Abstract. As a consequence of climate change and land subsidence, coastal zones are directly impacted by sea-level rise. In some particular areas, the effects on the ecosystem and urbanisation are particularly enhanced. We focus on the Emilia-Romagna coastal plain in Northern Italy, bounded by the Po river mouth to the north and by the Apennines to the south. The plain is ∼130 km long and is characterised by wide areas below mean sea level, in part reclaimed wetlands. In this context, several morphodynamic factors make the shore and back-shore unstable. During next decades, the combined effects of land subsidence and of the sea-level rise in consequence of climate change are expected to enhance the shoreline instability, leading to a further retreat. The consequent loss of beaches would impact the economy of the region, tightly connected with tourism infrastructures. Furthermore, the loss of wetlands and dunes would threaten the ecosystem, crucial for the preservation of life and environment. These specific conditions show the importance of a precise definition of the possible local impacts of the ongoing and future climate variations. The aim of this work is the characterisation of vulnerability in different sectors of the coastal plain and the recognition of the areas in which human intervention is urgently required. The IPCC AR5 sea-level scenarios are merged with new high resolution terrain models, current data for local subsidence and predictions of the flooding model `in_CoastFlood` in order to develop different scenarios for the impact of sea-level rise to year 2100. First, the potential land loss due to the combined effect of subsidence and sea-level rise is extrapolated. Second, the increase of floodable areas in consequence of storm surges is quantitatively determined. The results are expected to support the regional mitigation and adaptation strategies designed in response to climate change.

1 Introduction

The sea-level rise associated with global warming is a growing concern for the scientific community, as well as for governments, the media and the public. Climate-driven sea-level rise has a direct impact on the coastal zones, with threatening consequences on the ecosystem and urbanisation. The causes of contemporary sea-level rise have been reviewed by Nicholls and Cazenave (2010), who have also identified, globally, the coastal areas that are particularly vulnerable to flooding. These include low-elevation coastal zones, densely populated areas where the natural or human-induced rate of subsidence is appreciable, and regions characterised by a limited adaptation capacity. In addition, higher mean sea levels are expected to amplify flooding caused by storm surges and hurricanes, with an enhanced impact on population (Nicholls et al., 1999). The last Inter-

governmental Panel on Climate Change (IPCC) Fifth Assessment Report (AR5) has made a considerable progress toward an understanding of the 20th century sea-level rise and its variability on a global scale; furthermore sea-level projections for the 21th century have been greatly improved (Church et al., 2013). Nevertheless, detailed projections of sea-level rise at regional and local scale are still hampered by the complex local response of the coastal system to sea-level rise (Cazenave and Cozannet, 2014; Hinkel et al., 2015).

In the general context outlined above, this work focuses on the possible effects of sea-level rise on the coastal area of Emilia-Romagna (Northern Italy), one of the administrative regions of Italy facing the Northern Adriatic Sea (see Figure 1). The Emilia-Romagna (E-R) coastal plain has a crucial economical and naturalistic value. It is, indeed, the site of one of the largest tourism industries in Europe, the *Riviera Romagnola*, and it embraces the Po Delta protected area, which was recently included in the Man and the Biosphere Programme by Unesco[1]. Characterised by a gentle slope, the E-R coastal plain is high vulnerable in consequence of *i)* widespread coastal erosion, *ii)* seawater intrusions related to sea-level rise, *iii)* storm surges and *iv)* land subsidence. These four major threats have been exacerbated by the human pressure that took place since the 1940s, when a rapid urbanisation and a strong exploitation of underground resources (water and gas) initiated (Lorito et al., 2010; Perini and Calabrese, 2010). The reader is referred to the recent work of Aucelli et al. (2016) for the risk assessment of coastal inundation in another Italian area *i.e.,* the Volturno coastal plain in southern Italy, characterised by spread back-shore depressions and subsidence. On a nationwide scale, a detailed account for sea-level rise and potential drowning of the Italian coastal plains has been given by Antonioli et al. (2017). Finally, a sophisticated approach was taken by Wolff et al. (2016) who downscaled the Dynamic Interactive Vulnerability Assessment (DIVA) model (Hinkel et al., 2014) to the E-R contest. This model considers the effects of mean sea-level rise in terms of impacts on the population and on the existing assets. It also foresees that mitigation actions, as the building of dykes, will gradually accompany the sea-level rise to year 2100.

The awareness by the local authority *i.e.,* the Emilia-Romagna Regional Administration, that a holistic approach was desirable to properly manage the climate-related risks at coastal areas, motivated the set up of an integrated path, called "Gestione Integrata delle Zone Costiere" (GIZC) which led to the approval of specific guidelines[2]. The document recognises the need of putting the mitigation of local risk in the climate change framework, with a special attention to the sea-level rise issue. Subsequently, in 2007, the EU delivered the so-called "Floods Directive[3]" (FD) (European Parliament and Council, 2007) aimed at reducing and managing the risks posed by floods to human health, the environment, cultural heritage and economic activity. The recent Italian Environmental Ministry guidelines on coastal protection from erosion and climate change effects[4], delivered in cooperation with coastal regions in 2016 and in accordance with the FD, also highlight recommendations of the Emilia Romagna GIZC guidelines. The document remarks that long term climate change could not be excluded from the national and regional plans for the mitigation of the seawater flooding risks. These concepts are also included in the nationwide SNAC (National Strategy for the Adaptation to Climate Change)[5]. The development of these national and transnational laws and

guidelines drove the definition, by the Emilia-Romagna Regional Administration, of the "Path toward a strategy for the mitigation of climate changes[6]". This path includes the study of the climate change impact on coastal zones and the identification of the most vulnerable areas by means of models and cartographic analyses.

Within the multidisciplinary pathway above, it is crucial to identify and characterise the most vulnerable portions of the coastal plain, on which prevention and mitigation actions should be focused at first. Local and short term phenomena occurring in the E-R coastal plain and in its neighbourhoods have been put in a long term framework, which also includes regional and global climate change. The attention on the combined effects of climate-induced sea-level rise, of subsidence and coastal storm events along E-R shoreline arouse two decades ago, following the 1992 IPCC Supplementary Report (Intergovernmental Panel on Climate Change, 1992). Bondesan et al. (1995) preliminarily investigated the impact of these IPCC scenarios for sea-level rise to year 2100, in combination with expected subsidence and trends for storm surges. They concluded that the area potentially affected by the risk of flooding was doomed to increase in the future. Along these lines, in the work of Gonella et al. (1998) a numerical model based upon geographical information system (GIS) tools was applied for the first time to the 1992 IPCC scenarios, considering storm surge return periods of 1, 10, and 100 years. Their analysis was also extended to the risk assessment in terms of saltwater ingression and soil consumption. Recently, Antonioli et al. (2017) have used IPCC AR5 global projections at 2100 for sea-level rise with local assessment for subsidence derived from GPS and TG data. These have provided regional scenarios for different parts of the low elevation portion of the Italian peninsula, including the E-R coastal plain.

The main purpose of this work is the determination of the future impact of land subsidence and sea-level rise on the E-R coast. In particular, for the first time in this region, the focus will be on two aspects: *i)* the loss of territories that are currently at, or above, mean sea level (case study #1, CS1) and *ii)* the enlargement of the areas potentially affected by seawater flooding (case study #2, CS2). Our objective is twofold: *i)* the identification of those portions of the E-R coast which potentially could be flooded by the end of current century in the occasion of storm surges, and *ii)* the comparison of the results with the current hazard map for the ingression of the sea that resulted from the FD. In the following, CS1 and CS2 will be discussed taking the geomorphological and geodynamic complexity of the area into account, and adopting the mean sea level projections published in the IPCC AR5 (Church et al., 2013).

The paper is organised as follows. Section 2 describes the physical characteristic of the study region and the driving processes. The data and methods employed are presented in Section 3. The results, presented in Section 4, are discussed in Section 5. Our conclusions are drawn in Section 6.

2 Physical characteristics and driving processes

The E-R coastal plain develops along the south-eastern margin of Po Valley in Northern Italy; it is bounded to the north by the Po di Goro branch of the Po Delta and to the south by the Apennine Chain. The orientation of the chain and the direction of progradation of the Po River make the plain narrow to the south (a few kilometres in the EW direction), and broad to the north

[6]Deliberation n. 2200/2015, *Percorso verso una strategia di mitigazione dei cambiamenti climatici.*

where it exceeds 40 km (see Figure 2, left frame). The shoreline is about 130 km long and is characterised by low-elevation sandy beach ridges, occasionally associated with lagoons, wetlands and river mouths.

The coastal area and its shoreline can be divided into a northern (N) and a southern (S) sector, whose boundary can be placed around the town of Cervia (see Figure 1). The different physical characteristics of the two sectors, which are of relevance for the determination of the response of the coastal area to the marine ingressions, are detailed in Perini and Calabrese (2010). The vulnerability of the entire coastal area is mainly caused by the absence of dunes and by their discontinuity, especially in the S sector. A further cause of vulnerability is the presence, particularly in the N sector, of wide areas that are currently below mean sea level. Moreover, the combination of subsidence with the natural retreat of the shoreline due to the reduction of the river sediment discharge is responsible for a widespread coastal erosion, both on short and long term time scales (Perini and Calabrese, 2010).

