9 **Abstract** Shaanxi Province, located in Northwest China and spanning multiple hydroclimatic and geological zones, has
10 many areas largely suffering from rainfall-induced landslide and debris flow. The objectives of this study are to reveal the
11 spatiotemporal characteristics of the two hazards and identify their major controlling factors in this region based on a
12 region-wide, comprehensive ground survey-based hazard inventory dataset from 2009-2012. We investigated the
13 spatiotemporal characteristics of the two hazards and quantified the relationships between the occurrence rates of the two
14 hazards and their influencing factors, including antecedent rainfall amount, rainfall duration, rainfall intensity, terrain slope,
15 land cover type and soil type. The results show that landslide has a higher occurrence rate and more extensive distribution
16 than debris flow in this region, while the two hazards are both concentrated in the south with ample rainfall and steep
17 terrains. Both of the hazards show clear seasonalities: July-September for landslide and July for debris flow. Rainfall
18 characteristics (amount, duration and intensity) and slope are the dominant factors controlling slope stability across this
19 region. Debris flow is more sensitive to these rainfall metrics on the high-value ranges than landslide in this region. Land
20 cover is another influencing factor but soil type does not appear to impose consistent impacts on the occurrence of the two
21 hazards. This study not only provides an important inventory data for studying the landslide and debris flow hazards but also
22 add valuable information for modeling and predicting the two hazards to enhance resilience to these hazards in this region.

24 stability

25 **1. Introduction**

26 Landslides and debris flows are two widespread and destructive natural hazards around the world (Peruccacci et al.,
27 2012;Huang et al., 2017;Nicolussi et al., 2015;Blothe et al., 2015;Wooten et al., 2008;Hong et al., 2007), which can cause
28 large casualties and economic losses (Jaboyedoff et al., 2012;Hong et al., 2017b;Zhang et al., 2016). Globally, landslides are
29 responsible for approximately 1,000 deaths and about \$4 billion property losses per year (Pradhan and Youssef, 2010).

30 Landslide-caused fatalities accounted for 17% of fatalities due to natural hazards (Hong et al., 2015a). For debris flows, it is
31 more difficult to quantify the resultant casualties and damages because it is hard to distinguish debris flow-induced losses
32 with the losses caused by concurrent flood or the other hazards (Borga et al., 2014). China is one of the countries, which are
33 severely affected by geological disasters, including landslide and debris flow (Petley, 2010; Hong et al., 2015a). Statistical
34 report by Chinese Institution of Geological Environmental Monitoring showed that unexpected geological hazards led to
35 1,167 casualties and 6.4 billion CNY property losses per year (Zhang et al., 2017). Another research reported that landslide
36 disasters have caused about 1,100 fatalities and 5–10 billion US dollars in China since 2000 (Hong et al., 2017a).

37 Due to the massive casualties and property damages that the landslide and debris flow may cause, it is essential to have a
38 profound comprehension of the causes, e.g., heavy rainfall, earthquakes and human activities, of these disasters (Chen et al.,
39 2015b). The process of landslide occurrence is a complex non-linear process (Qin et al., 2001; Sorbino et al., 2010) that is
40 influenced by many different factors such as the geological features and hydrological conditions (Zhu et al., 2017). In many
41 regions, rainfall is the primary trigger (Milne et al., 2012) of shallow landslides and debris flows that have posed significant
42 threats to human lives and properties (Gariano et al., 2015; Pradhan and Youssef, 2010). Hence, numerous studies have been
43 conducted on understanding and modeling the rainfall-induced landslides and debris flows.

