26 **Abstract**

27 Megacities are predominantly concentrated along coastlines, making them exposed to a diverse mix of natural
28 hazards. The assessment of climatic hazard risk to cities rarely has captured the multiple interactions that
29 occur in complex urban systems. We present an improved method for urban multi-hazard risk assessment.
30 We then analyze the risk of New York City as a case study to apply enhanced methods for multi-hazard risk
31 assessment given the history of exposure to multiple types of natural hazards which overlap spatially and, in
32 some cases, temporally in this coastal megacity. Our aim is to identify hotspots of multi-hazard risk to support
33 the prioritization of adaptation strategies that can address multiple sources of risk to urban residents. We used
34 socio-economic indicators to assess vulnerabilities and risks to three climate related hazards (i.e. heat stress,
35 inland flooding and coastal flooding) at high spatial resolution. The analysis incorporates local experts'
36 opinions to identify sources of multi-hazard risk and to weight indicators used in the multi-hazard risk
37 assessment. Results demonstrate the application of multi-hazard risk assessment to a coastal megacity and
38 show that spatial hotspots of multi-hazard risk affect similar local residential communities along the
39 coastlines. Analyses suggest that New York City should prioritize adaptation in coastal zones and consider
40 possible synergies and/or tradeoffs to maximize impacts of adaptation and resilience interventions in the
41 spatially overlapping areas at risk of impacts from multiple hazards.

58 **1. Introduction**

59 Megacities (i.e. urban areas exceeding 10 M inhabitants) host 500 M people or 6.8 % of the global population,
60 a proportion that is projected to rise to 8.7% by 2030 (UNDESA, 2016). These urban agglomerations are
61 highly interconnected and vibrant centers in which enormous physical and intellectual resources are
62 concentrated. Mainly located along waterways and coastal areas, megacities tend to be more exposed to
63 disasters and suffer higher social and economic losses (UNDESA, 2016). Earthquakes, cyclones and flooding
64 are the major threats to megacities (Philippi, 2016). Large cities themselves modify the local and regional
65 environment, changing the microclimate (e.g. by creating urban heat islands), paving over soil and altering
66 ecosystem processes, and building up infrastructure (e.g. roads, buildings, pipes, wires), which, together with
67 projected impacts of climate change such as sea level rise, contributes to magnifying hazard impacts in coastal
68 inhabited areas (Pelling and Blackburn, 2013). New York City (NYC), a regional megacity, is highly exposed
69 to multiple hydro-meteorological hazards. For example, on the 29th of October 2012, hurricane Sandy made
70 landfall close to Atlantic City, New Jersey (US) with the intensity of a category 3 hurricane. Located
71 approximately 200 km north, the NYC area was severely affected by the hurricane, which surprised the city
72 largely unprepared to cope with the magnitude of such an event. The city suffered human losses, widespread
73 damage to buildings, power outages, interruptions in utility service and large-scale flooding. In the
74 Metropolitan region 97 people lost their life, thousands were displaced and economic losses amounted to
75 more than US\$ 50 billion (Abramson and Redlener, 2012). Hurricane Sandy triggered a series of responses
76 from the local administration. Since then, the NYC Office for Emergency Management has developed
77 multiple initiatives to decrease risk to coastal storms, as described in the 2014 NYC Hazard mitigation plan.
78 Additionally, the city established the Mayor’s Office for Recovery and Resilience in 2014. Innovative design
79 approaches lead to the recently approved “Big U” coastal resilience project that is planned as a fortification
80 of lower Manhattan to protect it from future storm surges and flooding. However, coastal hazards are not the
81 only extreme events that threaten New Yorkers. Heat waves kill on average more persons than any other
82 extreme event in NYC (Depietri and McPhearson, 2018). Additionally, extreme precipitation can cause havoc
83 in cities. In NYC even precipitation events as low as 38 mm are of concern to local authorities because they
84 create surface flooding which impact residents and infrastructures.

85
86 In general, hazards in urban areas also overlap spatially and/or temporally (e.g. high rainfalls and storm
87 surges, or heat waves followed by a storm), though these overlaps are rarely adequately captured by research
88 and policy. Attention has traditionally been paid to the physical components of risk to hazards, focusing on
89 the potential joint impacts that multiple hazards could have on the infrastructures and buildings within certain
90 sensitive areas or locations because of their frequency and intensity (e.g. Kappes et al., 2012a; van Westen
91 et al., 2002). There has been less study to assess the socio-economic components of multi-hazard risk in cities
92 in order to design combined plans and policies that can together address multiple sources of vulnerability and
93 risk (Johnson et al., 2016). Policies based on mono-hazard risk assessments could reduce or even increase
94 vulnerability and risk to other hazards affecting the same area. A multi-hazard risk assessment, instead
95 facilitates identifying potential synergies or tradeoffs for adaptation policies and specific interventions and

96 can maximize resilience and adaptation by meeting challenges posed by different sources of natural hazard
97 risk. For example, tree planting or green roof investments to increase stormwater infiltration can also be a
98 synergistic strategy for the reduction of the urban heat island (UHI).

99

100 The objective of this study is to provide an improved multi-hazard risk assessment methodology which is
101 then applied to NYC as a case study of how megacities in coastal areas are affected by multiple, spatially
102 overlapping hazards. NYC is an important megacity for examining multi-hazard risk given its global
103 prominence as the largest city in the U.S. with hundreds of US\$ billions in assets and millions of people at
104 risk. It is a coastal city threatened by multiple hydro-meteorological hazards, further exacerbated by climate
105 change. Here we report data on past and future, potential multi-hazards events in NYC and assess the
106 combined socio-economic risks of residents to three different sources of climatic hazards: heat waves, inland
107 flooding and coastal flooding. The analysis is based on the spatial features of hazards and social vulnerability
108 in the city to inform resilience and adaptation planning that typically focuses interventions on single hazards.
109 In this way we intend to provide a scientific basis with context specific and expert based input for improving
110 our understanding of multi-hazard risk in the city, for future planning in the city as well as recommendations
111 for real world implementation of such a multi-hazard assessment for other similarly exposed urban areas.

112

113 **1.1. Vulnerability and risk assessment to natural hazards**

114 The study of the impacts of natural hazards on the social-ecological systems has moved from the focus on
115 the geophysical, climatological or hydro-meteorological phenomena by considering first physical
116 vulnerability (i.e. exposure and fragility of the exposed elements) and only later the socio-economic,
117 institutional and cultural factors that increase the exposure, susceptibility and coping capacity of the system
118 (Bankoff et al., 2004; Birkmann, 2006; Cardona, 2004). In this perspective the occurrence of a hazard does
119 not necessarily lead to a disaster. Disasters are socio-cultural constructions mainly driven by the fragilities
120 of the affected social-ecological system, its health and it's management approach, which all contribute in
121 defining risk from hazards (Oliver-Smith, 2004). Risk thus concerns the values, knowledge and actions of a
122 particular society (Cardona, 2004; Wisner et al., 2014). Economic factors also play a role in defining
123 vulnerability and thus risk. For instance, poor populations tend to settle in hazard prone areas where housing
124 costs are lower, a result of past political, economic and cultural legacies that provide them with little
125 alternative, putting them at higher risk (Wisner et al., 2014). The same hazard can cause very different
126 impacts in adjacent areas but which differ for their socio-economic activities and institutional or governance
127 practices. An example from Collins (2010) describes how, in "Paso del Norte" (a city between two countries:
128 El Paso County, USA and Ciudad Juárez, Mexico), the impacts of floods, that occurred between July and
129 September 2006, were overall of an order of greater magnitude in the Mexican part of the city due to unequal
130 power relations expressed through the economic system. Risk is thus a complex concept that encompasses
131 both the features of the hazard and that of the system potentially affected.