The human pressure and the underground exploitation of the E-R coastal plain and of its surroundings have enhanced the expected effects of climate change, and particularly of coastal storms. The risk for sea flood has been magnified by the urbanisation that, since the end of the second World War, was increased by ∼400% in terms of occupied area (Lorito et al., 2010). In front of most coastal towns and resorts the dunes, which are the natural rampart against the sea flood and a natural reservoir of sand for the nourishment of the beaches, have been totally destroyed by urbanisation. In some cases the shorelines retreat have reached the buildings and infrastructures. This urbanisation, besides, is mostly concentrated along a narrow area along E-R coastal plain, bordering on the zone where normally most of the energy is dissipated during intense coastal storms.

The Emilia-Romagna shoreline is highly artificialized and shows different types of coastal flood defences. These are mainly composed by emerging or submerged longitudinal breakwaters and localised jetties, groynes and seawalls, especially in the Goro lagoon. In the N sector, following the extreme flooding event that occurred in 1966 (Perini et al., 2011), a long, 4 m high embankment was erected to protect the back-shore, at a distance ranging between 0.5 and 1.5 km from the shoreline. However, during the 1970s and 1980s, the vulnerability of the area between the shoreline and the wall was not considered a concern and an intensive urbanisation took place there. In the S sector, on the other hand, no coastal defences has been erected against marine inundations, while the sparse flood protection dykes are only aimed to defend local infrastructures from coastal storms. Against the coastal storms, it is common practice off-season (*i.e.,* during the winter) to build temporary embankments along the beaches. These, if properly designed, play a crucial role in the attenuation and mitigation of the effect of coastal storms, in reducing the ingression of sea water in the back-shore and in preventing erosion.

For each of the two sectors considered (N and S), the physical features of the E-R coastal plain are summarised in Ta- ble 1. These include the main geometrical features (the coastal plain width D and its elevation above mean sea level H), geomorphological characteristics, shapes and tendency, shoreline width D_S and average width $\bar{D}_S$, and shoreline backside usage. Furthermore, in the following of this Section, we provide an account of the processes that are responsible for the coastal vulnerability of the area. These are: *i)* land subsidence, *ii)* sea-level variability, and *iii)* storm surges.

2.1 Land subsidence

For those areas slightly above mean sea level, the main consequence of subsidence is an increased vulnerability to the effects of storm surges, since the progressive lowering of the ground below mean sea level will facilitate the marine ingression. Current average rates of land subsidence observed in the S sector of the E-R coastal plain, as well as in the southernmost part of the N sector, are close to 5 mm yr^{-1}. However, in some areas of the S sector and particularly at the mouths of rivers and in the back-shore of the Cesenatico and Rimini areas, they may exceed ~ 10 mm yr^{-1}. In the N sector, rates of subsidence are smaller, typically in the range of 0 to 2.5 mm yr^{-1}, while in the area of the Po Delta rates of ~ 10 mm yr^{-1} are again observed (Arpa-RER, 2012) (see Figure 2, right frame). Locally, land subsidence reaches 20 mm yr^{-1} due to gas extraction. This occurs, in particular, at the Fiumi Uniti river mouth. These significant present-day rates can result in a total subsidence of 2-3 meters in a century (Bondesan et al., 1995), as a consequence of the combined action of natural and anthropogenic factors.

The natural component of land subsidence is normally the result of tectonic activity, Glacial Isostatic Adjustment (GIA) and sediments compaction caused by the variability of water content in various geological layers, resulting in a reduction of their volume. Various works have investigated the geological and tectonic evolution of the area (Pieri and Groppi, 1981; Ricci Lucchi et al., 1982), the effects of GIA (Lambeck et al., 2011), and the quantification of subsidence in the Po Plain and in the Northern Adriatic coast (Carminati and Di Donato, 1999; Gambolati et al., 1999; Antonioli et al., 2009; Teatini et al., 2011a). These studies have concluded that the natural subsidence in the study region is dominated by the effect of sediment compaction that, along the costal belt, can reach levels comparable to the anthropogenic component of land subsidence. Furthermore, subsidence of glacial isostatic origin has been shown to have presently a minor role along the E-R coastal plain (Stocchi and Spada, 2009).

The anthropogenic subsidence is a consequence of land use and soil exploitation that followed the second World War and is mainly caused by water pumping and gas extraction. These activities have produced a rapid increase of ground subsidence, with rates sometimes exceeding the natural values by one order of magnitude. For example, in the municipality of Ravenna, the observed rate of subsidence rose from 5 (pre-war epoch) to ~ 50 mm yr^{-1} (after the war). A detailed discussion of the subsidence connected with the extraction activities can be found in Barends et al. (2005), Teatini et al. (2005) and Arpa Ingegneria Ambientale (2008). At present, following the reduction of most of the water extraction activities, the extraction induced subsidence is mainly attributable to gas fields (Angela-Angelina, see Figure 1), which are still in production. A comprehensive map of the expected regression for the Northern Adriatic coastline at 2100 was published by Gambolati et al. (1998). They also estimated the extent of the floodable area in consequence of the combined effects of subsidence and of a 50 cm increase in mean sea level, based upon a coarse DTM dataset (see Figure 1.18 in Gambolati et al., 1998).

2.2 Sea-level variability

During last millennia, the history of the E-R coast, as well as the Adriatic Sea, has been characterised by a significant sea-level rise and variability. In response to the rapid sea-level rise following the end of the last ice age, in the early Holocene the shoreline experienced a rapid migration from the current latitude of Pescara to approximately the present-day position of the coastline (Correggiari et al., 1996) (see Figure 1). This was followed by a stabilisation of the shoreline close to its present

position, although it has been recognised that, during the post-glacial period, small changes in the climate and in the eustatic component of sea level occurred at scales of decades and centuries (Bruckner, 1890; Friis-Christensen and Lassen, 1991). The migration of the shoreline toward the current position initiated between $4,000$ and $5,000$ years ago, driven by the progradation of the Po river delta and of the beach ridges. During this period, a slow subsidence was acting against the retreat of the sea water (Correggiari et al., 1996).

At time scales of decades to centuries, changes of the shoreline have been more complex but of smaller amplitude, with shifts up to a few kilometres, mainly driven by the dynamics of rivers (Calabrese et al., 2010) and connected with the ongoing climate change. During the last millennium, we remark the Medieval Climate Optimum (Veggiani, 1986) with a relative maximum in sea level (IX-X century) followed by the Little Ice Age (XVI-XIX century) with larger sedimentary production and a marine regression (Marabini et al., 1993; Brázdil et al., 2005).

During last century, tide gauges located across the Adriatic Sea have indicated a regional rate of sea-level rise of 1.25 ± 0.04 mm yr^{-1}, slightly less than the global secular average (e.g. Spada and Galassi, 2012). However, significant cyclic variations with a period of ~ 20 years, associated with the Atlantic decadal oscillations, have been observed as well (Galassi and Spada, 2015). Cerenzia et al. (2016) have recently studied the anomalous tide gauge record of Porto Corsini, which goes back to the late 1880s and shows long-term rates of relative sea-level change of 8-9 mm yr^{-1}. These rates, which strongly deviate from the typical rates across the Adriatic Sea (Galassi and Spada, 2015), testify an important role of local land subsidence, also driven by anthropogenic factors as water extraction and soil compaction (Teatini et al., 2005).

For our subsequent analysis, it is important to remark that in the Northern Adriatic Sea the effects of GIA on relative and absolute sea-level change are presently relatively minor, *i.e.* of a few fractions of millimetres per year (Stocchi and Spada, 2009; Galassi and Spada, 2015; Bonaduce et al., 2016). Future rates of GIA-induced sea-level variations across the whole Mediterranean Sea (Galassi and Spada, 2014) will not change with respect to current trends since this phenomenon only evolves on time scales of millennia.

2.3 Coastal storms

The entire northwestern coast of the Adriatic Sea is exposed to a high degree of inundation risk by sudden water level increase associated with certain coastal storms (Harley, 2017). The E-R coastal plain can be considered a low-energy environment with significant wave height $H_{sig} = 0.4$ m (period $T_{peak} = 4$ s) and semidiurnal and micro tidal regime, with an average maximum excursion of 0.7-0.8 m (IDROSER S.p.A., 1996; Harley et al., 2012). Wind waves are characterised by a significant height, with $H_s = 3.3$ m for 1 year return period (Armaroli et al., 2009), which are most frequently associated with the *Bora* weather conditions, blowing from east to northeast sectors. South-easterly winds (*Scirocco*) are generally not as intense as those generated by *Bora* winds (Deserti et al., 2006), due to sheltering produced by the Conero Headland (~ 100 km to the South, see Figure 1) and to the lower strength of *Scirocco*. Nevertheless, *Scirocco* is the main driver of storm surge, causing the push of water all along the Adriatic Sea.

