## 10 Abstract.

We address an approach for rockfall hazard evaluation where the study area resides below a cliff in an a priori exposure to rockfall hazard, but no historical documentation of rockfall events is available and hence, important rockfall hazard parameters like triggering mechanism and recurrence interval are unknown.

We study the rockfall hazard for the town of Qiryat-Shemona, northern Israel, situated alongside the Dead Sea Transform, at

- 15 the foot of the Ramim escarpment. Numerous boulders are scattered on the slopes above the town, while pre-town historical aerial photos reveal that boulders had reached location that are now town premises. We use field-observations and Optically Stimulated Luminescence dating of past rockfall events combined with computer modeling to evaluate the rockfall hazard. For the analysis, we first mapped the rockfalls source and final downslope stop-sites and compiled the boulder size distribution. We then simulated the possible rockfall trajectories using the field observed data to calibrate the simulation software by
- 20 comparing simulated and mapped boulders stop-sites along selected slopes, while adjusting model input parameters for best fit. The analysis reveals areas of high rockfall hazard at the south-western quarters of the town and also indicates that in the studied slopes, falling blocks would stop where the slope angle decreases below 5°-10°. Age determination suggests that the rockfalls were triggered by large (M >6) historical earthquakes. Nevertheless, not all large historical earthquakes triggered rockfalls. Considering the size distribution of the past rockfalls in the study area and the recurrence time of large earthquakes
- 25 in the region, we estimate a probability of less than 5% to be affected by a destructive rockfall within a 50-year time-window. We suggest here a comprehensive method to evaluate rockfall hazard where only past rockfall evidence exists in the field. We show the importance of integrating spatial and temporal field-observations to assess the extent of rockfall hazard, the potential block size-distribution, and the rockfall recurrence interval.

## 30 1 Introduction

Rockfalls are a type of fast mass movement process common in mountainous areas worldwide (Dorren, 2003; Flageollet and Weber, 1996; Mackey and Quigley, 2014; Pellicani et al., 2016; Strunden et al., 2015; Whalley, 1984). In this process, a fragment of rock is detached from a rocky mass along a pre-existing discontinuity (e.g., bedding, fractures) slides, topples or falls along a vertical or nearly vertical cliff. Individual fragments travel downslope by bouncing and flying or by rolling on

35 talus or debris slopes (Crosta and Agliardi, 2004; Cruden and Varnes, 1996; Varnes, 1978; Whalley, 1984, Wei et al., 2014). The rock fragments travel at speeds of a few to tens meters per second, and range in volume up to thousands of cubic meters. Different mechanisms are known to trigger rockfalls: earthquakes (Kobayashi et al., 1990; Vidrih et al., 2001), rainfall and freeze-and-thaw cycles (Wieczorek and Jäger, 1996; D'amato et al., 2016). Due to their high mobility, and despite their sometimes small size, rockfalls are particularly destructive mass movements, and in several areas they represent a primary cause of landslide fatalities (Evans and Hungr, 1993; Evans, 1997; Guzzetti, 2000; Keefer, 2002; Guzzetti et al., 2003; Guzzetti et al., 2005; Badoux et al., 2016). In mountainous areas human life and property are subject to rockfall hazard (Crosta and Agliardi, 2004) and efforts are made to mitigate the hazard. Mitigation measures for rockfall damage are primary based on hazard assessment, which integrates all available data to map and scale the hazard (e.g. Guzzetti et al., 2003). The spatial extent

- 5 of the hazard in many cases can be resolved using field observations of documented historical rockfalls (Wieczorek and Jäger, 1996) and computer modeled trajectories (Dorren, 2003 and references therein). The temporal aspect of hazard and the triggering mechanism usually rely on historical reports, but rarely on direct dating of past rockfall events (e.g. De Biagi et al., 2017; Kanari, 2008; Rinat et al., 2014). However, hazard estimation where no historical documentation of past rockfalls exists (hence no documentation of neither the spatial and temporal extents), nor any knowledge of the triggering mechanism, such as the case presented here, is rare or missing in literature.
- The current study evaluates the rockfall hazard for the town of Qiryat-Shemona (northern Israel), by (a) studying the extent and nature of past rockfall events using field observation; (b) Constraining the date of the rockfall events and their reoccurrence interval using optically stimulated luminescence (OSL) dating (Wintle, 2008). The possible temporal relation to known historical earthquakes, which might serve as a trigger, is also studied; (c) computer-modeling the most probable down-slope
- 15 rockfall trajectories which outline the hazard-prone area. Particular attention is given to the calibration of the computer modeling using mapping of past rockfall events and extracting geometrical and mechanical parameters needed for the simulations from the field observations. This study presents a methodology for rockfall hazard estimation where field evidence for past rockfalls are observed in the town vicinity, but the triggering mechanism, the timing of past rockfall events and recurrence intervals are entirely unknown.

## 20 2 Study Area

The town of Qiryat-Shemona (population 25,000) is located in the northern Hula Valley (Fig. 1), one of a series of an extensional basins developed along the active left lateral fault system of the *Dead Sea Transform* (DST) (Freund, 1965; Garfunkel, 1981; Quennell, 1958). The town is built at the foot of the fault-controlled Ramim escarpment, which rises 800 meters above the west part of the town. New quarters of the town are being planned and built below the escarpment and up the

- 25 slopes above the town. These slopes are dotted with cliff-derived boulders with measured volumes of more than 100 m<sup>3</sup>, which have apparently traveled down the slope to their current locations (Fig. 2). Aerial photos pre-dating the town establishment (dated ~1945) reveal additional rock blocks with similarly estimated volume-range within the now built town premises. Thus, the field observations and aerial photos interpretation suggest that the western neighborhoods of Qiryat-Shemona, located at the escarpment base, are subjected to rockfall hazard.
- 30 The rock sequence outcrops in the lower part of the slopes, west of the town (hereafter 'the study area'; Fig. 1b) consists of Lower Cretaceous rocks (Glikson, 1966; Kafri, 1991;): The sandstone of Hatira Formation outcrops at the base of the slope, overlain by limestone and marl of Nabi Said Formation. Further up-slope, about 350 m above the town, outcrops the biomicritic limestone of Ein-El-Assad Formation, creating a 40 m high sub-vertical cliff (Fig. 2). This cliff is the source for rockfalls in the study area (see below). The Ein El Assad Formation is overlaid by a ~700 m Lower to Upper Cretaceous carbonate rocks
- 35 (Sneh and Weinberger, 2003a, b). Colluvium and rock-mass movement deposits were mapped on the slopes near Qiryat-Shemona (Shtober-Zisu, 2006, Sneh and Weinberger, 2003a), identifying the blocks on the slope as originating from the Ein-El-Assad formation. The slopes are generally covered with up to a few meters of soil. The studied area is located along a primary fault zone of the DST (Weinberger et al., 2009).