132 **1.2. Multi-hazard risk assessment**

133 A subgroup of hazard risk-assessments that considers more than one hazard at a time are called multi-hazard
134 risk assessments. The UNSIDR glossary of term of 2009 defines multi-hazard as “(1) the selection of multiple
135 major hazards that the country faces, and (2) the specific contexts where hazardous events may occur
136 simultaneously, cascadingly or cumulatively over time, and taking into account the potential interrelated
137 effects.” The need for multi-hazard approaches is acknowledged at the local, national and international level.
138 Already in the early 1990s, the multi-hazard risk approach was proposed as a requirement for the
139 development of strategies aiming at sustainable urban development. The need for multi-risk assessment is
140 part of Agenda 21 for sustainable development, formulated during the UN Summit in Rio in 1992, which
141 requests “complete multi-hazard research” as part of human settlement planning and management in disaster-
142 prone areas (UNEP, 1992). This was reaffirmed in the Johannesburg Declaration of Sustainable Development
143 in 2002, which required “[a]n integrated, multi-hazard, inclusive approach to address vulnerability, risk
144 assessment and disaster management, including prevention, mitigation, preparedness, response and recovery”
145 (UN, 2002, p.20). The Hyogo Framework of Action 2005-2015 pledged for the introduction of “integrated,
146 multi-hazard approach[es] for disaster risk reduction [...] into policies, planning and programming related to
147 sustainable development, relief, rehabilitation, and recovery activities in post-disaster and post-conflict
148 situations in disaster-prone countries” (UNISDR, 2005). The Sendai Framework for Disaster Risk Reduction
149 2015-2030, which follows the Hyogo Framework of Action, calls for disaster risk reduction practices to be
150 multi-hazard, besides being multi-sectoral and inclusive. And yet, despite decades of attention, we still have
151 little understanding of risks posed by multiple hazards spatially and temporally interacting in sensitive area
152 around the world (Wipulanusat et al., 2011).

153

154 There are different ways to look at how multiple hazards affect a same area, or a group of subjects or objects.
155 A hazard can lead to another hazard through cascading effects (e.g. a heavy storm causing landslides) (1);
156 two or more hazards can simultaneously impact a same area (2); or hazards can impact in sequence a same
157 subject or object leading to cumulative effects (3) (Kappes et al., 2012b). Some studies have assessed
158 different aspects of multi-hazard risk in the recent literature. Bernal et al. (2017), adopt a probabilistic
159 approach to analyze physical risk to earthquakes, landslides, and volcanic eruptions jointly. A similar
160 approach to physical risk was adopted by van Westen (2002). Liu et al. (2015) propose a multi-hazard risk
161 framework, comparable to the one we apply in this study, but show an example of multi-hazard risk focusing
162 on physical vulnerability. Forzieri et al. (2016), look at the multi-hazard assessment in Europe linked to
163 climate change impacts, but considering the hazards features only and leaving for future investigation the
164 vulnerability component. Most of these case studies look at physical vulnerability and risk and consider
165 potentially cascading hazards. Few studies have looked at the socio-economic component of risk in multi-
166 hazards assessments (Greiving, 2006; Johnson et al., 2016). Here, we explore the socio-economic
167 vulnerability and risk spatially and by using an extensive survey amongst local experts and stakeholders to
168 identify sources of multi-hazards risk and derive weights assessing the importance of the different hazards
169 and the vulnerability indicators selected. This is an additional feature of this type of studies that aims at

170 further adapting the study to the local conditions. We thus developed a highly context specific case of multi-
171 hazard risk in NYC, but with a generalizable multi-hazard risk assessment approach that can be adapted to
172 other regions with variations on the choice of the hazards, vulnerability indicators and weights assigned to
173 the indicators themselves. The methodology, in fact, intends to add to the literature on multi-hazard risk
174 assessment by integrating locally adapted weights derived from expert opinions.

175

176 **1.2.1 Multi-hazard risk in urban areas**

177 Urban areas worldwide tend to suffer greater fatalities and economic losses when compared to their rural
178 counterparts due to the concentration of people, infrastructures and assets as well as to inadequate
179 management (Dickson et al., 2012). The high concentration of infrastructures in urban areas (water supply
180 network, sewage systems, transportation, subways, roads and railways, energy supply network,
181 telecommunication system, green infrastructures) put them particularly at risk in case of failure or damages
182 of these critical systems (Graham, 2010). Amongst the natural hazards, heat wave is a predominantly an
183 urban hazard, meaning that higher degrees of mortality and morbidity are experienced in cities compared to
184 rural areas (Clarke, 1972; D'Ippoliti et al., 2010). In coastal cities a high number of people are also exposed
185 to storm surges, water intrusion and erosion (Nicholls and Small, 2002). Coastal ecosystems are the most
186 productive as well as the most threatened by human activity and expanding urban development in these zones
187 with increasing concentration of infrastructure and people ultimately further increases risk (MA, 2005;
188 Pelling and Blackburn, 2013). Urbanization and climate change in coastal areas are on a collision course and
189 understanding and planning for multi-hazard risk is an increasingly critical part of climate change resilience
190 and adaptation planning, policy and management.

191

192 Different hazards such as floods, heat waves and earthquakes, when concentrated in densely populated urban
193 areas, make multi-hazard assessment an important yet challenging task for decision makers. A recent study
194 analyzed the risk to multiple hazards including landslide, typhoon and heat wave in two districts of Hong
195 Kong and found that, despite socio-economic differences of the two districts, both present comparable levels
196 of risk (Johnson et al., 2016). van Westen et al. (2002) looked at physical risk (i.e. of buildings and
197 infrastructures) in a spatial manner to suggest possible mitigation measures for Turrialba in Costa Rica, a city
198 exposed to flooding, landslides and earthquakes. Kappes et al. (2012a) assessed geo-physical risk of Faucon
199 municipality located in the Barcelonnette basin, in Southern French Alps, to debris flows, shallow landslides
200 and river flooding to support priority settings for users. Likewise, Lozoya et al. (2011) took an ecological
201 perspective to assess risk of multiple hazards such as riverine floods, storm-induced coastal floods and storm-
202 induced erosion in S'Abanell urban and touristic beach of Spain, finding that cultural and regulating
203 ecosystem services were the most affected by hazards in the area. Overall, few studies have focused on multi-
204 hazard risk assessment with a strong social component to understand vulnerability in coastal megacities of
205 the developed world.

206

207 Multi-hazard mapping, which consists of “the totality of relevant hazards in a defined area” (Kappes et al.,
208 2012b), is a fundamental approach for multi-hazard risk assessment in urban areas and relevant for the NYC
209 area. Such an approach allows for the identification of potential hotspots of risk and vulnerability derived
210 from spatial combination of more than one hazard. The effects of the hazards are considered as additive, with
211 overlapping degrees of impacts. In this way, the impacts acting in the same locations, without interacting
212 causally or coinciding contemporaneously, can be considered jointly. The approach facilitates the
213 identification of structural improvements that can lead to the combined reduction of the exposure to two or
214 more hazards in urban areas. The socio-economic determinants of vulnerability, which often lead to the
215 concentration of vulnerable people in certain areas of the city, are examined jointly and help the identification
216 of zones of the city more likely to suffer harm from multiple hazards and in which more resources should be
217 invested for adaptation. Multi-hazard risk is composed of two main steps: the analysis of the hazards and of
218 the vulnerability of the system. Thus it widely refers to the vast literature on disaster risk and vulnerability
219 assessment mentioned above (e.g. Birkmann, 2006; Birkmann et al., 2013; Bogardi and Birkmann, 2004;
220 Cardona, 2004; Pelling, 2003; Turner et al., 2003; Wisner et al., 2014). The vulnerability component
221 expresses the predisposition of the system to suffer harm and it generally expressed through the degree of
222 exposure of the system (or number of subjects or objects potentially affected by the hazard), the susceptibility
223 (or the fragilities of the system exposed such as the health of the population) and the lack of resilience (or
224 the incapacity to be prepared, cope and respond to the hazard) (Birkmann et al., 2013). Here, we analyze
225 how multiple hazard risks overlap spatially in New York City with the goal of supporting planning and policy
226 for three key objectives: 1) to improve risk reduction through multi-purpose strategies, 2) to improve adaptive
227 capacity of the city, and 3) to suggest a potential approach for similar multi-hazard risk assessments in other
228 vulnerable urban areas and settlements.