44 The methods used to predict landslide occurrence can be divided into two general categories, the statistical methods and the
45 physically based models. The representative statistical method is the rainfall threshold methods (Guzzetti et al.,
46 2007; Peruccacci et al., 2012; Gariano et al., 2015; Bogaard and Greco, 2018), which usually builds a simple statistical model
47 quantifying the relationship of landslide occurrence rate or probability with cumulated rainfall (the total rainfall measured
48 from the beginning of the rainfall event to the time of slope failure), rainfall intensity (the average rainfall intensity during
49 the rainfall event), and/or rainfall duration. The physically based models usually use the rainfall time series as the input data
50 to model the slope stability based on the physical processes and mechanisms. There are many physically based landslide
51 forecasting models such as TRIGRS (Baum et al., 2010; Alvioli and Baum, 2016), SHALSTAB (Montgomery and Dietrich,
52 1994), SLIDE (Hong et al., 2015b; Liao et al., 2012), and SLIP (Montrasio and Valentino, 2008). Recently, several studies
53 were conducted to couple the landslide models with distributed hydrological models to develop the coupled flood-landslide
54 models (He et al., 2016; Zhang et al., 2016). Modeling the movement and run-out extent of debris flow is a more complicated
55 process than modeling the slope failure or the landslide occurrence. Numerical simulation of the debris-flow process is
56 usually based on the shallow water equations (Han et al., 2017) and the numerical solutions of the mass and momentum
57 conservation equations using finite element and finite differential methods (Naef et al., 2006; Zhang et al., 2015).

58 Despite various advanced methods and models have been used for the prediction of landslide and debris flow, it is still
59 difficult to completely explain the physical mechanisms controlling slope failure and to accurately predict the occurrence of
60 landslide and debris flow in most areas (Hong et al., 2017a; Althuwaynee et al., 2014). Besides, there are limited efforts on

61 landslide and debris flow prediction in Shaanxi Province, China so far. Additionally, most of the previous studies were mainly
62 focused in understanding and modeling landslides and/or debris flows in small and medium-sized areas (Chen et al.,
63 2017; Sun et al., 2016; Chen et al., 2016; Zhuang and Peng, 2014). There is still limited knowledge on the characteristics,
64 distributions, and influencing factors of the landslide and debris flow hazards across this region.

65 Therefore, the objectives of this study are to reveal the spatiotemporal characteristics of rainfall-triggered landslide and
66 debris flow hazards in Shaanxi Province and to identify the major controlling factors of the occurrence of the two hazards.
67 To this end, we firstly compiled an inventory data of rainfall-induced landslides and debris flows events in Shaanxi Province
68 for the period 2009-2012 provided by the geological survey office of Department of Land and Resources of Shaanxi
69 Province. Considering the interannual and intraannual differences in rainfall, we then analyzed the characteristics of
70 spatiotemporal distributions of landslide and debris flow using statistical methods. Next, we derived the characteristics of
71 rainfall processes, terrain slope, land cover type and soil type for each grid cell. Finally, we studied the relationships of
72 landslide and debris flow occurrence rates with rainfall level, terrain slope, land cover type and soil type.

73 **2. Study area and data**

74 **2.1 Description of study area**

75 Shaanxi Province, situated in the inland of Northwest China, is located between 105°29' E-111°15' E longitude and 31°42'
76 N-39°35' N latitude with a total area of about 205,800 km². Statistical data show that more than 38 million people live in
77 Shaanxi. Altitude mostly ranges from 350 to 3500 m with a regional average slope of 19.9° (Fig. 1a). In Shaanxi, elevation is
78 higher in the north and south and lower in the middle (Fig. 1a). The average elevation of Qinling Mountains is more than
79 2000 m and it stretches from east to west, representing an important natural line of demarcation between North and South
80 China (Wu and Qian, 2017). The high elevations and relatively steep terrains in many areas of this region make them
81 susceptible to both landslide and debris flow. The Bei Mountains and Qinling Mountains divide Shaanxi Province into three
82 geographical regions: Shaanbei Loess Plateau in the north, Guanzhong Plain (also known as Wei River Basin) in the central
83 area and Qinling-Dabashan Mountains in the south (Jiang et al., 2015). Because of this, land cover shows a distinct regional
84 distribution from north to south: grasslands, cultivated lands and forests (Fig. 1b). The soil type in the study area is mainly
85 loam (Fig. 1c).