Large historic and prehistoric earthquakes (M >6.5) along the DST are well documented: Ben-Menahem (1991), Amiran et al.

40 (1994), Guidoboni et al. (1994), Guidoboni and Comastri (2005), Marco et al., 2003, Marco et al., 2005, Marco et al., 1996, Katz et al., (2010) and Wechsler et al., (2014). Recurrence intervals for  $M_W$  = 6.5 and  $M_W$  = 7.0 earthquakes was calculated to

800 and 3000 years in accordance (Begin, 2005), while another study suggests that the average recurrence interval for a large earthquake (M  $\geq$ 6.5) in this segment of the DST is ~1500 yr (Hamiel et al., 2009). Some of the significant historical earthquakes induced slope failures (Katz and Crouvi, 2007; Wechsler et al., 2009; Yagoda-Biran et al., 2010).

## **3 Methods**

## 5 3.1 Rock block inventory

In a given site, the size distribution of boulders resulting from past local rockfalls (recent or historical) is the best database for assessing predicted rockfall block size. Thus mapping the blocks is crucial for hazard analysis, as suggested by previous studies that required estimations or measurements of the number of blocks and their volumes (Brunetti et al., 2009, Dussauge-Peisser et al., 2002; Dussauge et al., 2003; Guzzetti et al., 2003; Malamud et al., 2004; Katz and Aharonov, 2006; Katz et al., 2011).

- In this study, a catalog of the past-rockfall derived boulders was constructed from two data sources: 76 blocks were mapped and measured in the field with volumes varying between 1 m<sup>3</sup> and 125 m<sup>3</sup> (green rectangles in Fig. 3a; their volume-frequency histogram is in Fig. 3b). Additional 200 blocks were mapped using pre-town aerial photos (dating to 1946 and 1951; yellow rectangles in Fig. 3a). 58 out of the 200 blocks mapped using the aerial photos were identified and measured in the field as well. These blocks were used to fit a correlation curve between field measured and aerial photo estimated block volumes. The
- 15 correlation was used for volume estimation of the blocks that were removed from the area during the construction of the town, but were mapped on the aerial photos predating the establishment (142 blocks out of 200). In summary, the catalog hosts a total of 218 boulders, which were mapped and their volumes were measured or estimated from aerial photos. This rock block inventory is the basis for the prediction of probabilities for different block sizes for the calculation of rockfall hazard and its mitigation.

#### 20 3.2 Rockfall simulations

The down-slope trajectory of a rock-block (or the energy dissipated as it travels) is affected by the geometry and physical properties of the slope and the detached blocks (Agliardi and Crosta, 2003; Guzzetti et al., 2002; Guzzetti et al., 2004; Guzzetti et al., 2003; Jones et al., 2000; Pfeiffer and Bowen, 1989; Ritchie, 1963). Parameters that quantify these measures are used as input for computer-simulation of rockfall trajectories. Several computer programs have been developed and tested to simulate

- 25 rockfall trajectories (Guzzetti et al., 2002; Dorren, 2003 and references therein; Giani et al., 2004). The current study uses the 2D Colorado Rockfall Simulation Program, CRSP, v4 (Jones et al., 2000) to analyze two significant aspects of rockfall hazard in the studied area: First, the expected travel distance of rock-blocks along the studied slopes, which signifies the urban area prone to rockfall hazard. Second, the statistical distributions of block travel velocities and kinetic energy, which serves as an input for engineering hazard reduction measures. For the current analysis the model input parameters are the topographic
- 30 profile of the slope (extracted from 5 m elevation contours GIS database and verified in the field), surface roughness (S), slope rebound and friction characteristics, (Rn: normal coefficient of restitution; Rt: tangential coefficient of frictional resistance) and block morphology. S was measured in the field according to Jones et al., (2000) and Pfeiffer and Bowen, (1989), where Rn and Rt were estimated via a calibration process (see below).

The CRSP algorithm simulates rockfall as a series of rock-block bounces, and calculates the changes in the block velocity after

- 35 each impact with the slope surface, taking into consideration the rock and slope geometric and mechanical properties. Model output is a statistical distribution of velocity, kinetic energy and bounce height along the downslope trajectory, including stopping distances of the blocks (Jones et al., 2000). The slope surface in CRSP is divided into slope cells, which boundaries are defined where the slope angle changes, or where the slope roughness changes (Jones et al., 2000).
- For the current study, we simulated the rockfalls characteristics along topographic profiles extending from the Ein-El-Assad 40 Formation, identified as the source for the rockfalls, downslope towards the town. 25 topographic profiles covering the study

area were extracted for the rockfall hazard analysis (Fig. 4), with high spatial density (30–100 m intervals) where the source for rock-blocks is exposed above the town and lower spatial density (150–500 m intervals) further southwards. A single simulation run (along each profile) modeled 100 rock-blocks, thus allowing the statistical analysis (Jones et al., 2000). CRSP results for each profile were later integrated spatially to compile rockfall hazard maps and other hazard properties as detailed

5 below. The simulated block volumes were binned into size scales of 1, 10, 50, 100, 125 m<sup>3</sup>, with corresponding block diameters of 1.3, 2.7, 4.6, 5.8 and 6.2 m, respectively (assuming spherical block geometry).

#### 3.3. CRSP calibration

The first step in hazard analysis using a computerized model is calibration of the model input parameter. Following Katz et al.
(2011), calibration was performed by comparing calculated traveling distance of rock blocks of a given size to field observed ones, while adjusting the assigned model-parameters until best-fit was obtained, i.e., back-analysis.