229

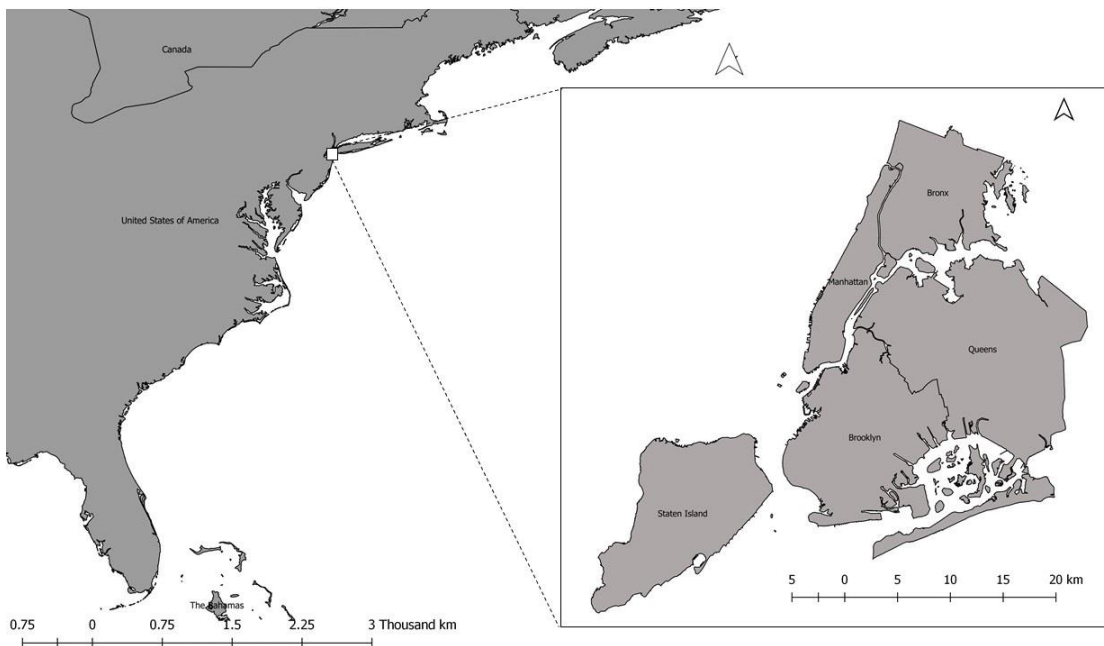

230 **1.3. New York City and disaster risk**

231 NYC is the largest city in USA and is located on the East coast (see Figure 1), with approximately 8.6 million
232 people in 2017 and just in the municipal area to U.S. Census Bureau. The NYC-Newark-New Jersey
233 metropolitan statistical area is much larger, with 20.3 Million people living in the region closely connected
234 socially, economically, and infrastructurally to NYC¹. The metropolitan area is also the largest economically
235 in the U.S. (U.S. Census Bureau, 2010). Approximately 1.4 million people aged 60 and older live in the city,
236 representing a particularly vulnerable group, especially for heat-related morbidity and mortality. Elderly
237 constitute 17% of the population at present, and this proportion is expected to grow considerably in coming
238 years (Goldman et al., 2014). NYC is also built around a network of rivers, estuaries and islands with much
239 of the Metropolitan region situated less than 5 m above mean sea level (Colle et al., 2008) which contributes
240 to the hazard context especially in terms of coastal flooding.

241

¹ <https://factfinder.census.gov/faces/tableservices/jsf/pages/productview.xhtml?src=bkmk> (retrieved on March 25th 2018)

242 We focus our analysis on three hazards that cause the highest human impacts in NYC (see Depietri and
243 McPhearson, 2018): heat waves, inland flooding and coastal flooding. Heat waves in NYC are defined by
244 the NYC Panel on Climate Change (NPCC) 2015 Report as three consecutive days above 90F (or about 32.2
245 °C) (Horton et al., 2015a). Inland flooding in NYC can be triggered by precipitation of more than 1.5 inches
246 (or 38 mm) of rain per day since the city’s drainage system is designed to handle heavy rainfall with
247 intensities of 1.5 inches (about 38 mm) per day in most areas of the city where sewers were built prior to
248 1960, and of 1.75 inches (about 44 mm) per day in locations with sewers were built after 1960 (Llyod and
249 Licata, n.d.). Coastal flooding is primarily driven by storm surge. NYC is affected by changing climate with
250 future projections including probable higher temperatures, increasingly frequent heavy downpours, and a
251 rising sea level that will further increase storm surge and coastal flooding (Garner et al., 2017; Horton et al.,
252 2015a; Lin et al., 2012, 2016; Reed et al., 2015; Rosenzweig and Solecki, 2015). In the next sections, we
253 describe each hazard and its local impacts. Information about multi-hazard risk in the city is scarce in the
254 available literature, consequently we have combined multiple sources of evidence of the occurrence of multi-
255 hazards events in NYC and review them in section 3.1.

256
257 **Figure 1.** Location of New York City and the map of its boroughs.
258

259 **1.3.1. Heat waves**

260 Heat waves in NYC are the largest cause of death due to socio-natural hazards (Depietri and McPhearson,
261 2018; NYC, 2014). Past disastrous heat waves include the July 1966 event, where the mortality rate increased
262 by 36% (Schuman, 1972) and the summer 1972 heat wave which caused 253 deaths on the 24th of July only
263 (Ellis et al., 1975). According to the NYC Department of Health and Mental Hygiene, 46 heat stroke deaths
264 resulted from two heat waves in July-August 2006 while 26 heat related deaths occurred during the heat wave
265 of July 2013 (NYC, 2006, 2014). Between 2000 and 2011, 447 patients were treated for heat illness and 154

266 died (CDCP, 2013). A study by Madrigano et al. (2015) reported up to 234 heat related excess death for the
267 same period. It has been documented that extreme heat impacts have been increasing at least for the period
268 1987-2005 (Anderson and Bell, 2011). However, numbers of deaths are significantly less pronounced if
269 compared to the first half of 20th century, showing an evidence of adaptation likely due to the use of air
270 conditioning (Depietri and McPhearson, 2018; Petkova et al., 2014).

271

272 Risk to heat waves is driven by several factors. Those with poor socio-economic status, for example black
273 (non-Hispanic) individuals, and the socially or linguistically isolated are more likely to die during a heat
274 wave (Madrigano et al., 2015). People with chronic physical or mental health illnesses (i.e. cardiovascular
275 disease, obesity, neurologic or psychiatric disease) also account for a large part of the causalities, together
276 with individuals subject to alcohol or drugs abuse (CDCP, 2013; Ellis et al., 1975). The ageing population is
277 the most at risk to suffer heat stroke during a heat wave (Luber and McGeehin, 2008; Oudin Åström et al.,
278 2011). Madrigano et al. (2015) also found that greener neighborhoods were less at risk in NYC, potentially
279 due to decreased urban heat island in those areas of the city. Increased rates of poverty and higher densities
280 of African-American populations were found to be highly correlated with the lack of green spaces in the city
281 (Klein Rosenthal et al., 2014). Low income and crowding were also elements of risk in the 1966 heat waves
282 according to Schuman (1972). Primary indicators of heat vulnerability are relatively consistent across studies
283 with poverty, poor housing conditions, low access to air-conditioning and seniors' hypertension associated
284 with elderly death due to heat stress in NYC between 1997 to 2006 (Klein Rosenthal et al., 2014).
285 Environmental conditions, previous land cover and aggregated surface temperatures were also found to be
286 positively associated with heat related deaths of elderly (Klein Rosenthal et al., 2014).