86 The hydrological conditions of Shaanxi Province are diverse due to the diversity of its physiographic features and climate,
87 which vary regionally and seasonally. The study area consists of three main climatic zones, semi-arid zone, semi-humid zone
88 and humid zone, distributed from north to south. Regional mean annual temperature is about 6.5-16.6 °C. However,
89 temperature decreases from south to north. Spatial average annual rainfall is 400-600 mm, 500-700 mm and 700-900 mm
90 in northern, central and southern areas, respectively, while precipitation decreases from south to north and is significantly

91 influenced by the mountains. In addition, rainfall has a strong seasonality in this region. Rainfall in summer is the greatest
92 and accounts for 40%-60% of annual rainfall. Rainfall of the remaining seasons decreases in the order of autumn, spring and
93 winter. As rainfall is mostly concentrated in the monsoon season (May-October), rainfall-triggered landslide and debris flow
94 occur frequently during this season.

95 **2.2 Datasets**

96 Data used in this study include rainfall, inventory data of geological hazards, digital elevation model (DEM), land cover, and
97 soil texture data. The rainfall, DEM, land cover and soil texture data are gridded data, while the inventory data of landslide
98 and debris flow hazards is a list of events with recorded locations (latitudes and longitudes), hazard types, causes, occurrence
99 times, and associated casualties.

100 The rainfall data are hourly observations from 756 stations provided by China Meteorological Administration (CMA). We
101 interpolated the site data into gridded data by using the inverse distance weighting method. The spatial resolution of grid is
102 90m. The geological disaster data are from geological survey office of Department of Land and Resources of Shaanxi
103 Province. The DEM data with a spatial resolution of 90m×90m were downloaded from the Geospatial Data Cloud
104 (<http://www.gscloud.cn>). This database covers land area from 60° N to 60° S and was released to the public in 2003.

105 The GlobeLand30-2010 Product is a product of global land cover at a spatial resolution of 30 m derived from remote sensing
106 images in 2010 (Chen et al., 2015a). The dataset covers land area from 80° N to 80° S and consists of 10 land cover types.
107 These 30 m data were aggregated to the 90-m resolution to match with the DEM data.

108 The soil data is from the Harmonized World Soil Database (HWSD) v1.2 (<https://daac.ornl.gov/SOILS/guides/HWSD.html>),
109 which were compiled from four source databases, the European Soil Database (ESDB), the 1:1,000,000 soil map of China,
110 various regional SOTER databases (SOTWIS Database), and the Soil Map of the World. The soil database used in the
111 research is classified based on the USDA classification method of soil texture, which includes 13 types. The soil data were
112 also reprojected and resampled to the 90-m resolution.

113 **3. Methodology**

114 To reveal the spatiotemporal distributions of the rainfall-triggered landslide and debris flow hazards, we analyzed the spatial,
115 latitudinal, interannual, and seasonal distributions of these hazard events and the relationship of the number of hazard events
116 with the corresponding rainfall amount.

117 To investigate the impacts of rainfall characteristics, including antecedent rainfall amount (P_a), rainfall duration (D) and
118 rainfall intensity (I), terrain slope (θ), land cover type (L) and soil type (S) on the occurrence rates (R) of the landslide and
119 debris flow, we first projected the locations of these recorded hazard events to the DEM grid with a spatial resolution of 90
120 m. If multiple events of the same type of hazard occurred on the same grid cell within one hour, these events are treated as

121 one event; the earliest occurrence time of these events is treated as the occurrence time of the combined event. From the 90
 122 m DEM, we further computed the slope angles for each grid cell. We then tabulated all of the above gridded data with the
 123 following attributes: grid cell ID, rainfall event ID, rainfall amount, rainfall duration, rainfall intensity, rain intensity class,
 124 slope, land cover type, soil type and hazard type. We defined a rainfall event as an event with continuous rainfall or a
 125 combination of several discontinued rains with the non-rain intermittent periods less than or equal to two hours.