In the current work, CRSP calibration using back-analysis was performed along four slopes (pink lines in Fig. 3) located at the N and S parts of the prominent Ein-El-Assad source outcrop, where a relatively high number of field mapped (50 blocks out of 76) and aerial photo mapped rock-blocks (65 blocks out of 200) were observed. As an index for calibration quality, we used

- 15 the difference between the *field-observed* down-slope maximal travel distance along a selected slope and the *simulated* maximal travel distance along this slope (hereafter  $\Delta MD$  in meters), for a given block-size bin. We considered the model parameters as calibrated when  $\Delta MD = \pm 60$  m (about 10% of average profile length). 80 simulation runs, modeling the largest blocks with diameters of D of 5.8 m and 6.2 m along the four profiles were used for calibration (Determined S value is 0.5 for D=5.8 and 6.2 m). These simulations resulted in the following coefficient value ranges:  $R_n = 0.2 0.25$ ;  $R_t = 0.7 0.8$ , which
- 20 are in agreement with suggested values for bedrock or firm soil slopes according to Jones et al. (2000). These values were further revised and refined following the initial velocity sensitivity analysis (detailed in the following). The predicted seismic peak ground acceleration (PGA) for the studied area is 0.26 g (Shapira, 2002). Assuming a PGA (*a*) of 0.3 g with frequency (*f*) of 1 Hz (Scholz, 2002), the calculated initial horizontal velocity ( $U_x$ ) of the rock block is 3 m/s ( $U_x = a/f$ ). Sensitivity analysis was performed for two end members of  $U_x=0$  m/s (simulating aseismic triggering of a rockfall) and
- 25  $U_x=3$  m/s (simulating seismic triggering). Where,  $R_n = 0.12$  yielded  $\Delta MD = -90$  m and -80 m for  $U_x = 0$  m/s and  $U_x = 3$  m/s, respectively; and  $R_n = 0.25$  yielded  $\Delta MD = +160$  m and +150 m for  $U_x = 0$  m/s and  $U_x = 3$  m/s, respectively. Thus, we infer that initial velocity has no significant effect on travel distance. An exponential regression curve was fitted for the above  $R_n$  values (0.12, 0.2, 0.25) vs their corresponding  $\Delta MD$  values (-90, -30, +160 m), which yielded  $\Delta MD = 0$  m (minimum difference between observed and simulated maximum travel distance) at  $R_n = 0.22$ . Thus, calibration was determined optimal for  $R_n =$
- 30 0.22. We estimate that 0.01 change in Rn will yield 15-30m change in maximum travel distance. Calibration profiles are 450 m-750 m, yielding 2%-3% variability for 0.01 change in  $R_n$ . CRSP output is less sensitive to changes in the tangential coefficient  $R_t$  in comparison to changes in the normal coefficient  $R_n$ . Hence  $R_t$  value was determined to 0.70 following our initial calibration value, which is also recommended by Jones et al (2000) for firm soil slopes.

To validate these coefficients, further simulation runs along the four calibration profiles were performed for all block sizes (D

- 35 = 1.3m-6.2 m), using the above detailed best-fit values  $R_n = 0.22$ ;  $R_t = 0.70$  and the field-measured surface roughness S values S=0.1, 0.3, 0.4 m for block diameters D=1.3 m, 2.7 m, 4.6 m respectively, and S=0.5 m for D=5.8 and 6.2 m (all S values were measured in the field per block diameter according to CRSP software manual). All slope cells were given the same values to maintain model simplicity. The travel distances of simulation results were compared with the observed travel distances (from field mapping and aerial photo mapping). The fit between observation and simulation is plotted in Fig. 5. These results can be
- 40 divided into two behavior patterns: (a) mid-size and large blocks ( $D \ge 3$  m; green, orange and red circles): the observed and simulated results are close to the 1:1 ratio; for large blocks ( $D \ge 4$  m), simulated travel distance is a little longer, which yields a more conservative result. (b) small blocks (D < 3 m): some blocks are close to the 1:1 ratio, while others demonstrate

significantly longer *observed* travel distances. This longer observed than simulated travel distance of smaller blocks may be explained in a few ways: First, smaller blocks may be more subject to creep, being more affected by water runoff and slope material movement due to their lower weight. Therefore they may travel further down after the rockfall event took place. Another possible interpretation is that the construction of town has created a different topographical setting than the slope at

5 the time of rockfall events in the past. To circumvent this discrepancy for the hazard analysis, we use only the larger blocks. Sensitivity analysis for block shape resulted in an insignificant difference between simulations done with sphere, disc or cylinder rock-block shapes. Accordingly, we used sphere shape rock-blocks in the prediction simulations because they yield maximum volume for a given radius and thus tend toward a worst-case scenario analysis (Giani et al., 2004; Jones et al., 2000).

#### 3.4 OSL age determinations

- 10 For OSL age determinations of rockfall events, colluvium or soil material from immediately underneath the rock blocks was sampled. This approach constrains the time since last exposure to sunlight before burial under the blocks (following Becker and Davenport, 2003). For sampling we excavated a ditch alongside the rock block to reach the contact with the underlying soil using a backhoe, then manually excavated horizontally under the block and sampled the soil below its center. The Sampling of soil was performed under a cover to prevent sunlight exposure of the soil samples. A complementary sediment sample was
- 15 taken from each OSL sample location for dose rate measurements. Locations of sampled blocks are marked in Fig. 3. Rockfall OSL age determination was based on the assumption that the sampled blocks did not creep or remove from their initial falling location. Thus, only very large blocks between 8 and 80 m<sup>3</sup>, weighing tens to hundreds of tons, were sampled. OSL equivalent dose De was obtained using the single aliquot regeneration (SAR) dose protocol, with preheats of 10 s @ 220-260°C and a cutheat 20° below preheat (Murray and Wintle 2006). "No. of discs" is the number from those measured that was used for
- 20 calculating the De. Over-dispersion (OD) is an indication of the scatter within the sample beyond that which would be expected from experimental uncertainties. Ages calculated using the Central Age Model after rejection of outliers. Gamma dose rates measured in the field using the gamma counter are lower than gamma dose rates calculated from the concentrations of K, U and Th (with the cosmic dose calculated from burial depth).

## **4 Results**

30

# 25 4.1 Size distribution of rockfalls

Rock-blocks, a result of rockfall events, are commonly observed along the slope west of Qiryat Shemona, at the foot of the Ein-El-Assad Formation. Their volume varies, from the smallest pebbles to boulders tens of cubic meters in volume. In places the blocks form grain-supported piles, revealing impact deformations on their common faces such as chipped corners and imbricated blocks separated along previous fracturing surfaces. To determine rockfall hazard and risk, information on the frequency-volume statistics of individual rockfalls is necessary (Guzzetti et al., 2004; Guzzetti et al., 2003).