287

288 Gedzelman et al. (2003) calculated the UHI of NYC to be on average approximately 4 °C in summer and
289 autumn and 3 °C in winter and spring according to measurement taken between 1997 and 1998 (Gedzelman
290 et al., 2003). Temperatures have been rising in Central Park between 1900 to 2013 (Horton et al., 2015a).
291 More in particular, it has been estimated that the temperature rose by 1.1 °C between 1900 to 1997 in NYC
292 (Knowlton et al., 2007). One third of the total warming of the city since 1900 was attributed to the
293 intensification of the UHI. Projections show that this trend is likely to continue in the future, with warmer
294 temperatures in NYC in the coming decades driven by UHI and increasing temperatures caused by climate
295 change (Horton et al., 2015a). A study by Knowlton et al. (2007) showed that, despite the possibility to adapt
296 to rising temperature, heat related premature deaths are likely to rise in projected future climates and affect
297 regions also beyond the urban core of the city. Spatial and temporal patterns of current risk combined with
298 projections for increasing temperatures and frequency and intensity of heat waves thus suggests the need for
299 extensive planning and management to reduce heat risk in NYC.

300

301 **1.3.2. Inland floods**

302 In the city, the built environment – dense and heavily paved built up areas and reclaimed wetlands – limit the
303 ground's capacity to absorb and drain water, raising the risk of urban or inland surface flooding. Sealed

304 surfaces cover 72% of the NYC areas according to the city Department of Environmental Protection. Much
305 of NYC's infrastructure, especially in low-lying or poor drainage areas, cannot cope with more than 1.5
306 inches per hour of rainfall (Lane et al., 2013). According to NYC (2014), communities in low-lying areas
307 with limited drainage capacity tend to experience sewer backups, street and basement flooding that can
308 expose them to contaminated storm water and wastewater. Combined sewer overflows, occurring when
309 sewage and storm water are discharged from sewer pipes without treatment, because of the treatments plants
310 are unable to handle flows, are frequent in NYC and are a significant source of environmental pollution
311 (Rosenzweig et al., 2006). Excessive rain washes away pollutants from the streets which end up in the
312 surrounding bodies of water. Exposure to contaminated water can have both short and long-term public health
313 effects. Flooded basements and houses increase allergies, asthma and other respiratory illness from exposure
314 to mold and fungus. However, flash floods in NYC are rarely life threatening because of the local topography
315 (Lane et al., 2013).

316
317 Recent research using historical data has suggested that for the NYC region, daily precipitation extremes are
318 increasing in the fall with less change in all other seasons (Frei et al., 2015; Huang et al., 2017, 2018).
319 However, projections from downscaled Global Climate Models (GCMs) provide less clear evidence for a
320 shift in the intensity of flood caused by rain events in the Northeast US (Knighton et al., 2017; Schoof and
321 Robeson, 2016). The city committed to a plan to invest in green infrastructures for storm water management,
322 investing US\$ 5.3 billion and saving approx. US\$ 1.5 billion by spending a portion of this investment on
323 green infrastructure in combination with traditional pipe and tanks improvements (NYC, 2010). The green
324 infrastructures planned include green and blue roofs, rain gardens, permeable pavements, bioswales and the
325 planting of street trees. However, inland flooding is likely to continue to pose significant risks to the urban
326 residents of NYC.

327

328 **1.3.3. Coastal flooding**

329 Almost 33 square miles (about 85.5 square km) of NYC are within the equivalent of a 100-year floodplain
330 (close to half of Brooklyn) (NYC, 2013). The most frequent coastal storms affecting NYC are nor'easters
331 (i.e. storms along the East Coast of North America, so called because the winds over the coastal area are
332 typically from the northeast, according to NOAA²). Even moderate nor'easters events can cause significant
333 flooding (Colle et al., 2008) and are often associated with extended periods of high winds and high water
334 (Orton et al., 2012; Rosenzweig et al., 2011). Extratropical first and then tropical cyclones tend to generate
335 the greatest storm surge heights and flooding in NYC (Catalano and Broccoli, 2017; Smith et al., 2010;
336 Towey et al., 2018), which can reach up to 5.12 m according to Lin et al. (2010). Extratropical storms account
337 for 80%–85% of total precipitation from December to May and 93%–100% of extreme precipitation from
338 November to May in the Northeastern coast of the U.S. (Agel et al., 2015). Hurricanes affect NYC more
339 infrequently. However the associated flooding are being exacerbated due to the increase of sea level and the

² <https://www.weather.gov/safety/winter-noreaster> (retrieved on the 16th of September 2018)

340 increase in the intensity of the hazard itself (Kemp and Horton, 2013; Reed et al., 2015). Five major
341 hurricanes of category 3 have affected the New York area between 1851 and 2010, mostly in the month of
342 September (Blake et al., 2011) and generally lead to large damages (Rosenzweig et al., 2011). In 2012,
343 Hurricane Sandy made landfall as a post-tropical cyclone in New Jersey with 70-kt maximum sustained
344 winds, driving a catastrophic storm surge into the New Jersey and New York coastlines (Blake et al., 2013).
345 In NYC the storm surge was of 2.81 m and was at the origin of most of the damages and losses (Kemp and
346 Horton, 2013). Hurricane Sandy caused 43 deaths in NYC and nearly half were adults aged 65 or older
347 (Kinney et al., 2015). According to Lane et al. (2013), death was caused most frequently by drowning
348 associated with the storm surge. Other deaths were caused by falling trees, falls, electrocution, and other
349 traumas. Further, Sandy caused at least \$19 billion in economic losses to the city (NYC, 2013), left hundreds
350 of thousands without power, some for many weeks (Lane et al., 2013). It was also found that power outages
351 increase risk of death in NYC (Anderson and Bell, 2012). Five hospitals shut down due to Sandy, three of
352 them had to evacuate patients after the storm hit because of flood damage to critical equipment; power losses
353 in these facilities further complicated evacuation operations (Lane et al., 2013). Nearly 70,000 buildings were
354 damaged by the storm or destroyed by related fire especially in south Brooklyn, South Queens and Staten
355 Island; the subway system was seriously affected; roads, railroads and airports were flooded; while the
356 communication system was disrupted in many areas (NYC, 2013).

357

358 Since Hurricane Sandy, the city established a US\$20 billion plan to adapt to climate extremes with 257
359 initiatives which span from coastal protection, economic recovery, community preparedness and response,
360 and environmental protection and remediation (NYC, 2013). Additionally, the Mayor's Office of Housing
361 Recovery Operations was established in 2013 to oversee housing recovery in NYC.

362

363 Increasing hurricane intensity over time has been detected (Gornitz et al., 2001; Knutson et al., 2015).
364 Additionally, three of the nine highest recorded water levels in the New York Harbor region have occurred
365 since 2010, and eight of the largest twenty have occurred since 1990 (Talke et al., 2014). 40% of sea level
366 rise in NYC is driven by subsidence and the rest by global climate change, amounting in total to 25,4 mm
367 per decade since 1900 (Horton et al., 2015b). Due to sea level rise, which is projected to accelerate during
368 this century to reach up to 1.2 m in the coming century (Kopp et al., 2014), coastal flooding in NYC is
369 expected to become more frequent and intense, even in absence of changes in intensity and frequency of
370 storms (Colle et al., 2008; Gornitz et al., 2001; Horton et al., 2015b). A recent study has shown that, by 2030-
371 2045, the megacity could be affected by significant flooding on average every 5 years (Garner et al., 2017).
372 This is ever more significant when considering the high and increasing concentration of assets and people
373 exposed in the coastal areas of the city (Aerts and Botzen, 2012). According to Aerts et al. (2013), the
374 estimated flood damage to buildings for NYC is between US\$ 59 and 129 million/year, while the damage
375 caused by a 100-year storm surge is within a range of US\$ 2 to 5 billion.