A detailed analysis of the storm surges was carried out by Masina and Ciavola (2011) using the tide gauge data from Porto Corsini (RA). Their analysis has identified extreme levels of 0.85, 1.05 and 1.28 m on mean sea level for a return period of

2, 10 and 100 years, respectively. The corresponding non-tidal residuals, computed for the same return periods, are 0.61, 0.79 and 1.02 m on mean sea level; such values are in use in Emilia Romagna Region for the computation of total water level in the flooding scenarios used for the FD maps (Perini et al., 2012).

In the occurrence of storm surges, however, the coastal sea level can vary significantly with respect to the predicted combination of tide and wave. This is consequence of the coarse resolution of the model with respect to local morphology and of the spatial variability of wave characteristics along the coastline. A statistical analysis of the comprehensive dataset of coastal storms during the period 1946-2010 (Perini et al., 2011) allowed the definition of threshold values for wind waves and surges above which significant events, in terms of effects on population, landscape and urban structures, were recorded (Armaroli et al., 2012). These thresholds are in use in the "coastal alert" procedure adopted by the E-R Regional Civil Defence Agency since 2012.

The stronger impacts are those associated with the coupling between winds from the first quadrant (N and NE) and exceptional tide peaks, known as *"acqua alta"* (Pirazzoli, 1981). The latter, indeed, appears to be crucial for the occurrence of the coastal flooding (Perini et al., 2011). During the observation period 1946-2010, the most critical season has been late autumn (November and December) while in the last five years these events have been recorded even in February. The most relevant event was that of November 1966 (Malguzzi et al., 2006; Trincardi et al., 2016), which impacted the whole Northern Adriatic coast (De Zolt et al., 2006). This boosted the completion of most of artificial defences currently in place along the E-R coastal plain. With respect to the damages, these events commonly affect the touristic infrastructures along the coast (*e.g.,* the resorts located along the beaches) in consequence of the combination of flooding and of beach erosion. In some cases, the effects are exacerbated by the overflow of the rivers and channels whose discharge is obstructed by the storm surge, causing flooding in the surrounding urbanised areas and consequently increasing the impact on infrastructure and population. The complex factors outlined above have prompted us to simulate complex meteorological event scenarios, taking into account the main parameters, namely surge, astronomical tide and wave setups, which are already considered in the application of the FD.

3   Data and Methodologies

The purpose of this work is to analyse the impact of the predicted relative sea-level change at 2100 along the E-R coastal plain. Two distinct aspects will be modelled and discussed. The first is the increase in the extension of land with elevation below mean sea level and possibly of submerged areas, while the second is the effect of storm surges in terms of floodable areas. In both cases, the combined effects of sea-level rise and subsidence will be properly taken into account. In the following of this Section we describe the sea-level projections that have been employed in this work (3.1), some fundamental assumptions in modelling (3.2), and the details of the models adopted (3.3).

3.1   Projected mean sea level

For an assessment of future sea-level rise, we adopt the Representative Concentration Pathways (RCP) scenarios reported in the IPCC AR5 (Church et al., 2013). By the Coupled Model Inter-comparison Project Phase 5 (CMIP5), the IPCC AR5 has

defined RCPs that account for the evolution of the climate variables, and in particular of the CO_2 concentration. The RCPs are used for climate modelling to describe four distinct future climate scenarios, characterised by different amounts of greenhouse gas emission. The four RCPs 2.6, 4.5, 6, and 8.5 are named after the possible range of radiative forcing values to year 2100 relative to pre-industrial values, *i.e.* +2.6, +4.5, +6.0, and +8.5 W m^{-2} (see Van Vuuren et al., 2007; Clarke et al., 2007; Fujino et al., 2006; Riahi et al., 2007, respectively).

The global mean sea-level rise predicted for the four RCPs to 2081-2100 with respect to 1986-2005 is given in Table 2, whereas the projected sea-level rise is shown in Figure 3. Table 2 also shows values of sea-level rise expected across the Adriatic and the Mediterranean Sea, obtained by averaging the AR5 sea-level rise grids downloaded from the Integrated Climate Data Center (ICDC)[7]. We note that values of sea-level rise expected across the Adriatic Sea are systematically lower than those relative to the Mediterranean Sea. These, in turn, do not exceed the globally averaged values. Therefore, the use of globally averaged values for the IPCC projections like in Antonioli et al. (2017) would overestimate, along the E-R coast, the total amount of sea-level rise.

To focus on the Northern Adriatic Sea, we have extracted from the global AR5 maps the mean sea level projections for the grid cell closest to the E-R coast, namely the one centred at latitude 44.5° N and longitude 13.5° E (see Figure 1). For any RCP, the E-R coast sea-level rise values is found to be slightly lower than those pertaining to the whole Adriatic Sea. We are aware that in semi-enclosed basins like the Mediterranean Sea the ocean model component of sea-level rise could be affected by a limited precision, since the number of models contributing to the "ensemble mean" in these boxes is sub-optimal (Mark Carson, personal communication, 2013). However, we have kept these local projections since the members of the ensemble used to obtain them provide predictions that are broadly consistent with those in the nearby Atlantic Ocean boxes. In the Adriatic Sea cell considered, the assessed GIA component of future relative sea-level rise is -0.022 ± 0.005 m to year 2100 with respect to 1986-2005, where the uncertainty arises from the different predictions of two independently developed GIA models[8].

3.2 Assumptions

The phenomena associated with long-term sea-level rise depend on geodynamic, morphodynamic, hydrodynamic and sedimentary factors. In consideration of the challenge of creating a model that accounts for all the aspects of the problem and to limit the computational burden, we have decided to take into account only the changes in the topography due to subsidence, which is the best monitored driving process along the coast. Moreover, several assumptions are necessary to control possible sources of uncertainty, as well as to ease the interpretation of the results.

Specifically, in the process of modelling the effects of sea-level rise to year 2100 (case study CS1) it will be assumed that: *i)* no human intervention, such as for example the reconstruction of the dunes system and the build up of artificial barriers, occurs (no action hypothesis); *ii)* the local rates of subsidence will remain constant over time and equal to those currently observed;

---

[7]See `goo.gl/QGV5md`.

[8]See the README.txt at *ftp://ftp.icdc.zmaw.de/ar5_sea_level_rise/*.

iii) changes in the coast morphology will be only a function of the rates of subsidence (this implies, in particular, that reshaping of the beaches in consequence of morpho-dynamic processes will also be neglected).

In case study CS2, a coastal storm scenario will be considered, combining the effects of wave and storm surge. In addition to the three assumptions adopted for CS1, in CS2 it is assumed that *iv)* the coastal storm conditions at 2100 are unchanged with respect to the present ones. It is worth to remark that diverging future predictions for the rate of storm surges expected at along the E-R coastal plain have been proposed, based on different analyses. In the framework of the MICORE project[9], and by means of time series analysis, Ciavola et al. (2011) have evidenced a tendency to an increase in the rate of storm surges over time, with an unvaried storminess. Besides, by a different approach based on climate models, Lionello et al. (2012) have predicted a decrease in the storminess.

3.3 Modelling

The modelling is based on a GIS cartographic system exploiting the Emilia-Romagna region database. This provides a quick sketch of the apparent effects of the sea-level rise, highlighting those areas where the impacts could be more critical. To describe the land surface, we have made use of a digital terrain model (DTM), incorporating LIDAR (Light Detection and Ranging) renderings and a Digital Vertical Movement Model (DVMM), at various spatial resolutions. A comprehensive summary of the datasets used is gathered in Table 3 and described below.   T3

3.3.1 Case study CS1

In case study CS1, for the determination of the areas with elevation below the mean sea level, the datasets in Table 3 have been merged in a DTM with a 5×5 m planimetric resolution (DTM2012-RER). This has been preferred to a more detailed and complex Digital Surface Model (DSM) that incorporates LIDAR renderings including infrastructures, building and vegetation. Specific tests have been performed, which have confirmed that the former provides more realistic results. The DVMM is the result of the interpolation of data acquired by means of PS-InsSAR[10] (Arpa-RER, 2012). This DVMM has been used to project the expected subsidence at 2100 on a 5×5 m grid. The expected total vertical displacement at 2100 results from the assumption of constant rates of subsidence equal to those currently observed. The DTM2100 has been obtained adding the total displacement to the DTM2012-RER.

In the framework of CS1, the sea-level variation S to year 2100 is expressed as the combination of three components:

$$S^{CS1}(\omega) = S_{RCP} + S_{GIA} + S_{SUB}(\omega), \tag{1}$$

where $\omega = (\theta, \lambda)$ with θ and λ denoting colatitude and longitude, respectively, S_{RCP} is the contribution according to a specific RCP, S_{GIA} is the GIA contribution, and S_{SUB} accounts for the effects of subsidence. Note that S_{GIA} and S_{RCP} are assumed to be constant for the study area, while S_{SUB} is spatially variable along the E-R coast (see Figure 2, right frame).