We used the field mapped blocks to determine their volume distribution. In total, we consider this field catalog complete for block size >1 m<sup>3</sup> and consists of 76 blocks ranging in volume up to 125 m<sup>3</sup> (mode = 56 m<sup>3</sup>). Following Malamud et al. (2004), the volume distribution of the mapped blocks is determined using the probability density, *p*, of a given block volume Eq. (1):

$$p = \frac{dN}{NdV} \sim V^{\alpha} \tag{1}$$

35 where N is the total number of blocks, dN is the number of blocks with volume between V and V+dV, and  $\alpha$  is the scaling exponent. Our results show that the volume of the individual rock blocks from the studied area exhibits a distinct negative power law behavior, with a scaling exponent of the right tail of  $\alpha$  = -1.17 (R<sup>2</sup> = 0.72; Fig. 6). This conforms to what was found by others who examined natural rockfalls with observed  $\alpha$  ranging: -1.07 - -1.4, e.g., Guzzetti et al. (2003) Malamud et al. (2004) Brunetti et al. (2009). The scaling exponent is also similar to the value  $\alpha$  = -1.13 obtained experimentally by Katz and Aharonov (2006), while Katz et al. (2011) found a larger scaling exponent,  $\alpha = -1.8$ . Since our data yield a moderate inner consistency R<sup>2</sup>=0.72 we round the power to -1.2 (instead of -1.17). In accordance, the probability density function (PDF) for rockfall volume (*p*) may be presented as a power law of the form (Dussauge-Peisser et al., 2002; Dussauge et al., 2003; Guzzetti et al., 2003; Malamud et al., 2004) Eq. (2), where *V* is the given block volume in m<sup>3</sup>:

5  $p = 0.4V^{-1.2}$  (2)

To simplify the hazard evaluation and relate to the more prominent hazard which larger block sizes impose (thus removing the 1 m<sup>3</sup> smaller blocks from the simulation runs) the block volumes were binned into size scales of 10, 50, 100, 125 m<sup>3</sup>, with corresponding block diameters of 2.7, 4.6, 5.8 and 6.2 m respectively (assuming spherical block geometry). Field mapped cumulative frequencies were used to derive cumulative probabilities for each block size (Table 1). The probability values per block diameter (Table 1) were fitted a regression curve in Excel (R<sup>2</sup> = 0.97), yielding the probability (*p<sub>D</sub>*) for a block of given

diameter (D) or smaller following Eq. (3):

10

$$pD = 0.412Ln(D) + 0.262 \tag{3}$$

The cumulative probability calculated from Eq. (3) per block diameter differs from the cumulative probability calculated in Eq. (2) per its matching block volume because of the differences in data-sets and usage of the two equations: Eq. (2) powerls law details our full field-observed data of block sizes and is used to characterize the dataset and compare it to other block catalogs in other studies. While Eq. (3) yields a simulation-specific empirical prediction for probability of occurrence for the larger block diameters (D>=2.7 m; V>=10 m<sup>3</sup>), which were actually used later in the CRSP simulations for hazard analysis.

#### 4.2 Simulations of block trajectories

For the hazard analysis, we ran computer simulations along 25 profiles including the four profiles used for the calibration (Fig.
3), using the calibrated parameters and the measured topographic-profiles as the model input. A total of 100 computer runs were performed (four runs on each of the 25 profiles, using block dimeters of 2.7, 4.6, 5.8, and 6.2 m separately), each run simulating the fall of 100 individual blocks (totaling 10,000 simulated single block trajectories). These results were used to analyze the hazard in the study area.

## 4.2.1 Stop angle and stop swath

- 25 The 'x% stop angle' is defined as the slope angle of the profile cell at which cumulated x% of simulated blocks stop and, in accordance, the 'stop swath' is defined as the distance (m) that the simulated blocks covered until all of them (100%) stopped. Example: if the total 100% of the simulated blocks stopped within a profile cell that has 5° slope and the last one of them stopped after covering 65 meters along that cell the 100% stop angle is 5° and the stop swath is 65 m. The 50% and 100% stop angle and stop swath data were extracted from the CRSP simulation analysis (Fig. 7). 100% stop angles for all profiles
- 30 (red circles in Fig. 7) vary between  $3^{\circ}-12^{\circ}$  with a mean of  $7.7^{\circ}$  and  $SD = 2.3^{\circ}$  ( $1\sigma = 5.4^{\circ}-10.0^{\circ}$ ); 50% stop angles (blue triangles) vary between  $3.2^{\circ}-25.8^{\circ}$  with a mean of  $10^{\circ}$  and  $SD = 5.3^{\circ}$  ( $1\sigma = 4.7^{\circ}-15.3^{\circ}$ ). All other cell slope angles in all profiles (gray circles) vary widely between  $7^{\circ}-88^{\circ}$  with a mean of  $29.4^{\circ}$  with  $SD = 17^{\circ}$  ( $1\sigma = 12.4^{\circ}-46.4^{\circ}$ ). Among them very few are less than  $10^{\circ}$ . Stop swath distances range between 8-105 m, with a mean of 38 m and SD = 24 m ( $1\sigma = 14-62$  m). Only in two profiles (out of 25) did the stop swath distance exceed 65 m. In both these cases, 100% stop angle is steeper than in most other profiles
- 35 (10°-11°). Further details and illustration for slope cells and stop angles are given in Fig 7. No significant correlation was found between 100% stop angle and stop swath distance.

#### 4.2.2 Rockfall hazard

Rockfall hazard map for Qiryat-Shemona is presented in Fig. 8. The hazard map was compiled from the simulated maximal travel distance (where 100% of blocks stop) of the largest blocks (D > 4.6 m,  $V > 50 \text{ m}^3$ ) with the probability of occurrence, pD

= 11% (Eq. 3). The calculated block trajectories cross the town border and mark the town premises that are subject to rockfall hazard along 8 out of 25 simulated profiles (#8 – #14 and #16, marked by † in Fig. 9). The area subjected to rockfall hazard is about 1.55 km<sup>2</sup>, currently including several houses (according to the last updated google Earth image from Nov 2014). For D=4.6 m, block impact velocity varies between 9.5–13.7 m/s and kinetic energy between 7,400–16,300 kJ (Table 2). CRSP

5 simulated maximal travel distance and CRSP velocity and kinetic energy analysis points at town border impact locations are plotted in Fig. 9. Yellow line represents the CRSP 100% stop line calculated for large blocks (D is 5.8 m and 6.2 m). Yellowblack triangles mark simulated stop points; Orange-black triangles mark simulated town border impact points (those labeled with a sword '†' mark locations of rockfall impact at town border) where kinetic energy was calculated. For details of the kinetic analysis at these locations refer to Table 2.