2. Methods

2.1. Multi-hazards events in New York City and indicators weighting

We present an improved method for multi-hazard risk in cities generally, and applied to the case study of NYC as a coastal megacity. Similar methodologies have been presented by Johnson (2016) and Grieving (2006), however here we integrated weights derived from local expert opinions. We assessed past heavy precipitation and extreme high temperatures based on daily precipitation and daily max temperatures recorded in Central Park from 1876 to 2016 and made available by the US National Oceanic and Atmospheric Administration (NOAA) to examine how temporally consecutive events occur in the city as part of a broader study initially presented in Depietri and McPhearson (2018). We conducted an analysis of daily NOAA's meteorological records (including daily precipitation, max and min temperatures) to identify dates in which an event of extreme heat would be immediately followed by a storm (or vice versa), two consecutive heat waves events (happening within 3 days max away from each other's) and consecutive flooding events (two consecutive days of extreme precipitation). We then manually investigated the New York Times database for relevant articles appearing in the edition of the day following the multi-hazard event identified, this to analyze more in depth the occurrence and social, infrastructural and economic impact of cumulative events. We then conducted a survey of local experts and decision-makers with a principal objective to collect weights multi-hazard risk assessment for indicators and sub-indicators selected, but also to collect information of past and future, potential multi-hazards event occurring in the city.

For the survey, we drafted a comprehensive list of the local authorities' representatives, researchers and other local actors such as NGOs whose daily work is related to different aspects of vulnerability and risk to hazards in NYC. The respondents to the survey were thus identified as being highly knowledgeable and to have experience of the local hazard risks and impacts. The institutional, urban planning, environmental planning, disaster risk reduction, health and social sectors were represented in the survey. A total of 122 invitation e-mails were sent to contact persons belonging to local and federal institutions as well as local NGOs. Of these, 10 were no longer valid and we subsequently collected 65 responses with a 58% response rate. The survey was anonymous but almost 60% of the respondents belonged to local jurisdictions, about 15% to NGOs, 10% to local universities, while state agencies, federal agencies, and companies represented less than 5% each. No further information about the respondent identity were collected to ensure anonymity.

The list of indicators and sub-indicators weighted by the respondent of the questionnaire were derived from the relevant literature. The final list included those indicators able to describe the vulnerability to the three hazards jointly for which data was available. For the weighting of indicators, we adopted the method of budget allocation, a participatory method (Saisana and Tarantola, 2002). Respondents were asked to rate each indicators by assigning 100 points distributed amongst the set of indicators describing the composite index. Final weights were derived by averaging the scores assigned by each respondent and dividing the means by 100. The weights thus derived were normalized to a fraction of to 1 for each category. Unlike other methods such as analytic hierarchy process (AHP) and Delphi, the technique of budget allocation is intuitive,

415 computationally simple, but accurate, and therefore widely used (Saisana and Tarantola, 2002). The weights
416 obtained are listed in Tables 1 and 2. Additional questions in the survey were related to multi-hazard risk in
417 NYC and the city preparedness to cope with different hazards. The results are presented in section 3.1.

418

419 **2.2. Multi-hazard risk assessment**

420 We assessed multi-hazard risk to the main three hydro-meteorological hazards affecting NYC described
421 above. In this study, we emphasize the inclusion of social factors of risk by adapting our methodology from
422 Greiving (2006) who carried out a multi-hazard risk assessment at the country level for Europe and from
423 Johnson et al. (2016) who applied a similar methodology to the case of two Hong Kong districts. Overall, the
424 methodology consists of generating hazards maps, one for each hazard (which are then combined in a multi-
425 hazard map) and a common vulnerability map to the three hazards that includes socio-economic indicators.
426 We then obtained the final risk map as the product of the combined multi-hazards map and the common
427 vulnerability map. Note that all variable used have been normalized and expressed as levels, ranging from 1
428 to 5, of hazards intensity, exposure, susceptibility, lack of coping capacity and then vulnerability and risk.
429 This normalization, widely in use in vulnerability and risk assessments, allowed us to conduct analyses across
430 different, otherwise incommensurate, variables.

431

432 **2.2.1. Hazards mapping**

433 Multi-hazard risk assessment consists of an initial study of combined hazards which overlap temporally and
434 spatially in the megacity. We created a raster surface for each hazard by categorizing the hazard intensity
435 into five ordinal scales of 1 to 5, which are equivalent to standardized hazard levels of very low, low, medium,
436 high and very high. We used Natural Break (Jenks) method of data classification in ESRI's ArcGIS software
437 as the method considers both the span of values and the number of observations for each category (Smith et
438 al., 2007), and is widely used for classification in mapping (Huang et al., 2011).

439

440 Especially in the urban context, hazards present a significant social component which magnify impacts due
441 to the high modification of the environment. For creating heat wave hazard surface, we maintained that the
442 hazard affects the entire city with different intensities according to two aggravating factors: surface
443 temperature and air pollution. Surface temperature was derived from thermal band of 2011 Landsat imagery
444 captured on the 15th and 31st of July, while air pollution layer was developed based on raster surfaces of 300-
445 meter resolution for 2010 with annual average values of PM_{2.5} and ozone O₃ concentrations. PM₁₀ and O₃ are
446 the main contributors to extreme heat mortality besides heat itself (see Depietri et al., 2011 for a review). We
447 acquired the air pollution data from New York City Community Air Survey (NYCCAS) carried out by the
448 New York City Department of Health and Mental Hygiene, Queens College Center for the Biology of Natural
449 Systems, and Zev Ross Spatial Analysis. Indicators used to develop the heat hazard map were weighted
450 according to the survey responses (see Table 1 and Equation 1 and 2), and then combined resulting in a raster
451 surface with values ranging from 1 to 5.

452

453 $AP = 0.483 O + 0.517 PM$ (Eq. 1)

454 $HW = 0.632 ST + 0.367 AP$ (Eq. 2)

455

456 where AP stands for air pollution, O for ozone and PM for particulate matter smaller than 2.5µm. HW stands
 457 for heat wave hazard and ST for surface temperature. Additional scenarios for applying weightings could be
 458 applied that take into account different priorities amongst diverse stakeholders in the city and here we present
 459 a single scenario where the mean weight from all respondents was applied which has proved to be informative
 460 about the nuances of the factors determining multi-hazard risk in NYC.

461

462 **Table 1.** Hazard indicators selected, and weights derived from the survey with standard deviations (SD).
 463 (The SD are equal due to the weighting method which required the allocation of 100 points amongst the sub-
 464 indicators indices).

465

Hazards (H)	Weight	SD	Indicator	Weight	SD	Sub-indicator	Weight	SD
Heat waves (HW)	0.378	0.127	Surface temperature (ST)	0.632	0.156			
			Air pollution (AP)	0.367	0.156	Ozone (O)	0.483	0.156
						Particulate Matter <2.5µm (PM)	0.517	0.156
Inland flooding (IF)	0.205	0.080	311 calls					
Coastal flooding (CF)	0.417	0.132	Hurricane inundation zones					

466

467

468 The inland flooding map was derived through a spatial interpolation of 311 calls for street flooding (data
 469 available between January 2010 and December 2015) and basement flooding (data available between July
 470 2011 and December 2015). The 311 calls were obtained from a spatial database developed and maintained
 471 by the city of New York which comprises of all sorts of complaint calls. When preparing the inland flooding
 472 layer, we removed from the dataset the complaint points that had been recorded during or one day after the
 473 event of coastal storms, this to maintain differences between precipitation driven inland flooding and coastal
 474 flooding driven by storm surges. The dates and times of storm surges in NYC coastal area were obtained
 475 from NOAA’s storm events database³ under the keywords “coastal flooding”, “high surf”, “tropical storm”,
 476 “storm surge/tide”. The 311 calls dataset has nonetheless some limitations worth a mention. For instance, it
 477 does not account for possible differences in the likelihood of reporting flooding amongst populations (e.g.

³ <https://www.ncdc.noaa.gov/stormevents> (retrieved on February 23rd 2017)

478 depending on income). However, this is the only available dataset on inland flood occurrence and allows us
479 to consider one of the most frequent and perennial natural hazards affecting NYC – flooding driven by
480 precipitation. Still, NOAA tide gauge data at the Battery in NYC is a useful source of continuously recorded
481 water surface elevation and therefore could be used as an indicator of storm surge heights, though not
482 included in this analysis.

