in-depth exploration, defining the basis for analysing the feasibility of its implementation, including its technical and economic viability.

The involvement and support of relevant stakeholders in charge of the risk management process is essential for the success and usefulness of the method. Their encouragement has been one of the priorities throughout the application of the method to achieve the main objective of minimizing the consequences that a potential tsunami could trigger in this area.

Through the example shown for the area of Muscat International Airport, it has been illustrated the usefulness of the methodology, which can be applied in other parts of the world facing other natural events that may trigger a disaster. Local conditions should be always considered in the definition of the vulnerability indicators, in order to integrate site-specific conditions.

In this sense, with the aim of producing a useful outcome for the risk management, all the results obtained and the detailed description of the method were compiled in two handy management tools. These tools permit to analyse and facilitate the decision-making, to replicate and to update the study by the tsunami disaster managers of Oman, thus contributing to the connection between science-based risk results and disaster risk management.

5 Acknowledgements

The authors thank the Ministry of Transport and Communications of the Government of the Sultanate of Oman (MOTC), the Public Authority for Civil Aviation (PACA) and the Directorate General of Meteorology (DGMET), for supporting and funding the project "*Assessment of Coastal Hazards, Vulnerability and Risk for the Coast of Oman*" *during the period 2014-2016*. We also thank and appreciate the collaboration of the International Oceanographic Commission of the United Nations Educational, Scientific and Cultural Organization personnel (IOC-UNESCO).