## 10 4.3 OSL age determination of rockfalls

OSL ages were determined for nine rock blocks with volume range of  $8 \text{ m}^3 - 80 \text{ m}^3$ . The location of these blocks is marked in red circles in Fig. 3. These ages range from 0.9 to 9.7 ka, with uncertainties of 6% - 14% (Table 3).

#### **5** Discussion

#### 15 5.1 Triggering conditions for rockfalls in the studied area

We interpret the field observed grain supported structure of aggregations of blocks of various sizes, with impact deformations (e.g., chipping) on their common faces as evidence for catastrophic events, involving numerous blocks. Long-term erosion which results in single sporadic block failures would have resulted in matrix-supported blocks and not in the evidence observed here. We conclude that the rockfalls were mainly triggered by discrete catastrophic events such as earthquakes or extreme

- 20 precipitation events. The question of a triggering mechanism in the case of a catastrophic rockfall event is an important one when attempting to evaluate the temporal aspect of rockfall hazard. The recurrence time of an extreme winter storm or a large earthquake may give some constraints on the expected recurrence time of rain-induced or an earthquake-induced rockfall, respectively. Furthermore, it might suggest a periodical probability for the next rockfall to occur when hazard is calculated. The correlation of rockfall events to historical extreme rainstorm events is limited due to the lack of long enough historical
- 25 rainstorm record. However, in the 74 years of documented climatic history for the studied area (measurements at the 5 km away Kfar-Blum station since 1944; IMS, 2007) no significant rock-mass movements and rockfalls were reported in the study area. This period includes the extremely rainy winters of 1968/69 and 1991/92, in which annual precipitation in northern Israel was double than the mean annual precipitation (IMS, 2007). Furthermore, the winter of 2018-2019 (during which the current study is being prepared for publication) breaks a five-year drought that was the worst Israel has experienced in decades (Time
- 30 of Israel, 2019), with massive floods, snowfall, overnight freeze and rainstorms in Northern Israel, including in the study area. The authors of this study received 1<sup>st</sup>-hand personal correspondence (photos, videos and descriptions) from hikers on the studied slope, which observed some dismantling of rock blocks in their location during one of the large rainstorms in Jan-2019. Yet no rockfall events were documented in the study area during this extreme winter season. Contrastingly, Wieczorek and Jäger (1996) reported that out of 395 documented rockfall events in the Yosemite Valley which occurred between 1851
- 35 and 1992, the most dominant recognized trigger for slope movement was precipitation (27% of reported cases), and point out the influence of climatic triggering of rockfall. Based on this significant difference of observations for rockfall triggering mechanisms, we suggest that rainstorms may not provide a major triggering mechanism for rockfalls in our study area. A possible correlation between the dated rockfall events and historical earthquakes is analyzed below.

## 5.2 Non-random temporal distribution of rockfalls and correlation to earthquakes

The following discussion relates to blocks of sizes equal or larger than 8 m<sup>3</sup> (D>2.5 m) as the OSL dated blocks were of sizes 8-80 m<sup>3</sup>). These volumes fit the CRSP simulation analyses of all blocks in the study, as the smallest simulated block for the hazard estimation was 10 m<sup>3</sup> (D=2.7 m).

- 5 The wide range of OSL ages, between 0.9 ka and 9.7 ka before present (Fig. 10 and Table 3), rules out the possibility of a single rockfall event. Given the rich historical earthquake record in the vicinity of the studied area, the positive correlation between rockfall events and historical earthquakes may shed light on the triggering mechanism of the rockfalls. A similar approach was used by Matmon et al. (2005), Rinat et al. (2014) and Siman-Tov (2009). The latter dated rockfall events ~30 km SW of the studied area, where he found a positive correlation between rockfall events and historical earthquakes, dated
- 10 749 AD and 1202 AD. To analyze this possible correlation, we overlaid the 9 OSL ages with a set of 9 large historic earthquakes (Table 4, Fig. 10), which comply to these cumulative terms: (a) they occurred within the time spans of the OSL ages; (b) their maximum estimated intensity is at least 'IX' in EMS (European Macroseismic Scale) and/or their estimated momentmagnitude is 6 or larger; (c) the distance between our study area and affected localities does not exceed 100 km (following Keefer, 1984).
- 15 The 9 OSL ages (Table 3; Fig. 10) span over the past 9700 years with a mean of one occurrence per 1,000 years. The validation of OSL age clustering was obtained performing a binomial distribution test, which gives the discrete probability distribution P(k,p,n) of obtaining exactly k successes out of n trials. The result of each trial is true (success) or false (failure), given the probability for success (p) or failure (1-p) in a single trial. The binomial distribution is therefore given by Eq. (4):

$$P(k, p, n) = \binom{n}{k} p^{k} (1-p)^{n-k}, \text{ where } \binom{n}{k} = \frac{n!}{k!(n-k!)}$$
(4)