483

484 For coastal flood inundation we used the local expert map obtained from the NYC Office of Emergency
485 Management (OEM) with hurricane inundation zones published in 2013. Local authorities suggested that we
486 adopt the hazard map produced after Hurricane Sandy as this would be a more conservative starting point.
487 However, we opted for the general map considering multiple levels of hazard as this had predefined
488 categories of hazard and thus was better able to be compared with the other hazards in a multi-hazard analysis.

489

490 The hazards' weights reported in Table 1 indicate that, according to the surveyed respondents, higher impacts
491 would be caused by coastal hazards. This result might be justified by considering the recent occurrence of
492 Hurricane Sandy and its high impacts which triggered high concern amongst local authorities. A final multi-
493 hazard map (H) was generated by adding weighted values of the three hazard layers (IF - inland flooding; CF
494 - coastal flooding), as presented in Equation 3. The resultant composite hazard layer also has values ranging
495 between 1 and 5 to represent the five respective classes of hazard intensity.

496

$$497 \quad H = 0.378 HW + 0.205 IF + 0.417 CF \quad (\text{Eq. 3})$$

498

499 The weighted linear combination of the three hazards intensities considers the hazards to spatially overlap
500 without any additional quantifiable interactions.

501

502 **2.2.2. Vulnerability and risk maps**

503 To be compatible with computation of hazard layers, we developed raster surfaces of 30m spatial resolution
504 for different socio-economic and demographic variables relevant for the three hazards, describing the three
505 components of vulnerability as listed in Table 2. For this reason, we disaggregated the 2010 census data made
506 available by the US Census bureau at the block group level. Disaggregation of census data using dasymetric
507 approaches to a finer spatial scale follows Mennis and Hultgren (2006). We used the number of residential
508 units, land use type, and building type as ancillary information to convert demographic totals from census
509 block groups to spatially corresponding cadastral lots for each vulnerability indicator. The disaggregated data
510 layers were then resampled to a spatial resolution of 30 m to maintain uniformity with the spatial resolution
511 of hazard data layers. These data were used to derive a vulnerability map based on indicators describing
512 exposure, susceptibility and lack of coping capacity. Selection of these indicators stemmed from the review
513 of available literature covered in sections 1.3.1 to 1.3.3 and the weights derived from the survey are presented
514 in Table 2.

515

516 **Table 2.** Vulnerability indicators and weights derived from the survey with standard deviations (SD). (Note:
 517 the SD for the two indicators of Lack of coping capacity are equal due to the weighting method which
 518 required the allocation of 100 points amongst the sub-indicators indices).
 519

	Component	Indicator	Weight	SD
<i>Vulnerability (V)</i>	<i>Exposure (E)</i>	Population (P)		
	<i>Susceptibility (S)</i>	Pop over 65(El)	0.351	0.146
		Children (<18) (C)	0.212	0.098
		1- Median income (I)	0.191	0.112
		African Americans (AA)	0.170	0.085
		No schooling completed (NS)	0.117	0.062
	<i>Lack of coping capacity (CC)</i>	Speak no English (L)	0.516	0.168
		One-person household (HH)	0.484	0.168

520
 521 Vulnerability is defined as the “propensity of exposed elements such as physical or capital assets, as well as
 522 human beings and their livelihoods, to experience harm and suffer damage and loss when impacted by single
 523 or compound hazard events” (Birkmann et al., 2013, p.195). This vulnerability perspective in risk reduction
 524 particularly looks at the socio-economic, institutional and cultural conditions of people and physical assets
 525 which can be affected by a hazard as well as at their capacity to prevent and cope with the impacts of that
 526 event. As mentioned, in Birkmann et al. (2013, p.200), vulnerability is described through three components
 527 defined above: exposure, susceptibility and lack of coping capacity.

528
 529 The first step in the socio-economic vulnerability assessment was to identify the exposed subjects. Exposure
 530 (E) was calculated as the number of inhabitants (P) for each 30 x 30 m spatial unit. The other two components
 531 of vulnerability are susceptibility (S) and lack of coping capacity (CC). Like the hazards mapping described
 532 above, we reclassified each of the indicators into five intensity categories represented by the values of 1 to 5
 533 in such a way that 5 represents the highest level of intensity. For example, smaller values in median income
 534 layer represent higher degree of susceptibility and hence were given higher intensity values. The two
 535 components of vulnerability (S and CC) were calculated according to Equation 4 and 5:

536
 537
$$S = 0.351 EL + 0.212 C + 0.191 I + 0.170 AA + 0.117 NS \quad (\text{Eq. 4})$$

538
$$CC = 0.516 L + 0.484 HH \quad (\text{Eq. 5})$$

539
 540 where EL stands for elderly, C for children, I for median income, AA for African Americans, NS for no
 541 schooling, L speak no English, HH one-person household. We aggregated the indicators as a weighted sum,
 542 as each indicator contributes for a fraction of the susceptibility or lack of coping capacity. The S and CC
 543 layers thus generated have values ranging between 1 and 5.

544
 545 Some indicators (i.e. homes in deteriorated or dilapidated buildings, mold in home, asthma, heart attack
 546 hospitalizations, overweight, adults reporting heavy drinking, crowding, air conditioning, adults with

547 personal doctor and adults with health insurance) were considered but excluded in the final list because they
548 were not available at the low scale for NYC or because some were not relevant for the three hazards when
549 jointly considered. Respondents to the survey also suggested some additional indicators to consider and are
550 summarized in the results section.

551 The final vulnerability (V) map was generated by adding exposure (E), susceptibility (S) and lack of coping
552 capacity (CC) layers with equal weights (Equation 6):

553

$$554 \quad V = \frac{1}{3}E + \frac{1}{3}S + \frac{1}{3}CC \quad (\text{Eq. 6})$$

555

556 We aggregated the three components of vulnerability by summing equally weighted values, a general
557 approach adopted in the literature due to the difficulty to assigning different weights to these three
558 components (see for instance Welle and Birkmann, 2015). Risk to natural hazards, such as hydro-
559 meteorological, climatological or geophysical hazard, is the combination of the probability or likelihood in
560 time and space of a natural hazard to occur and to affect a vulnerable system (UNISDR, 2015). In the disaster
561 risk reduction literature, risk is commonly defined as the product of hazard and vulnerability. The final
562 aggregated risk map was calculated by multiplying the final aggregated hazard map with the vulnerability
563 map (see Equation 7):

564

$$565 \quad R = H * V \quad (\text{Eq. 7})$$

566

567 where R is risk, H is multi-hazards and V vulnerability. We multiplied hazard per vulnerability because,
568 following to the definition of risk, with no hazard or no vulnerabilities there would be no risk. The final risk
569 map thus derived comprises of 16 classes with the values ranging from 1 to 25. As for the hazard and
570 vulnerability maps mentioned above, the final aggregated risk is also displayed using five intensity classes.

571

572 Our method of aggregation, which first quantifies the indicators of hazard and vulnerability into five ordinal
573 categories and then uses weighted linear combination, is drawn from the existing literature hazard and
574 vulnerability assessment. Previous studies on hazard risk mapping have documented the robustness and
575 accuracy of this method (Greiving, 2006; Greiving et al., 2006; Johnson et al., 2016; Michael and Samanta,
576 2016; Zhou et al., 2016).

577

578 To compare the plausibility of our results, we also followed an additional method of aggregation, which is
579 collectively described as the fuzzy-defined weighted combination (Aydi et al., 2013; Janke, 2010). We
580 followed the same procedural steps, weights, and aggregation formulae except that the numerical values of
581 each of the hazard and vulnerability layers were standardized between 0 and 1 (i.e. 0-100%) instead of the
582 five ordinal classes. When displayed the final risk layer by reclassifying into five categories based on natural
583 break (Jenks), the map was very similar to the final map generated following the method we describe above.