---

[9]See *http://www.micore.eu/*

[10]goo.gl/OQZE1a

Starting from Eq. (1), two different scenarios have been defined. The first, referred to as the HIGH-END case scenario, corresponds to the S_{RCP} value associated with RCP8.5 plus 1σ (*i.e.*, 0.57 m). The second, referred to as the LOW-END case scenario, is based on RCP2.6 minus its 1σ (*i.e.*, 0.23 m, see Table 2). For both scenarios, the contribution of subsidence is

$$S_{SUB}(\omega) = r_{SUB}(\omega)\Delta t, \tag{2}$$

where $r_{SUB}(\omega)$ represents the rate of subsidence at a given location (in meters per year) and Δt is the elapsed time span in years. Furthermore, according to the IPCC AR5 assessment (see Section 3.1 above), the projected GIA component is

$$S_{GIA} = -0.022 \pm 0.005 \text{ m}. \tag{3}$$

Thus, Eq. (1) gives

$$S_{HE}^{CS1}(\omega) = 0.55 \text{ m} + S_{SUB}(\omega) \tag{4}$$

and

$$S_{LE}^{CS1}(\omega) = 0.21 \text{ m} + S_{SUB}(\omega), \tag{5}$$

for scenarios HIGH-END and LOW-END, respectively.

3.3.2 Case study CS2

The objectives of CS2 are *i)* the determination of the potential floodable areas to year 2100 combining the effects of waves and storm surges and *ii)* the comparison of these results with the hazard map for the seawater flooding processed in the framework of the FD (European Parliament and Council, 2007). This topic has a crucial impact in the Emilia Romagna region, in view of the continuous loss of natural areas and the strong impact that a possible flooding may have on urban areas and on the tourism infrastructures. This methodology, which follows the approach adopted for CS1, has been based on the modelisation of the future topographic surface and on the simulation of the flooding in consequence of sea-level rise in scenarios LOW-END and HIGH-END described above.

To effectively represent the impact of storm surges to year 2100, the sea-level rise $S(\omega)$ predicted by Eqs. (4) and (5) is combined with the typical S_{STS} rise associated with characteristic storms in the region, *i.e.,*

$$S_{HE,LE}^{CS2}(\omega) = S_{HE,LE}^{CS1}(\omega) + S_{STS}, \tag{6}$$

where HE and LE denote the HIGH-END and LOW-END scenarios, respectively, and S_{STS} is the total sea water level at the shoreline during coastal storms, calculated by combining the effects of surge, of the astronomical tide and wave set up. For the S_{STS} component of sea-level change, three scenarios have been adopted in order to process the hazard maps as requested by the FD. Each of them is associated with a different return period: Frequent (10 years return period, P3-FD), Less Frequent (100 years, P2-FD), and Rare ($\gg$ 100 years, P1-FD, see Table 4) (Perini et al., 2012, 2016; Salerno et al., 2012).   T4

This study is based on the GIS model named `in_CoastFlood`[11] developed by *Servizio Geologico, Sismico, e dei Suoli* of Emilia Romagna Region (SGSS-RER) (Perini et al., 2012), which merges the sea surface in the different weather conditions with the land topography (DTM lidar). A damping was applied as a function of the distance from the shoreline, with the exception of those areas which are not directly connected to the sea (Perini et al., 2012; Salerno et al., 2012). Different tests have been applied to validate the model and to choose the most appropriate scenario. This resulted to be P2, the one with a return period of 100 years (a standard in the field of country planning) and characterised by more robust reference values. Scenario P3 was discarded since it affects only a limited portion of the coast, while P1 was discarded because its return period ($\gg 100$ years) is not clearly defined from a statistical standpoint (Perini et al., 2016).

Once the reference values have been selected (P2-FD), some local tests have been performed to verify if short-term scenarios are worth to be considered, as they are mainly used in urban planning. The tests have confirmed that short-term scenarios (*e.g.,* P2-FD in combination with the pessimistic HIGH-END scenario at year 2030) have low significance in terms of change of the floodable areas when compared to those reported in map for P3 at present, and as a consequence short-term effects were discarded. Then we used the most detailed DTM available (DTM LIDAR by ENI, 2012) whose resolution (1×1 m) exceeds the one used for CS1. The choice of this different dataset was motivated by its higher resolution, necessary to run the `in_CoastFlood` model. The model has been used to quantify the change in floodable areas by storm surges at 2012 (P2DTM12, present scenario) and 2100 (P2DTM2100, future scenario).

The importance of high resolution data and models has been also emphasised by Wolff et al. (2016), who first downscaled the global DIVA approach to the case study of the E-R coastal plain. As pointed in the Introduction, Wolff et al. (2016) produced a similar work on the E-R costal plain. A comparison with our results below is not straightforward, since their work was mainly aimed at testing the sensitivity of DIVA in such a complex local case study, with attention to the impact on population and potential economical loss. What is relevant to the purpose of our work is their conclusion about the key role of detailed DTM elevation models at to provide realistic assessments at regional scale. In general, previous impacts assessments performed in the same region are based on a methodology that compares water levels to terrain elevation, *i.e.,* the *bath-tub* method. On the contrary, the model employed in this work incorporates the bath-tub method also accounting for the hydrological connectivity between grid cells; only cells directly connected to the sea and with inundated nearby cells are considered flood prone.

To optimise our computations and for ease of understanding, the simulation has been performed across five distinct areas, highlighted in Figure 4. From South to North, the areas range from Cattolica to Rimini (Area 1), from Rimini to Cesenatico (2), from Cesenatico to Fiumi Uniti (3), from Fiumi Uniti to Porto Garibaldi (4), and from Porto Garibaldi to Gorino (5). In Section 5 the results are gathered to provide a comprehensive overview at the full E-R regional scale.

4 Results

4.1 Results for CS1

Aim of this Section is to determine those areas whose elevation at 2100 would move from above to below mean sea level, by means of realistic estimates of the relative height of the ground. Henceforth we consider the HIGH-END scenario, which implies a relative sea-level rise of about 55 cm to year 2100.

A first analysis has been performed considering the E-R portion of the Po plain, having an extension of $\sim 9,300$ km^2. On this basis, we have computed the variation of land with height above mean sea level by intersecting of DTM2100 with the sea level at 2100, obtained by shifting the present chart datum by $+55$ cm (see Figure 5). As summarised in Table 5, the effect of subsidence would contribute to the loss of ~ 101 km^2 of land above mean sea level, whereas considering the combined effect of subsidence and sea-level rise (HIGH-END scenario) the extension of the areas below mean sea level could reach ~ 346 km^2. It is apparent from Figure 5 that the difference is only restricted to the coastal plain and that large discrepancies exist between the N and the S sectors of the E-R coast. For this reason, we opted for a more detailed analysis by splitting the E-R coastal plain, whose total area is $\sim 3,043$ km^2, into three sectors that differ for the morphology and for the response to the scenarios, *i.e.*, the Ferrara, Ravenna, and Rimini sectors. Figure 5 shows, in the HIGH-END scenario, the extent of the areas that will be located below mean sea level to year 2100 (red). In the same Figure, the areas that today are below mean sea level are marked in yellow. The largest portion of potentially low land areas to year 2100, is limited to the Ravenna district (right frame in Figure 5). This is in consequence of the high rates of subsidence observed in the area, which is characterised by a low elevation above mean sea level (see Table 6). It is important to underline that the submerged areas mostly consist of land not directly connected to the sea ("low land areas" or polders).

4.2 Results for CS2

The maps obtained for CS2 (see Figures from 6 to 10) show a large increase in the risk of flooding during coastal storms along the whole E-R coast, in particular in Area 3, from Ravenna to Cesenatico. For the Areas 1 to 5, we now describe in detail the increase of the floodable areas in case of storm surge with respect to the current scenario at 2012 (P2-DTM2012).

4.2.1 Area 1

In Area 1 (Figure 6), the effects of subsidence are found to be very small in comparison with other areas; they result in an increase of the floodable area of $+47\%$ with respect to the one predicted by model P2-DTM12. In the LOW-END and HIGH-END sea-level scenarios to year 2100, these values increase to $+85\%$ and $+141\%$, respectively. Remarkably, the area mostly affected by the sea-level component in comparison to subsidence is the center of the town of Rimini, but also the mouths of the rivers are impacted. In Area 1, the extension of the floodable area is limited to 50-100 m landward with respect to that predicted by P2-DTM12.

4.2.2 Area 2

The results for Area 2 are shown in Figure 7. Compared with other areas, Area 2 is characterised by smaller rates of subsidence, smaller depressed regions and higher average elevations above the sea level, which naturally mitigates the combined effect of subsidence and of sea-level rise. The increase of the areas exposed to potential flooding to year 2100 is limited to +65% with

5   respect to present for the only effect of subsidence, while for the LOW-END and HIGH-END scenarios we obtain +102% and +167%, respectively, also including the effects of land subsidence. From the map in Figure 7, we recognise that from the N border to the Uso river mouth, the extension of the area at risk of flooding is dominated by the effects of subsidence. South of the Uso river mouth, the opposite occurs, with a dominating effect of sea-level rise especially for the HIGH-END scenario. We note that some large portions of urban areas are involved, especially in the municipality of Bellaria-Igea Marina and north of

10 the Rimini harbour.