- A 'success' was defined when the date of a given earthquake (out of the nine candidates in Table 4) with a ±50 years time window, coincides in time with one of the OSL ages with the same error range (±50 years). Since the selected limited time window is ±50 years (±0.05 ka), the test was performed only for OSL ages that correspond to relatively accurate historically recorded earthquakes (last 2,800 years): 759 and 199 BC, 363, 502, 551, 659, 749, 1033 and 1202 AD. The OSL ages within this range are of QS-3 (1.6±0.1 ka), QS-4 (1.0±0.1 ka), QS-6 (2.1±0.2 ka) and QS-11 (1.7±0.2 ka). The selected nine historical
- earthquakes, each with a ±50 year time window, span over 900 years out of the given 2,800 years period (for each event, a ±50 year time window spans 100 years). Therefore, the probability *p* for a single random earthquake to occur within this period is p = 900/2800=0.32. The number of trials *n* is the number of earthquakes n = 9. In five cases (the earthquakes of 199 BC, 363 AD, 502 AD, 1033 AD), a success (match between an earthquake and an OSL age) is obtained (363 AD matches two OSL ages QS-3 and QS-11), therefore the number of successes is k = 5. This fit between OSL ages and earthquakes is detailed in
- 30 Fig. 11. Accordingly, the binomial distribution is P(k, p, n)= P(5, 0.32, 9) = 0.09, i.e., there is a 9% probability to randomly obtain such a distribution of events in time. Hence, we suggest that the OSL age distribution is significantly clustered around dates of the discussed historical earthquakes, with 91% confidence level, thus suggesting a likelihood of seismic triggering for the rockfalls in the studied area. Assuming that M≥6 earthquake needed for rockfall triggering (following Keefer, 1984) and based on the recurrence time of 550 years given for these earthquakes (Hamiel et al., 2009), we predicted a ~550 years
- 35 recurrence time for rockfalls in the studied area.

Not all historic earthquakes are represented in our OSL data set, such as the 1759 AD (Ambraseys and Barazangi, 1989; Marco et al., 2005) and 1837 AD (Ambraseys, 1997; Nemer and Meghraoui, 2006) earthquakes, which both induced extensive damage to cities not far from the study area (Katz and Crouvi, 2007). This lack of evidence could be explained by OSL under-sampling, or because earthquakes only trigger rockfalls that were on their verge of instability (Siman-Tov et al., 2017).

- 40 Based on the above analysis we correlate the past rockfalls to historic earthquakes as follows:
  - a. QS-4 (1.0±0.1 ka) fits the historical earthquake of 1033 AD.

- b. QS-3 (1.6±0.1 ka) and QS-11 (1.7±0.2 ka) fit the historical earthquakes of 363 AD and 502 AD, and only lack ~40 years in error margin to fit the one of 551 AD. Since the 502 AD was reported on shoreline localities only in the DST area, we find the 363 AD a better rockfall triggering candidate. We suggest that the two ages are clustered around one of these earthquakes, hence suggesting they represent one rockfall event in the 363 AD earthquake. however, we cannot completely
- 5 rule-out the possibility that these were two separate rockfall events, both triggered by large earthquakes in 363 AD and 502/551 AD.
  - c. QS-6 (2.1±0.2 ka) fits the 199 BC earthquake.
  - d. QS-13 (3.2±0.4 ka) lacks ~30 years in error margin to fit the 759 BC earthquake.
  - e. QS-5 (4.0±0.7 ka), QS-9 (4.3±0.6 ka) and QS-12 (4.5±0.4 ka) fit the 2050/2100 BC earthquake (or two separate events)
- 10 suggested by Migowski et al. (2004). This also fits the findings of Katz et al. (2011) and Yagoda-Biran et al. (2010), who found evidence for earthquake and earthquake-induced slope failure east of the Sea of Galilee (ca. 50 km south from study area, along the DST) with OSL ages of 5.0±0.3 and 5.2±0.4 ka, respectively, suggesting the area had experienced one or more strong earthquakes. We therefore suggest that these OSL ages cluster around a single rockfall event triggered by a large earthquake within the period of 3.7-4.9 ka.
- 15 f. QS-1 (8.7±1.0 ka) may correlate with an earthquake event suggested by Daeron et al. (2007) on the Yammunneh Fault in Lebanon dated to 8.4–9.0 ka (identified in a paleoseismic trench 50 km north of the study area).

## 5.3 Area subject to rockfall hazard

The nature of the analyzed past rockfall events in the studied area can be used to constrain the possible characteristics of the expected future rockfall events and direct hazard mitigation. The predicted probabilities  $P_D$  for specific rock fall with a given

- 20 block diameter or smaller, derived from the regression curve (*Eq. 3*), are presented in Table 1.  $P_D(2.7)$ , the cumulative probability for a block of D = 2.7 m (V = 10 m<sup>3</sup>) or smaller is 0.67. Consequently, the probability for traveling blocks of 2.7< D< 6.2 m (10< V< 125 m<sup>3</sup>), is  $1-P_D(2.7) = 0.33$  or 33%. The occurrence of larger, more destructive blocks amongst these (D = 4.6 m - 6.2 m or respectively, V = 50 - 125 m<sup>3</sup>) is  $P_D = 11\%$ . Despite their lower probability, these blocks would reach the farthest distances; and hence pose the largest hazard to town.
- 25 About 50,000 m<sup>2</sup> (0.05 km<sup>2</sup>) of the westernmost inhabited and built urban area is mapped under direct rockfall hazard (considering the large blocks: D = 4.6 m 6.2 m), as well as the slopes above this part of the town (Fig. 8). This hazard mapping may be used to plan mitigation actions and also as a basis for future urban planning.

We note that the main road connecting the town southwards, which can serve as evacuation route, is marginally beyond the rockfall hazard mapped zone (Fig. 8). We also note that some smaller blocks ( $D \le 3$  m) were mapped from the historical aerial

- 30 photos predating town establishment further down slope below the simulated 100% blocks stop (Fig. 3; blue circles in Fig. 5). As suggested above these might be blocks that traveled farther downslope by creeping after the rockfall event. Another possible explanation is that these now inhabited parts of the slope were altered and even levelled by the construction works. Hence the simulated profile extracted from current topography is different from the slope topography on which these smaller blocks traveled before the construction of town. No detailed topography maps pre-dating town establishment is available to verify
- 35 this.

The stop angle results (Fig. 7) indicate that most blocks (>50%) keep traveling down-slope until the slope angle decreases to 10°-15°. All blocks stop where the slope angle decreases to values between 5.5°-10.0°. Combined with the stop swath distance results (Sect. 4.2.1 above), considering the means and SD's, CRSP results indicate that falling blocks would stop after covering

40 a distance of 14 m- 62 m from the source on a slope angle of 5°-10° at the point of stopping. This conclusion may help when considering rockfall mitigation design.

## 5.4 Rockfall hazard probability

We discuss the hazard probability by addressing three terms: time dependency, size dependency and susceptibility.