584

585

586 **3. Results**

587 **3.1. The qualitative results of the NOAA-NYT search and the survey**

588 Most of the temporally overlapping extreme events identified in NOAA database between 1876 to 2016 were
589 related to multiple heat waves happening at distance of up to 3 or 4 days (13 events), followed by two
590 consecutive days of extreme precipitation (9 events) and days of extreme heat followed by high precipitation
591 (3 events). However, given a broader review carried out on the New York Times and described in Depietri
592 and McPhearson (2018), we were able various additional interrelated multi-hazards incidents in NYC,
593 meaning that multi-hazard events have more interrelated impacts which might not depend only on the high
594 intensity of the hazard alone.

595

596 The stakeholders who compiled the questionnaire were also asked to provide information related to past and
597 present multi-risk events as well as strategies that they would prioritize for the city. In a multi-hazard
598 perspective, the results of the survey indicated that heat waves in NYC would highly positively interact (i.e.
599 increasing their impacts) with droughts, but also with inland and coastal flooding, although these would have
600 opposed interactions too. Inland and coastal flooding can have additive impacts if they occur at the same time
601 or successively. Furthermore, respondents indicated that other interactions between the wider ranges of
602 hazards affecting NYC have occurred in the past and may occur in the future (summarized in Table 3 and 4
603 respectively). In this study we cover many of these situations although further analysis can be envisaged to
604 better understand the interaction between the hazards and infrastructures failures.

605

606 **Table 3.** List of multi-hazard events that happened in the past according to the respondents of the
607 questionnaire.

608

Type	Combination of multi-hazard events that occurred in NYC in the past
1	Hurricane & Cold spell & Inland flooding
2	Heat waves & Thunderstorms & Inland flooding
3	Hurricane & Infrastructure failure

609

610 **Table 4.** List of multi-hazards events that the city should adapt to as these could occur in the future.

611

1	Coastal flooding & Exposure to toxic substances
2	Coastal flooding &

	Inland flooding
3	Coastal flooding & Cod Spell
4	Coastal storms & Power outages
5	Heat waves & Hurricane
6	Heat waves & Power outages
7	Heat waves & Severe thunderstorm
8	Heat waves & Drought

612

613 **3.2. Multi-hazard risk assessment**

614 Figures 2 a, b, and c present the mapped analytical results for each of the three hazards considered. Except
615 for heat stress, which is distributed across the whole city with points of low hazard intensity corresponding
616 to the urban parks, the hazards intensities are mainly concentrated along the coast, especially in Manhattan
617 and in Brooklyn.

625
626
627
628
629
630
631
632

Figure 3 displays the joint multi-hazard map with higher intensities in most of the coastal areas. Coastal flooding was assigned a larger weight with respect to the other two hazards based on survey responses, which drives the hotspot analysis somewhat. At present the city is still largely unprepared to cope with flooding and is highly exposed to this type a hazard, a condition that was particularly clear after Hurricane Sandy. Inland flooding was shown to be most intense along the coast, further strengthening the presence of hazards along coastal areas, though further modeling is required to better understand the drivers of inland flood hazards and where they are likely to occur in the future.

634
635

636 **Figure 3.** Spatial variation in the combined hazards including weights derived through expert input.

637
638

Exposure

- Very Low
- Low
- Medium
- High
- Very High

639
640

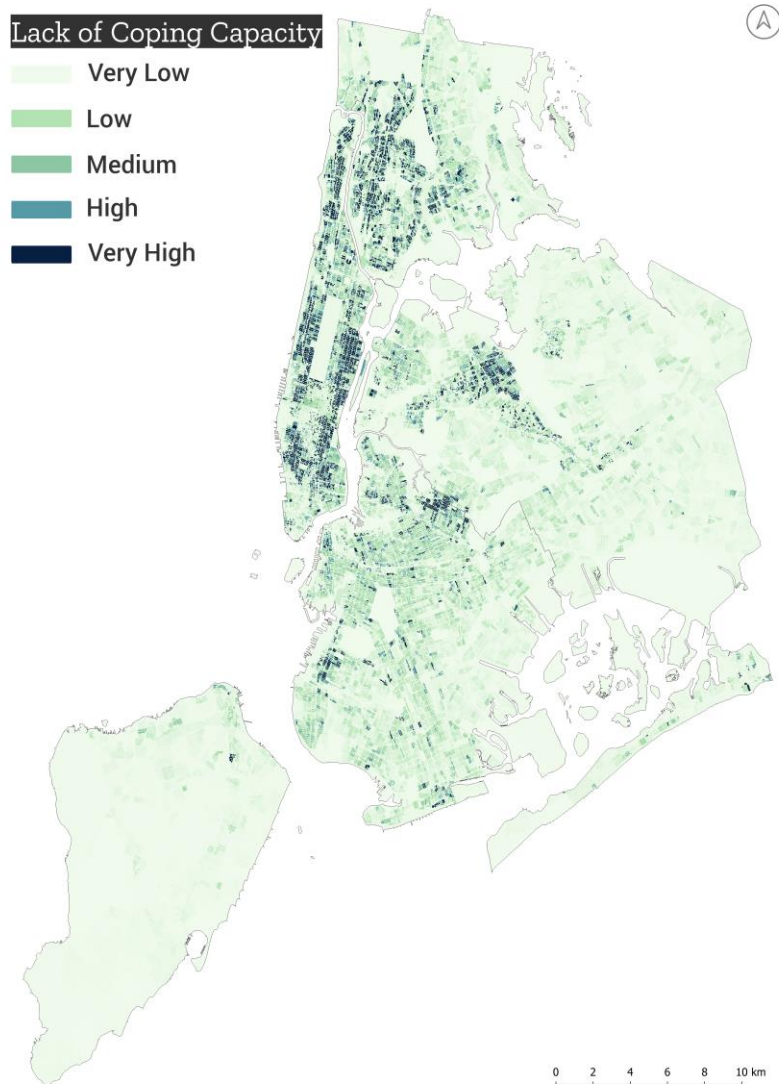

641

a. Map of exposure

b. Map of susceptibility

642

c. Map of lack of coping capacity

643

644 **Figure 4 a, b and c.** Spatial variation in three components of vulnerability (exposure, susceptibility and
 645 lack of coping capacity) to multiple hazards.

646

647 Figure 4a shows the exposure of the city based on the population. Since Manhattan has the highest density,
 648 it is where the highest exposure values are found. Parts of Brooklyn and the Bronx also have high densities
 649 but are overall less concentrated than Manhattan. The susceptibility map of the city (Figure 4b) shows that
 650 the most fragile members of the population in socio-economic terms are in some parts of Brooklyn and the
 651 Bronx. As most people living alone are in Manhattan, this area shows higher values of lack of coping
 652 capacity. While linguistic isolation (non-English speaking) explains some lack of coping capacity in part of
 653 Brooklyn and the Bronx (Figure 4c).

654

Vulnerability

655
656
657
658

Figure 5. Map of Vulnerability

659 The resultant vulnerability map (Figure 5) shows highly vulnerable populations located mainly in the Bronx,
660 large parts of Brooklyn and some parts of Manhattan (such as Harlem) and the Queens. Staten Island appears
661 as the least vulnerable compared to other parts of the city.

662

663 The survey’s respondents suggested other important indicators that can be considered in a vulnerability
664 assessment (see Table 5). These fall into the categories of indicators that we had to exclude either because
665 they were not directly relevant to the three hazards we focused on jointly, or because data were unavailable
666 at the spatial scale we conducted our analysis. Despite their exclusion from the study, we report these results
667 as a useful piece of information for further research.

668

669 **Table 5.** Indicators that have been suggested by the survey and that could be further integrated in this type
670 of assessment depending on the availability of the data.

Additional Indicators	
Disabled	Air conditioning and cooling centers
Power housing	Health conditions
Type of housing structure	Proximity to transportation
Political orientation as a measure of awareness	Housing conditions
Family size	Proximity to nuisance flooding
Social isolation	Proximity to industries
Location of the house	Undocumented residents
Home ownership vs rent occupier	Below poverty Status
Social Cohesion	Access of equity capital

a. Multi-hazard risk map

b. Detail of the multi-hazard risk map

675 **Figure 6 a and b.** Final multi-hazard risk map and detail of the high spatial resolution risk map for Lower
676 Manhattan and parts of Brooklyn.