4.2.3 Area 3

Area 3 (Figure 8) turns out to be the most critical of the E-R coast in consequence of the high rate of subsidence that char- acterises its northern portion, between Fiumi Uniti and Cervia. Here we observe the most significant increase (+248%) for the floodable area to year 2100 with respect to 2012 (P2-DTM12), as a consequence of current subsidence rates. When the

15 expected sea-level rise is also taken into consideration, the increase rises up to +308% and to +404% for the LOW-END and the HIGH-END scenarios, respectively. These values evidence that the effect of the sea-level rise is marginal with respect to subsidence, at least for scenario LOW-END. However, it should be remarked that also in this area the effect of the storm surge would flood the entire coast with a frontal ingression that could extend several hundred meters, exceeding up to 0.5 km the present scenarios, involving large urban areas.

20 ### 4.2.4 Area 4

In Area 4 (Figure 9), the scenarios predicted to year 2100 are sharpened by the presence of wide low-elevation regions, with some of them currently below the mean sea level. This is exacerbated by two factors. The first is the total absence of natural or artificial defences such as dunes and embankments that could counteract the marine action. The second is the high rate of subsidence, reaching 15 and even 20 mm yr^{-1} at some locations like Porto Corsini, Lido Adriano and Lido di Dante. The

25 increase of the floodable area, only in consequence of the subsidence, would be of ~153% relative to P2-DTM12. This rises to +214% and +294% when the predicted sea-level rise at 2100 is taken into account, according to the LOW-END and HIGH-END scenarios, respectively. In this model, the ingression would occur along the whole coast, involving urban areas as well as natural reserves. The expected inner limit for the areas reached by the flooding would move inland by about 1 km with respect to P2-DTM12. Furthermore, in case of flooding no natural barriers are present. We should remark, however, that the recent

30 assessment by Arpa-RER (2012) for the subsidence in this area has revealed a strong decrease to values of 6-7 mm yr^{-1}. This suggests that these proposed scenarios could be revised in the near future, and possibly replaced by more optimistic ones.

4.2.5 Area 5

The results for Area 5, shown in the map of Figure 10, indicate an increase of ∼59% of the floodable area in case of storm   F10
surge with return period of 100 years (P2 in Table 4), when only the effects from land subsidence are considered (see green
coloured areas). This result is crucial, since currently in the Po Delta area the subsidence is assumed almost completely natural

5 (Teatini et al., 2011b), with rates that locally reach 11 mm yr^{-1}. Accordingly, it appears unlikely to expect a reduction, neither
natural nor induced, in the next 100 years. If we include the effect of the predicted sea-level rise at 2100, the percent increase
of the floodable areas rises to 102% and 214% for the LOW-END and HIGH-END scenarios, respectively (yellow and red
areas). It should be remarked that a large portion of those areas that will become floodable at 2100 are currently protected by
embankments. The above estimates imply that the current artificial defenses would loose their functionality at 2100. Further

10 considerations relate with the inward displacement of more than 2 km of the floodable area boundaries relative to the P2-
DTM12 predictions. This would in fact largely involve urbanised areas although the propagation inward of the sea would be
localised at weak or low points along the embankments. As a consequence, a constant and efficient maintenance is required for
the embankments to counteract the effects of subsidence and of future storm surges.

4.3 A regional synthesis for CS2

15 Based on the analysis above, the combined effect of subsidence and sea-level rise in terms of increase of the floodable areas
at 2100 can be summarised as follows (see Table 7). *i)* Land subsidence plays a non negligible role, leading to an increase of   T7
the floodable areas of ∼95% with respect to that predicted by P2-DTM12 along the entire E-R coastal plain to year 2100; *ii)*
the superimposition of the HIGH-END scenario for sea level would enlarge the extension of the floodable areas in case of P2
event by more than three times (+236%) with respect to P2-DTM12; *iii)* the most critical portion of the E-R coast in terms of

20 increase in the floodable area is recognised as the central one, corresponding to Areas 3 and 4; in this respect Area 1 turns out
to be the less critical; *iv)* in the E-R coast portion that extends between Casal Borsetti and Cervia (Areas 3 and 4), the increase
is dominated by subsidence which tapers the effect related to sea-level rise. *v)* To the North, areas where subsidence dominates
are alternated with those in which sea-level has a major role. Those are mainly localised where defences are in place but gaps
are present.

25 For a correct interpretation of our results, it should be remarked that in CS1 we have only considered the combined effect of
subsidence and sea-level rise while in CS2 we have also included the effects of storm surges. In both cases, we are omitting the
effects of the coastal morfodynamics and of the solid transport by the sea and by the rivers, as well as the anthropogenic factors
that could concur in modifying the landscape by the end of the century. These, in some cases, could contribute to mitigate the
effects of the predicted sea ingression.

5   Discussion

Our study relies upon a a number of important assumptions, regarding: the role and the rate of land subsidence, the morphological conditions, and the adopted sea-level projections. Each of these assumptions implies some uncertainties, which required some further discussion.

The surmise of a linear trend of subsidence can be motivated observing that the major temporal variations in the rates are observed in confined areas, where groundwater exploitation and anthropic impact are particularly strong (for various specific case studies, see for example Le Mouélic et al., 2005; Wang et al., 2012; Raucoules et al., 2013). In the remaining parts of the E-R coastal plain, which cover most of the study area, the subsidence rates measured during the different monitoring campaigns are comparable. We interpret this spatial and temporal distribution as a constant background signal, likely due to natural subsidence, with overlapping local perturbations due to human activity. These are difficult to model because of the large number of variables and the complexity of the driving processes. In addition, measures imposed by the the Emilia-Romagna Regional Administration over the last 30 years to reduce the fluids extraction have allowed a progressive stabilization of subsidence rates in most of these critical areas. Thus, assuming that the measures will be maintained, future rates of subsidence will not be likely to exceed the current ones. Current subsidence rates were then used in modelling as they well describe the geodynamic condition of the Emilia-Romagna coast at regional scale, pointing out the present state of the highly subsiding areas. It is implied that the results in Table 5 implicitly reflect the benefits of the ongoing adaptation strategy consisting in mitigating subsidence through reduced fluid extractions.

Regarding the morphological changes, it was chosen to consider a rigid substrate modified only by the subsidence (translation), since, at present, it has not been possible to apply a dynamic modelling approach integrating also long term coastal evolution (e.g. beach changes) at the regional scale, or land use projection. In this view, the model excludes the natural adaptation of the coastal system as well as it funds on the assumption of "no intervention" by man (no nourishment, no upgrading in coastal defense systems, etc.).

Another important source of uncertainty arises from the sea-level projections along the E-R coastal plain. In this work, we have relied upon projections based on global scenarios reported in the IPCC AR5 (Church et al., 2013), and corresponding to specific RCPs. However, recent ensemble simulations from Adloff et al. (2015) have shown that projections within the Mediterranean Sea are particularly sensitive to the conditions assumed in the near-by Atlantic region, which is uncertain in the general circulation models. According to Slangen et al. (2017), the minimum uncertainty associated with the sea-level projections to year 2100 is $\pm \sim 10$ cm, which is comparable with the uncertainty associated to our projections in Table 2, for all the possible RCPs. This enlightens the need, in future studies about the impacts of sea-level rise along the E-R coastal plain, of high quality regional ocean models.

6   Conclusions

In this work we have performed a GIS analysis aimed at identifying those areas of the E-R coastal plain that would suffer, by the end of this century, from an increased vulnerability in response to land subsidence and sea-level rise. These will cause the

loss of large portions of emerged land, in particular, beaches, wetlands and dunes. While the first would have a relevant impact on the tourism industry of the region, wetlands and dunes would threaten valuable ecosystems, essential for the preservation of nature and of life. A second major effect would be the enlargement of the portions of land exposed to water flooding in case of storm surges.

5   The effects of sea-level rise have been modelled in terms of land loss and increase of floodable areas, assuming storm surges with a return period of 100 years. The distribution of floodable areas has been compared with current scenarios designed by the Emilia-Romagna authority in the framework of the DLGS 49/2010, national emanation of the Flood Directive (EU 2007/60). The high quality of the data sets employed both at regional and local scale and their enhanced spatial resolution have allowed for a detailed analysis, with a focus on the effect of the single components. The eustatic effect coupled with subsidence has, in

10   the context of the E-R plain, a relevant long-term impact, although in different ways along the coast. The subsidence appears to be the most significant cause in some areas, such a the Ravenna district. The combination of a 55 cm increase in sea level (HIGH-END scenario, based on the IPCC AR5 projections) with a widespread subsidence that is expected to affect with different rates the entire coastal area, results in an increase of about 346 km^2 of the land that could be partly below mean sea level. The new areas below mean sea level could be directly connected to the sea and therefore potentially floodable. This would lead to

15   an increase of the former wetlands reclaimed at the beginning of the last century.