**Time dependency:** we derive the recurrence time for rockfalls in the study area by correlating OSL dating of rockfall events to past earthquakes, as detailed above. Thus, we can calculate the probability of a rockfall occurrence  $P_{EQ}$  in the next 50 years,

5 assuming earthquake magnitude Mw = 6 as the threshold for rockfall:  $P_{EQ} = 50/550 = -0.09$  or 9%. We do not present a timedependent earthquake recurrence interval calculation because the time passed since the last large earthquake is not well constrained.

**Size dependency**: Based on the field mapping of block sizes and the expected block sizes which correspond both to the sizes of OSL dated blocks and the CRSP simulation block diameters (Table 1; Fig. 3), the probability of a given block size or smaller

10 is predicted by Eq. (3). Considering the time dependent probability and the probabilities for given block sizes detailed above, the probability for rockfall hazard per specific block size ( $H_R$ ) may be predicted as Eq. (5):

$$H_R = (1 - P_D) \cdot P_{EQ} \tag{5}$$

where  $P_D$  is the cumulative probability per block diameter D (Table 1) and  $P_{EQ}$  is the rockfall occurrence probability calculated above to be 9%. Accordingly, predicted  $H_R$  for the next 50 years for block diameters D between 2.7-6.2 m is ~3% and for larger blocks, D between 4.6-6.2 m is ~1%.

**Susceptibility:** As presented in Figures 8-9, the urban area and the area of open slopes above it subjected to rockfall hazard extends to about 1.55 km<sup>2</sup>. We conclude that this area has a probability  $H_R$  of ~1%-3% for impact by rockfall in the next 50 years.

#### 6. Conclusions

15

- 20 In this work, we studied rockfall hazard for the town of Qiryat-Shemona (northern Israel) to demonstrate computer-simulation based hazard evaluation in cases where the study area is residing in an a priori exposure to rockfall hazard, but no documentation of past rockfall events is available. To overcome this lack of observations, we derived the needed geometrical and mechanical parameters for the computer hazard modeling from a field study of downslope blocks. In particular, we analyzed the spatial distribution of individual rock-blocks which are the result of the past rockfalls and used this analysis for
- 25 calibration of the model parameters.

OSL age determination of several past rockfall events in the study area suggests that these rockfalls were triggered by large (M > 6) historical earthquakes, and in accordance, the estimated rockfall recurrence interval is hundreds of years. Nevertheless, we conclude that not all historical large earthquakes triggered rockfalls in the studied area. Additionally, we infer that the downslope travel distance of the blocks is not significantly affected by the magnitude of seismic accelerations. However,

30 earthquakes appear to play a significant role as the triggering mechanism of the rockfall. We found that falling blocks would come to a stop once the slope angle decreases to around  $5^{\circ}$ - $10^{\circ}$ .

The field-calibrated simulation results indicated rockfall hazard at the south-western quarters of town as well as at the slopes above the town. Considering the size distribution of the past rockfalls in the study area and the recurrence time of large earthquakes in the area, the probability to be affected by a destructive rockfall within a 50 years time-window is less than 5%.

# 35 Acknowledgments

This work was funded by the National Steering Committee for Earthquake Preparedness in Israel. We wish to thank the Nature & National Parks Authority of Israel, allowing field-work at the Qiryat-Shemona National Park. MK wishes to thank Gal Hartman, Gaby Yelin, Shalev Siman-Tov and Yariv Nofech for their great help in field work. We thank two anonymous reviewers for their valuable comments and suggestions that significantly improved the manuscript.

# Tables

Table 1. Size distribution of the mapped rock blocks (N=76)									
Volume bin (m <sup>3</sup> )	Diameter (m)*	Cumulative frequency*	predicted cumulative Probability P <sub>D</sub> **						
1	1.3	-	-						
10	2.7	50	0.67						
50	4.6	71	0.89						
100	5.8	74	0.99						
125	6.2	76	1						

\* No data collected for blocks smaller than 1 m<sup>3</sup> (cumulative frequency is zero).

5 \*\*  $P_D$  is calculated using Eq. [3] for a given block diameter or smaller.

10

Table 2. Predicted velocity (m/s) and kinetic energy (kJ) of falling blocks at town border*										
D (m)	1.3		2.7		4.6		5.8		6.2	
Profile	Vel	Ек	Vel	Ек	Vel	Ек	Vel	Ек	Vel	Ек
14	12.3	290	10.8	1,950	12.1	12,400	11.7	23,000	12.3	28,500
13	12.5	310	12.2	2,600	12.6	13,900	12.4	27,100	12.6	34,000
12	11.1	240	10.0	1,700	11.7	11,500	11.3	22,000	11.4	27,500
11	12.4	295	11.5	2,300	12.0	12,300	12.7	27,300	12.7	34,000
10	9.3	165	8.3	1,200	9.5	7,400	9.3	14,600	9.3	19,000
8	10.5	220	11.3	2,200	11.5	11,400	11.6	22,900	13.8	40,300
9	n/a	n/a	13.0	2,950	13.7	16,300	13.8	32,300	11.7	29,000

\* Values presented are maximal simulated velocity (Vel) and kinetic energy (E<sub>k</sub>) per rock diameter (D). Profiles listed (7 out
of total 25 simulated profiles) are only those which are predicted to impact town border. Analysis points located at distances along slope which are equal or up to 50 m shorter than the town border. See text for detail.

Table 3. OSL age field and laboratory data, with age determination results													
Sample*	Block No.	Depth (m)	γ+cosm. (μGy/a)	K (%)	U (ppm)	Th (ppm)	Ext.α (μGy/a)	Ext.β (μGy/a)	Total dose (μGy/a)	No. of discs	OD (%)	De (Gy)	Age (ka)
QS-1	015	1.2	945	0.80	1.3	6.0	7	745	1697±102	21/22	36	15±2	8.7±1.0

QS-4	010	0.6	577	1.0	1.6	6.6	8	910	1495±77	21/24	51	1.6±0.1	1.0±0.1
QS-5	007	0.5	744	0.76	1.3	4.0	6	680	1429±85	25/25	29	5.4±0.3	3.8±0.3
QS-6	064	0.4	554	0.46	1.3	4.9	6	520	1080±64	22/25	42	2.3±0.1	2.1±0.2
QS-9	013	0.3	455	0.65	1.6	7.1	8	712	1175±62	24/25	62	5.0±0.6	4.3±0.6
QS-11	016	0.3	536	0.58	1.7	6.3	8	665	1209±67	22/23	60	2.1±0.3	1.7±0.2
QS-12	036	1.2	905	1.08	1.9	9.0	10	1041	1256±108	23/25	38	8.8±0.6	4.5±0.4
QS-13	017	0.4	486	1.05	1.8	8.6	10	1003	1481±73	24/25	53	4.7±0.5	3.2±0.4

5 \* Grain size for all samples is 74-125 μm, except for samples QS-1 and QS-2, for which grain size 88-125 μm was used. Water moisture estimated at 15±5%. The quartz was etched by concentrated HF for 40 minutes.