677
678 Combining multiple hazards and vulnerability assessment produced final multi-hazard risk assessment map
679 at high resolution for NYC (Figure 6a). We find that the coastal areas of Brooklyn, Manhattan and Harlem
680 are the most at risk from the three hazards considered given the methodological approach and expert input
681 affecting weighted indicators. Figure 6b, shown in detail, demonstrate the relatively high spatial resolution
682 of the analysis and the utility for decision-making for prioritizing investments within neighborhoods and
683 down to building scale for multi-hazard risk reduction.

684
685 Adapting to coastal threats remains a high priority for the city post-Sandy, but results here suggest that coastal
686 areas are also at risk from a multi-hazard perspective. This result is further supported from expert input
687 gathered through the survey of local stakeholders who see the city the least prepared to cope with coastal
688 flooding, second only to earthquakes (see Figure 7). Of note is that some of responses appear to be
689 contradictory, e.g. snowstorms are often associated with nor'easters while hurricanes are associated with
690 coastal flooding with different degrees of preparedness. This inconsistency might be explained by the variety
691 of hazards respondents were asked to assess.

692

693
694 **Figure 7.** Survey result's regarding the level of city's preparedness to impactful hazards potentially affecting
695 NYC out of a maximum of 5 points.

696

697 4. Discussion

698 Based on the NOAA-NYT quali-quantitative assessment of multi-hazard climatic events, the responses of the
699 survey as well as from the analysis carried out for a companion study by Depietri and McPhearson, (2018),
700 NYC can be described as at risk from multiple and overlapping hazards, both spatially and temporally. Multi-
701 hazard risk is therefore a reality that is important to further understand and plan for in NYC. We also suggest
702 other similar located coastal megacities would benefit from a multi-hazard perspective on planning and policy

703 for climate adaptation and resiliency which integrates context specific weight based on expert opinions. We
704 focused on heat waves, inland and coastal flooding multi-hazard risks and assess how these are spatially
705 distributed leading to overlapping risks. We find that the hazards considered mainly affect the coastal areas
706 while the socio-economic vulnerability is concentrated in central areas of Brooklyn where the poorest
707 segments of the population reside and in the Bronx. Parts of Manhattan are also highly vulnerable, likely due
708 to the concentration of elderly and people living alone in these areas of the city or to the poverty that
709 characterizes certain neighborhoods, such as Harlem. Coastal areas of the city facing the open sea as well as
710 large areas of Manhattan and the Bronx were also the most at risk from the multiple hazards considered. We
711 suggest that adaptation strategies should prioritize these areas. Further soft or hard infrastructures need to be
712 adapted to potential inland flooding and heat waves for instance through enhanced infiltration and reduction
713 of the urban heat island by improving the distribution of green infrastructures. No part of the city is totally
714 devoid of potential impacts from these hazards and synergies and tradeoffs should be carefully evaluated.
715 Coastal flooding also appears to be one of the hazards the city is least prepared to, followed by heat waves
716 and inland flooding, amongst the hazards considered in this study. Results support current priorities in the
717 city to invest resources to improve coastal areas, such as Jamaica Bay and its remaining wetlands.

718
719 The quantitative analysis we conducted principally considered the social aspects of vulnerability and risk.
720 We illustrate that parts of the city potentially affected to multiple hazards do not necessarily correspond to
721 the areas with highest densities of vulnerable people live. A further development of this study could include
722 indicators of infrastructural vulnerability especially in reference to inland and coastal flood risk. Some of the
723 indicators that could be used to extend this analysis include: the conditions of exposed buildings; roads,
724 railroads and the subway system; and other critical infrastructures that supply energy, support communication
725 or treat wastewater.

726
727 Multi-hazard risk indicator weights were derived from expert-input through a survey methodology where
728 experts ranked indicators and sub-indicators. This survey approach allowed for the development of an
729 assessment specific to the case of the city of New York. Higher multi-hazard risk in coastal zones is partially
730 driven by weights derived from survey respondents and may depend on the recent awareness raised by
731 disastrous impacts caused by Hurricane Sandy and generally because of the high infrastructural and social
732 impacts these hazards have on the city. We initially calculated risk through all steps described but with equal
733 weighting. The results still showed that the coastal areas of Brooklyn, Harlem and the Bronx were the most
734 at risk to multiple hazards. This suggests that the methodology is robust and would not lead to major changes
735 in the results with a change of weights. However, at the high resolution the study is carried out, context
736 specific weights become important to the overall understanding of risk from multiple hazards.

737
738 The choice of the 311 calls to represent inland flooding allowed us to include an element of the disaster scape
739 of NYC which, to our knowledge, has not been explored in previous studies. Despite the potential limitations
740 of the approach, areas identified at high risk of inland flooding due to 311 calls varied little with changes in

741 the classification method. The methodology can potentially be expanded to accommodate other indicators,
742 for instance to produce hazard-specific vulnerability maps instead of a common assessment. By including a
743 broader range of vulnerability indicators and by conducting hazard specific vulnerability assessments each
744 step of the methodology would potentially be reinforced and provide additional insights.

745
746 The quantitative aspects of this work also show the significance of every step of the methodology. Each map
747 provides valuable information to detecting risk in the city beyond the final aggregated risk map. For instance,
748 the maps of the components of vulnerability show that high exposure (or where most of the people are
749 located) does not correspond to areas where people are the most vulnerable. Further, the final risk map, when
750 compared with the combined hazards maps, shows that the main determinant factor of risk is the level of
751 multi-hazard rather than the vulnerability of the population. The detailed spatial resolution of the risk
752 assessment provides decision makers with the possibility to prioritize areas of intervention at high spatial
753 resolution, down to the building and street level where most planning and development decisions actually
754 occur. The use of context specific weights allow for differentiating the role of each hazard and of each
755 indicator in shaping vulnerability and risk in NYC. By considering the three hazards jointly, no inhabited
756 area of the city is exempt from risk, while other areas show an accumulation of risk and thus locations that
757 should be prioritized for adaptation and mitigation interventions.

758

759 **5. Conclusions**

760 This study provides a comprehensive assessment of the relevance of a multi-hazard approach in a coastal
761 megacity and its application to three of the main hazards that affect New York City: heat waves, coastal
762 flooding and inland flooding. The results of a NOAA NYT database search and the experts' responses to a
763 questionnaire illustrate the relevance of considering risk in NYC in terms of multi-hazard risk. The
764 quantitative analysis showed that risk to multiple hazards in NYC is mainly driven by the distribution of the
765 hazards rather than by vulnerability. The concentration of people, the susceptibility and the lack of coping
766 capacity play a secondary role in determining risk which is instead dominated by the magnitude and
767 distribution of the hazards combined.

768

769 For the three hazards considered, we focus on a significant spatial overlap in where hazards and risk exist in
770 the city. The results showed that the city is most at risk in the coast areas of midtown and downtown
771 Manhattan, Harlem and the coastal areas of Brooklyn, especially those surrounding Jamaica bay. A
772 predominant role is thus played by coastal flooding. The analysis of these results suggest that decision makers
773 should prioritize strategies that protect the city from coastal flooding while considering at the same time that
774 those areas are also affected by other hazards and should be jointly addressed. These considerations are
775 supported by the responses from the survey that emphasize how the city is little prepared to cope with coastal
776 flooding.

777

778 Further research should consider additional indicators of physical vulnerability and cascading effects
779 provoked by climatological hazards and leading to failure of critical infrastructures dangerous for human
780 health (e.g. power outages and exposure to toxic substances). We suggest that it is important for not only
781 NYC, but other coastal megacities, to adopt a multi-hazard approach to understanding climate related risk
782 and for designing and prioritizing action to maximize interventions and investments in ways that reduce risk
783 and build resilience to multiple hazards.