In a step forward, we have combined the above results for the LOW-END (+23 cm) and HIGH-END (+55 cm) sea-level scenarios with the predicted effects of effects of coastal storm phenomena, *i.e.* total sea water level, based on the model "in_CoastFlood" with scenarios with return period of 100 years. The results have evidenced that: *i)* subsidence and storm surges would lead to an increase from 29 to 59 km^2 of floodable areas at 2100; *ii)* when subsidence and storm surges are

20   combined with sea-level rise, the increase of floodable areas is +133 and +236% for the LOW-END and HIGH-END scenarios, respectively. In our study, we did not consider possible changes in the current observed rates of subsidence and storminess, nor any human intervention to adapt the existing coastal defence to the evolving shape of the coastline. This work, indeed, discusses the scenario of maximum vulnerability for the case of "no intervention", with the aim of defining the most appropriate actions to be applied in the updating of the FD plan, expected for year 2021.

25   Integrating the above results with the flooding maps produced in the framework of the DGLS 49/2010, it has been possible to compare the current situation with possible future scenarios. The methodology implemented, which demands relatively limited computational resources, will allow new analyses and further maps to plan new possible mitigation actions as well. This would leave however the Emilia-Romagna coastal plain exposed to a certain level of risk, in consequence of its natural shape and geology. We expect that the output of our analysis will support the planned activities for the second stage of the Flood

30   Directive 2007/60, *i.e.* the updating of the knowledge framework and hazard and risk maps by 2019. These should include, in fact, the risks assessment driven by the climate change, which was not presented in the first cycle of the directive application, in order to identify mitigation and adaptation measures. Likewise, we expect that this work can provide an important contribution to the working group on the Regional Climate Change Strategy, which aims to develop an action plan by 2018. In this respect, this work can be considered the starting point for decision makers as well as for the scientific community to define the areas

exposed to a major risk, the possible actions to mitigate the predicted risks, and the strategies to handle the forthcoming strong surges and flooding.

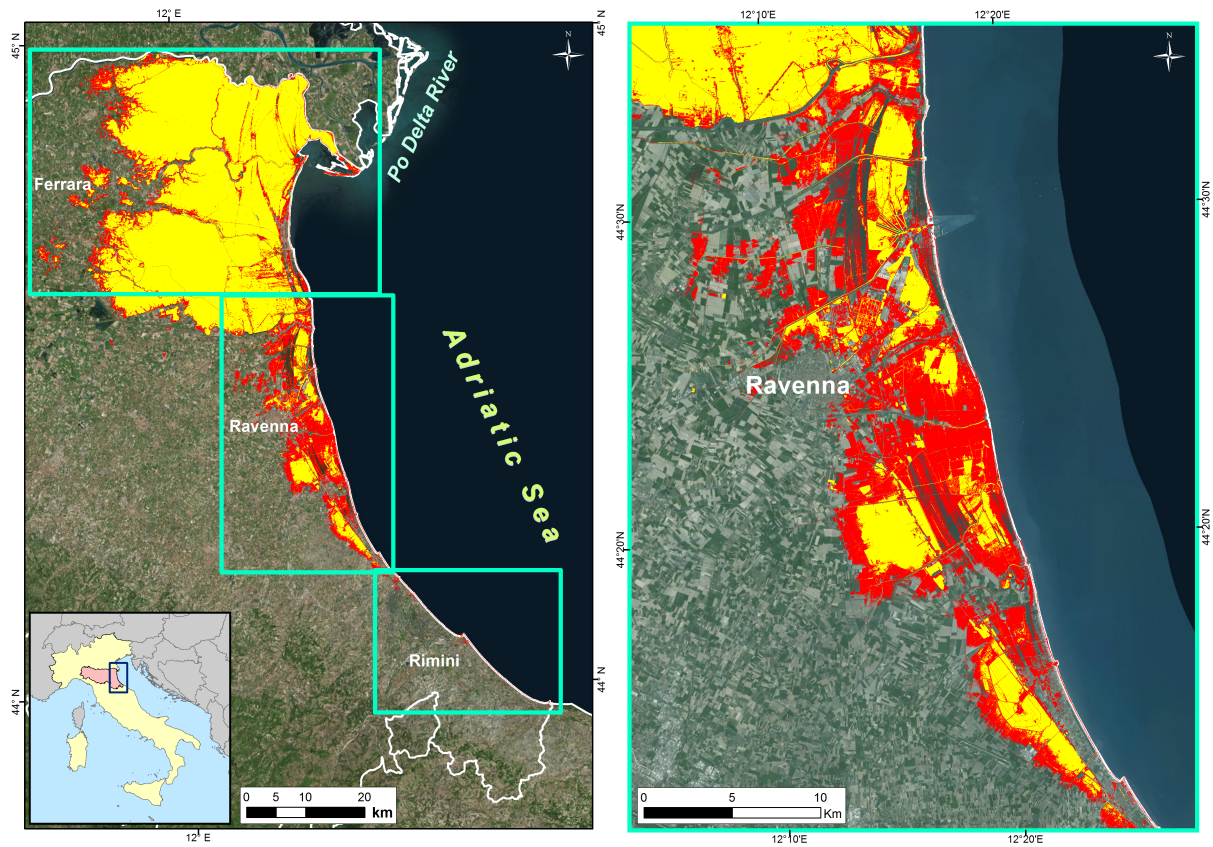
Figure 1. Map of the Northern Adriatic Sea and of the surroundings. Horizontal ticks on the East coast of Italy mark the northern and southern limits of the E-R shoreline. The hatched rectangle shows the cell of the IPCC AR5 discretisation of the global oceans used to represent the projected sea-level change in front of the E-R coast (RA: Ravenna, AA: Angela-Angelina gas field, PE: Pescara). The town of Cervia divides E-R coast into two sectors, referenced to as North (N) and South (S) in the body of the paper.
Figure 2. Left: the altimetry and morphology of the E-R coastal plain resulting from a high resolution Digital Terrain Model (DTM). The reference height in the map is the zero of the Italian geodetic network. The remarkable difference between the N and the S sectors in term of the extension of low lands is evident. Right: Subsidence rate map of the E-R coastal plain according to the InSAR monitoring for the time period 2006-2011 (Arpa-RER, 2012).
Figure 3. Sea-level pathways according to IPCC AR5. Dashed lines show the lower and the upper limits of the projections, corresponding to the upper limit of RCP 8.5 and to the lower limit of the RCP 2.6. Projections are referred to the average sea-level values in the period 1986-2005.
Figure 4. Location and boundaries of the five areas (Area 1 to Area 5) on which the E-R coastal plane has been divided.


Figure 5. Results for the simulations in CS1, at the E-R coastal plain scale (left) and for the area of Ravenna (right). Lands that are currently located below sea level are evidenced in yellow. New areas predicted to be located below sea level at 2100 are marked in red.
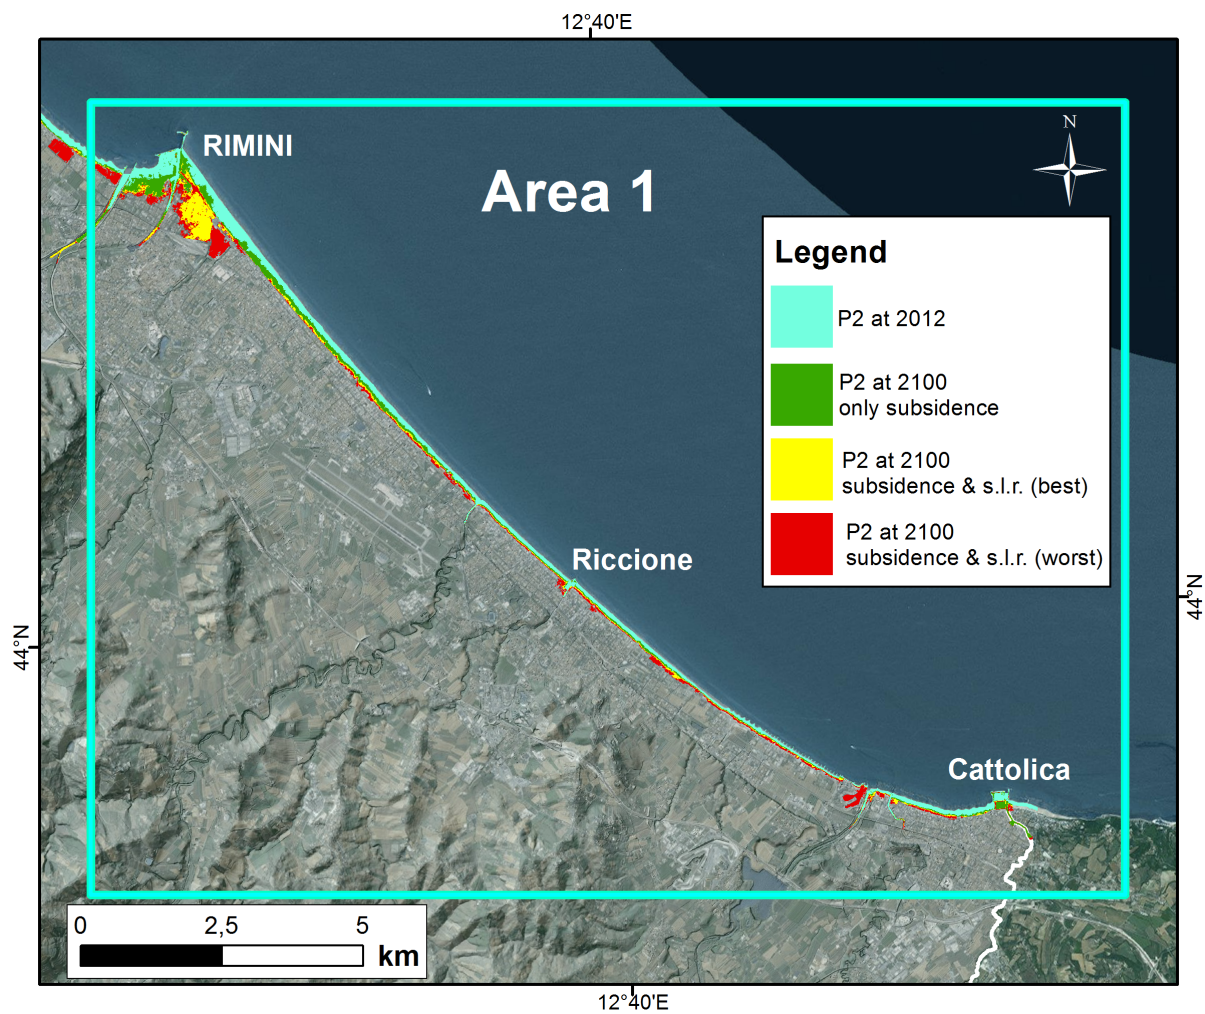