Table 4. Selected historic earthquakes, candidates as possible rockfall triggers in the study area*								
Date	Age	Max estimated age cluster local int./Mag.		OSL samples				
1202 AD	0.81 ka	IX	no-fit					
1033 AD	0.97 ka	IX-X	1.0 ±0.1 ka	QS-4				
749 AD	1.26 ka	Х	no-fit					
659 AD	1.35 ka	IX	no-fit					
551 AD	1.46 ka	VIII-IX		QS-3				
502 AD	1.51 ka	Х	1.7 ±0.25 ka	QS-3, QS-11				
363 AD	1.64 ka	IX		QS-3, QS-11				
199 BC	2.21 ka	Х	2.2 ±0.60 ka	QS-6				
759 BC	2.77 ka	- (M 7.3)	$3.2\pm0.45$ ka	QS-13				
2050-2100 BC	Ca. 4.2 ka	M 6.8-8.0	4.3 ±0.6 ka	QS-5, QS-9, QS-12				
n/a	Ca. 9 ka	M 7.0	8.7 ±1.0 ka	QS-1				

5 \* A list of candidate rockfall triggering earthquakes, which contains historical earthquakes that: (a) occurred within the time spans of the OSL ages; (b) maximum estimated intensity is at least 'IX' on an EMS macroseismic local intensity scale and/or their estimated moment-magnitude from previous paleoseismic studies is 6 or larger; (c) the distance between the study area and affected localities reported does not exceed 100 km (following Keefer, 1984).

# **Figure Captions**

Figure 1 (a) Location map of the study area detailing the major fault segments of the DST (Ro=Roum, Y=Yammuneh, H=Hatsbaya, Ra=Rashaya; S=Serghaya); Inset shows the plate tectonic setting of the DST; (b) Orthophoto map of the study area (black rectangle). The rockfall source, Ein-El-Assad Formation (EEA), is marked by a blue line; town border in red dashed line; yellow rectangle marks the location

5 of block 016 shown in Fig. 2.

> Figure 2 The source for rockfalls, the cliff of Ein El Assad Formation, at the back and a rock-block at its stop site. This large boulder, ~41 m<sup>3</sup>, is block no 016 (Table 3), under which sample QS-11 for OSL age determination was excavated. Photo taken from east to west showing the source of rockfall in the background. The location of the block in the photo is plotted in a yellow rectangle in Fig. 1.

Figure 3 (a) Map of fallen rock-blocks in the studied area. Green rectangles are the 76 blocks mapped in the field within the area marked 10 by green outline; these blocks were used to calculate the block volume distribution (PDF) detailed in Fig. 6; Yellow rectangles are 200 blocks mapped using aerial photos within the area marked by black rectangle; blocks sampled for OSL age determination are marked in red circles. Size of rectangles denotes block diameter bins, see legend. Pink lines represent slope profiles used for CRSP calibration simulations. (b) Histogram of the block volumes for the 76 boulders measured in the field (marked in green rectangles in map).

Figure 4 Location of 25 simulation profiles of rockfall trajectories. Faults traces are from Sneh and Weinberger (2003a). The source for the 15 rock-falls (Ein-el-Assad formation) is marked with blue line.

Figure 5 Field observed distance from the source and maximal simulated travel distances of rock blocks. Block diameters are both size- and color-coded. The 1:1 line (x=y) is plotted in gray.

Figure 6 Probability density function (PDF) of field measured,  $D > 1 \text{ m}^3$ , block volumes (N=76).

- Figure 7 (a) Schematic illustration of the CRSP modelled slope cells and explanation of the terms 'x% stop angle' (e.g. 50% stop angle is 20 the angle of the slope cell where 50% of the blocks stop) and 'stop swath' (the farthest distance along the slope where 100% of the blocks stop). (b) Slope gradients of slope cells and gradients at stop angles. Tangential axes (X and Y axes) denote simulated profile numbers 1 to 25. Radial axis denotes the slope angles. Gradients for all cells per profile are plotted on an arc between 0 and 90 degrees: Red circles are 100% stop angles (slope angle of the profile cell at which cumulated 100% of simulated blocks stop); blue triangles are 50% stop angles; gray circles are all other cells in the profile. For example: the cells along profile 16 have slope angles that vary between 8°-36°; the 100%
- 25 stop angle is 11° (red circle) and the 50% stop angle is 8° (blue triangle). The red line represents the mean of all 100% stop angles for all profiles at 7.7° and the thick black lines represent its SD of 2.3°.

Figure 8 Rockfall hazard map of the study area. The area subject to rockfall hazard is defined from the source escarpment to 100% stop line. Map compiled from maximal travel distance of 25 rockfall simulation profiles performed using CRSP (green lines in Fig. 4).

Figure 9 Rockfall hazard map for the town of Qiryat Shemona. Yellow line represents the CRSP 100% stop line calculated for large blocks 30 (D is 5.8 m and 6.2 m). Yellow-black hazard triangles mark simulated stop line and town border impact location for each profile; Orangeblack hazard triangles mark simulated town border impact location for each profile; profile numbers in yellow refer to simulated profile numbers; indices with sword label '†' mark locations of rockfall impact at town border. Map location is shown on the inset.

Figure 10 Summary of OSL ages (black circles with error bars) plotted in chronological order and selected historical earthquakes suggested as rockfall triggers (shown as vertical gray lines, chronologically labeled at top axis); see text for details.

35 Figure 11 Clustering of rockfall events using binomial non-random temporal distribution using a ±50 years time window. Dated OSL rockfall ages marked in black circles by their central OSL ages with ±50 years black error bars and their lab reported error ranges in lightblue bars. Historical earthquake dates are marked on top axis and plotted with ±50 years time window (red stripes bounded by red solid lines represent time windows). See text for details about binomial distribution results and usage.