Figure 6. Floodable regions across Area 1 in case of storm surge for case P2 at 2100. The assumptions in modelling are color-coded in the inset. In Figures 6-10 "best" and "worst" refer to the LOW-END and HIGH-END scenarios described in the body of the paper, respectively

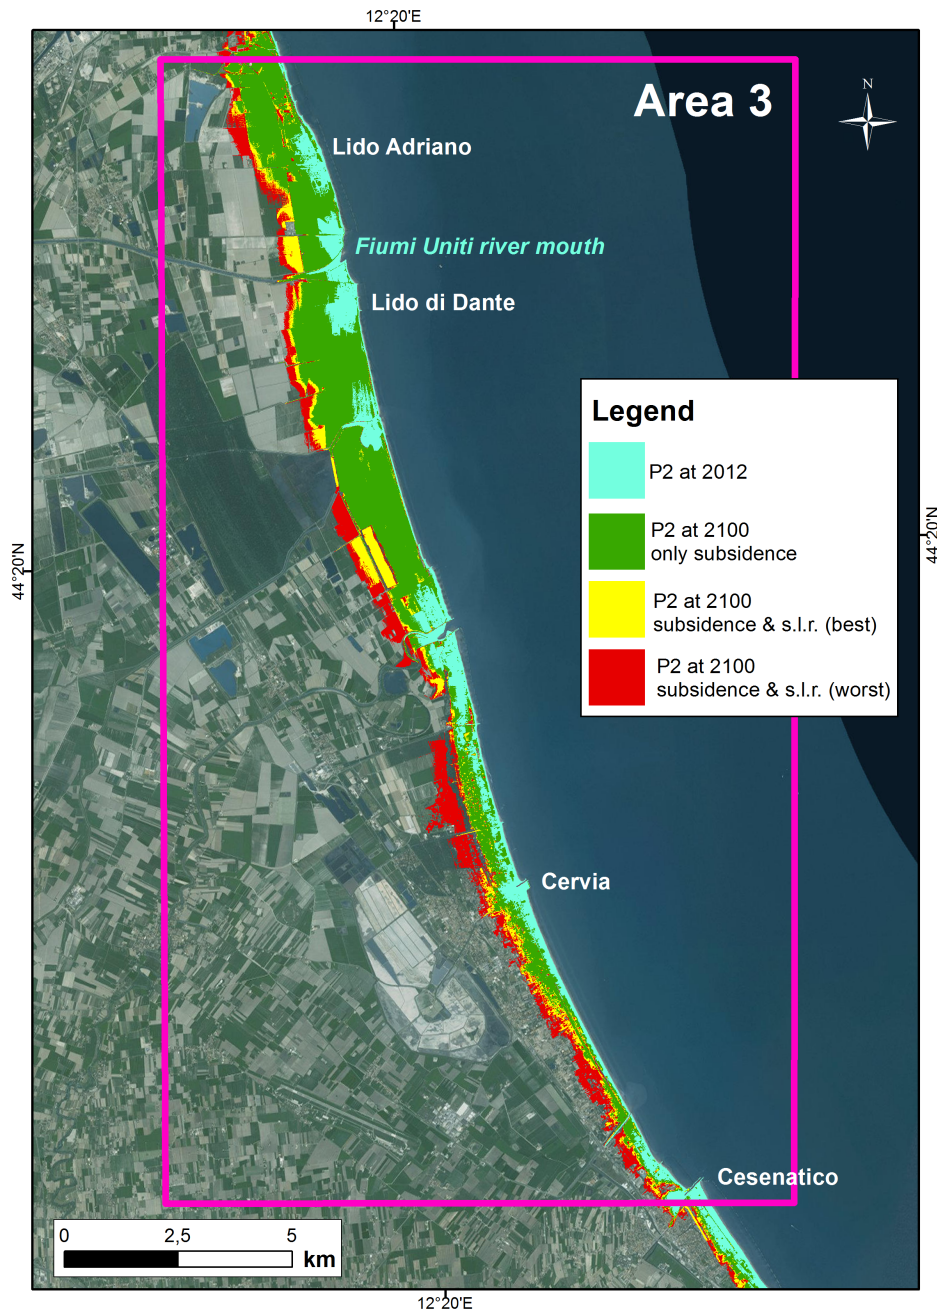
.
Figure 7. The same as in Figure 6, but for Area 2.


Figure 8. The same as in Figure 6, but for Area 3.
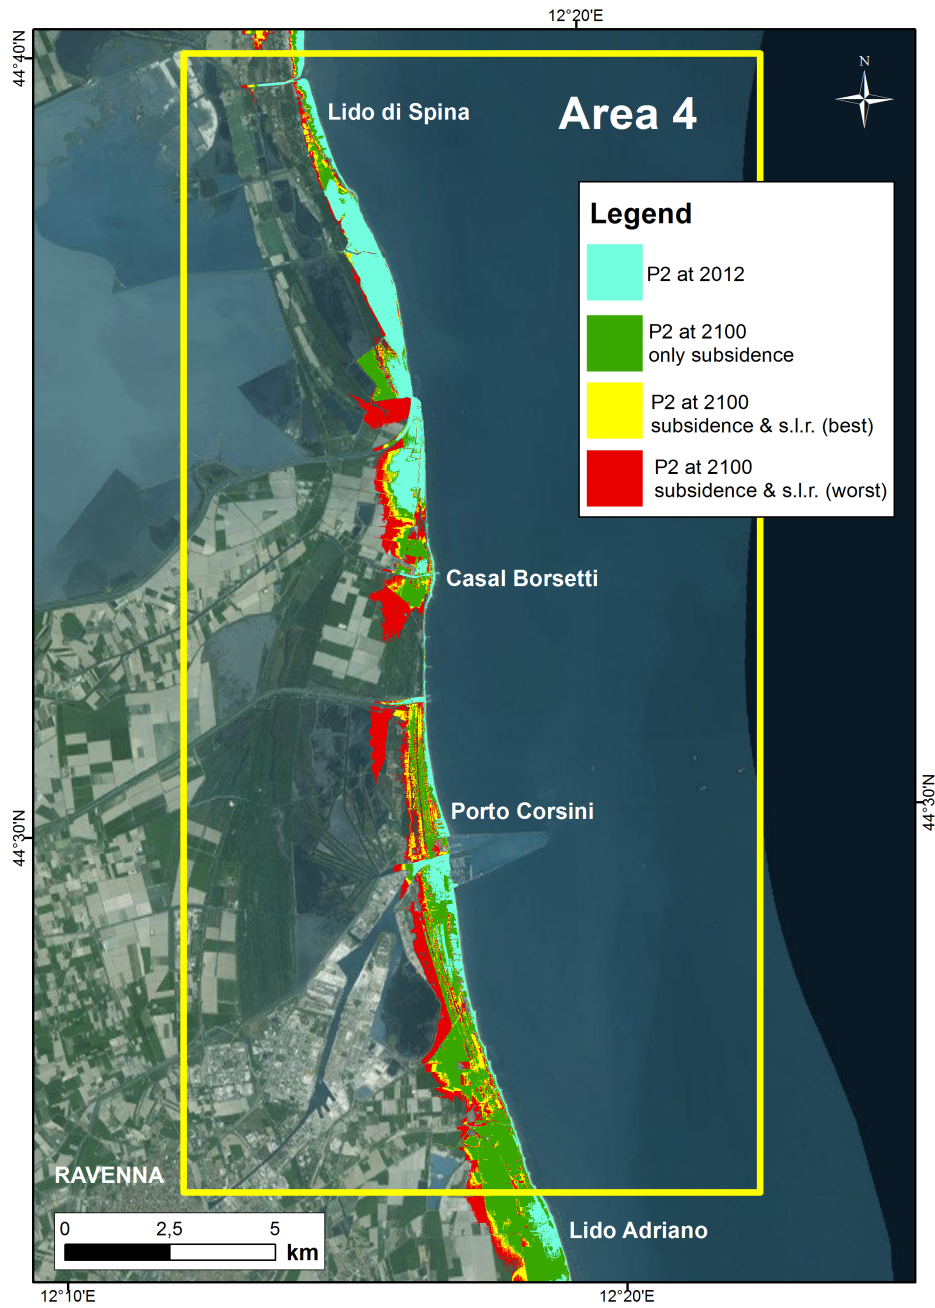

Figure 9. The same as in Figure 6, but for Area 4.
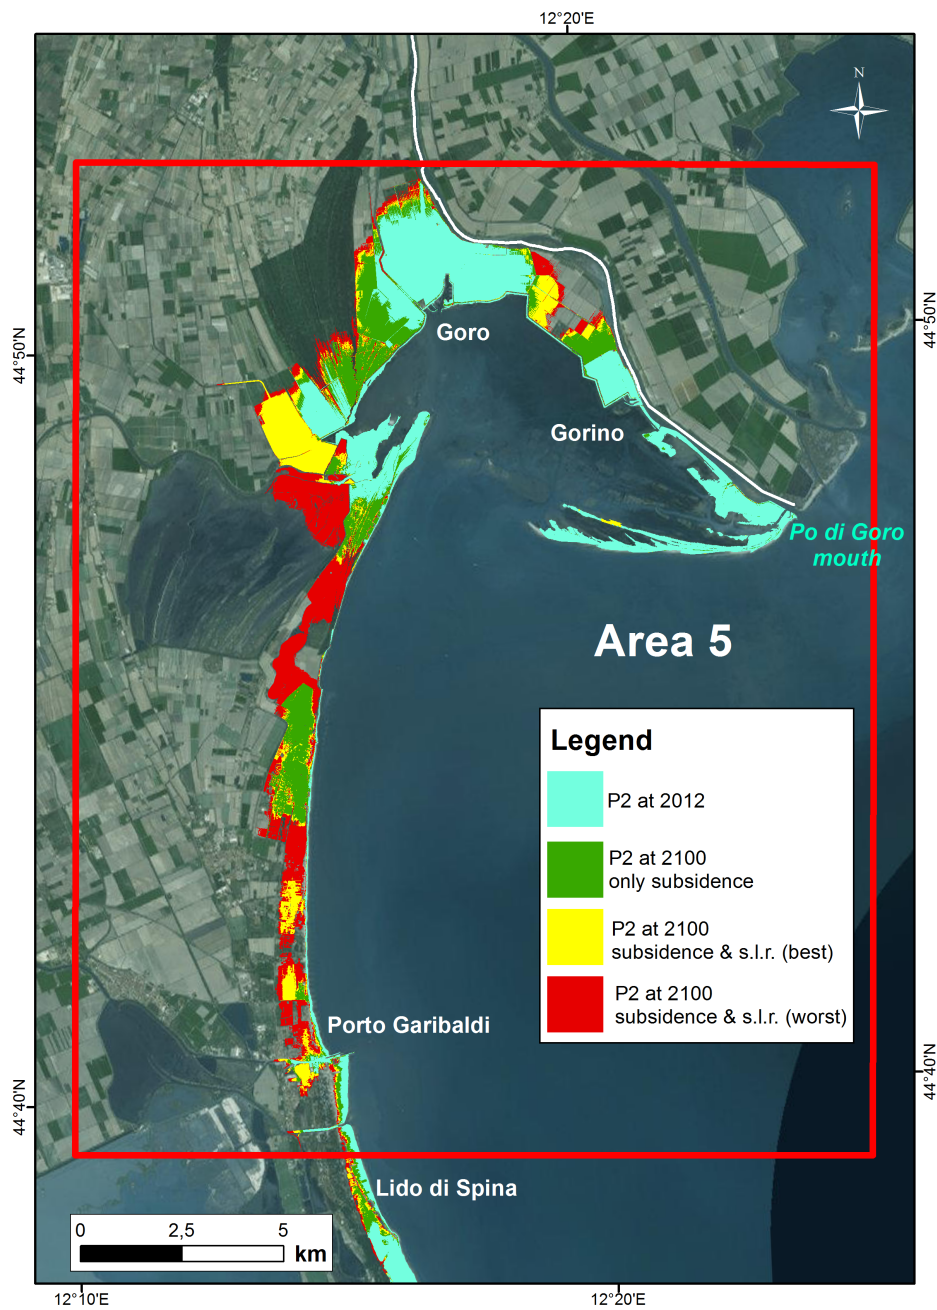

Figure 10. The same as in Figure 6, but for Area 5.

Table 1. Summary of the physical characteristics of the E-R coast. The N and S sectors are defined in Figure 1.

	North sector (N)	South sector (S)
Coastal plain width (D)	$5 < D < 40$ km (from South to North)	$0.8 < D < 5$ km (from South to North)
Dominant elevation above sea level (H)	$-1 < H < 1$ m	$0 < H < 3$ m
Dry beach width (D_s)	$0 < D_s < 300$ m, mean value $\overline{D}_s = 60$ m	$10 < D_s < 180$ m, mean value $\overline{D}_s = 80$ m
Geomorphological features	Beach ridges, dunes, lagoons, wetlands, reclaimed areas, sand spits	Beach ridges, dunes (only towards the north), saltpans
Shape of the shoreline	Wavy, convexities at river estuaries, more complex at river spits	Straight with asymmetric wedges at Cesenatico and Rimini harbors
Backshore land use	Urbanized areas, agriculture, vegetation and wetlands	Wide urbanized areas, agriculture and vegetation
Medium/long term tendency	Variable, tending to rectify	Stable, with local changes

Table 2. Sea level predicted during the time interval 2081-2100 with respect to 1986-2005, according to the four IPCC AR5 RCPs. The Adriatic and Mediterranean values are averaged values across these seas. These projections do not include the GIA component of sea-level change.

RCP	E-R coast	Adriatic	Mediterranean	Global
	m	m	m	m
2.6	0.30 ± 0.07	0.31 ± 0.01	0.36 ± 0.02	0.38 ± 0.15
4.5	0.34 ± 0.09	0.37 ± 0.01	0.42 ± 0.03	0.45 ± 0.16
6.0	0.33 ± 0.08	0.36 ± 0.02	0.42 ± 0.03	0.47 ± 0.16
8.5	0.45 ± 0.12	0.48 ± 0.02	0.57 ± 0.03	0.60 ± 0.19

Table 3. Description of the four input models employed for the definition of case studies CS1 and of CS2.

Input dataset name	Interpolated points	Altimetric tolerance	Output dataset name	Grid size
LIDAR 2008 PNT	2 p/m^2	± 15 cm	DTM 2008 PNT	2×2 m
LIDAR 2010 RER	4 p/m^2	± 10 cm	DTM 2010 RER	1×1 m
LIDAR 2012 ENI	4 p/m^2	± 10 cm	DTM 2012 ENI	1×1 m
PS-InSAR 2006-2011 PNT	1 p/26 m^2	$\pm$ 2 mm	DVMM	5×5 m

Table 4. Expected sea-level rise in the occurrence of different type of characteristic storm surges and their expected return period (Perini et al., 2012, 2016; Salerno et al., 2012).

Type of surge	Return period	Sea surface elevation
	years	m
Frequent (P3)	10	1.49
Less Frequent (P2)	100	1.81
Rare (P1)	$\gg 100$	2.50

Table 5. Areas expected to be above and below mean sea level (m.s.l.) to year 2100, compared to year 2012. Upperscript [a] denotes only subsidence; [b] includes subsidence and sea-level rise.

Year	Above m.s.l.	Below m.s.l.	Lost area above m.s.l.
	km^2	km^2	km^2
2012	8083.8	1216.4	
2100 [a]	7982.5	1318.3	101
2100 [b]	7737.6	1563.2	346

Table 6. Detail of the future areas below sea level, compared to year 2012.

Area	at 2012 km^2	at 2100 km^2	Difference km^2
Ferrara	1143.32	1331.41	188.09
Ravenna	72.00	224.28	152.28
Rimini	0.72	6.34	5.61

Table 7. Regional floodable areas in case of storm surges for case P2 described in Table 4. The increase in amount of flooded area is relative to P2-DTM12. Upperscript [a] denotes only subsidence, [b] includes subsidence and sea-level rise (LOW-END scenario), [c] includes subsidence and sea-level rise (HIGH-END scenario).

Case	Flooded area km^2	Increase %
P2-DTM12	29	
2100 [a]	59	95
2100 [b]	72	133
2100 [c]	105	236