126 When we calculated the occurrence rate of one type of hazard, we excluded all grid cells without any reported event of this
 127 type of hazard and all rainless events from the analysis. The occurrence rate of a k th type hazard conditional on a given
 128 explanatory variable or its class J ($R_{j,k}$) is define as:

$$129 \quad R_{j,k} = \frac{n(J==j \text{ and } K=k)}{n[J==j \text{ and } (K=k \text{ or } K=0)]} \quad (1)$$

130 where K is the hazard type (0, 1 and 2 for rainfall event without causing any geological hazard, rainfall-induced landslide,
 131 rainfall-induce debris flow, respectively); J is the class of P_a , D , I , θ , land cover type and soil type; $n(J == j \text{ and } K = k)$
 132 is the number of events of a given hazard k when the corresponding J belongs to the j th class; $n[J == i \text{ and } (K = k \text{ or } K =$
 133 $0)]$ is the number of positive and negative events of a given hazard k when the corresponding J belongs to the j th class. In
 134 this study, we classified the rainfall amount, rainfall duration, rainfall intensity, and rain type into five (0-10, 10-30, 30-60,
 135 60-100, and >100 mm), five (0-3, 3-12, 12-24, 24-36, and >36 hours), five (0-1, 1-2, 2-3, 3-5, >5 mm hour⁻¹), and four
 136 classes (light rain, moderate rain, heavy rain, and violent rain), respectively. Following American Meteorology Society
 137 (Huschke, 2000), the light rain, moderate rain, heavy rain, and violent rain are defined as rains when the precipitation rate is
 138 < 2.5 mm hour⁻¹, 2.5-7.6 mm hour⁻¹, 7.6-50 mm hour⁻¹, and >50 mm hour⁻¹, respectively. We categorized the slope, land
 139 cover type and soil type into five (0-2°, 2-5°, 5-10°, 10-20°, and >20°), three (cultivated land, forest, and grassland), and
 140 three classes (loamy sand, loam, and clay), respectively. The other land cover types and soil types are not used in the
 141 computation of the hazard occurrence rates because we did not find any reported landslide or debris flow event under these
 142 types.

143 4. Results

144 4.1 Spatiotemporal distributions of landslide and debris flow events

145 The locations of the recorded landslide and debris flow events and the resultant casualties from 2009 to 2012 are shown in
 146 Fig. 2. It clear that all of these recorded landslide and debris flow events are located in the south of 36° N (Fig. 2).
 147 Relatively, debris flow events are distributed further south than landslides. Most of the landslide and debris flow events are
 148 near the rivers and/or in the areas with steep slopes (see Fig. 2 and Fig. 1a). In addition, the landslide events outnumber the
 149 debris flow events (Fig. 2), indicating that landslide occurs more frequently than debris flow in this region.

150 There are a total of 1177 reported rainfall-triggered landslide events in Shaanxi Province from 2009 to 2012 with respective
151 69, 619, 332 and 157 events in the four years (Fig. 3a), while a total of 209 rainfall-triggered debris flow events occurred in
152 this province during the same period, with respective 6, 175, 13 and 15 events in the four years (Fig. 3a). More than half of
153 the two types of events occurred in 2010. The corresponding casualties are clearly proportional to the number of hazards
154 (Fig. 3a). In particular, landslides and debris flows in 2010 killed 72 and 73 peoples, respectively. During the four-years
155 period, the reported landslide and debris flow hazards caused the deaths of 131 and 78 people, respectively (Fig. 3a),
156 indicating that the two types of hazards are destructive in this region. Relatively, debris flow is even more destructive than
157 landslide. Although the number of debris flow events account for only 15 % of the total events of the two hazards, the debris
158 flow-caused fatalities are 37.32 % of the total deaths caused by the two hazards (Fig. 3b). The above results suggest that
159 debris flow imposes a higher threat to people in this province per event than landslide.

160 In terms of interannual distributions of the two hazards, annual total numbers of landslide and debris flow hazards show a
161 correlation with annual rainfall amount (Fig. 4a). However, annual rainfall amount is not the only factor influencing the
162 occurrences of the two hazards. For example, there is more annual rainfall in 2011 and 2012 than in 2010, but the total
163 numbers of landslide and debris flow events in 2011 and 2012 are actually lower than these in 2010 (Fig. 4a). In terms of
164 intra-annual distributions of the two hazards, landslide events are mainly distributed between July and September, which are
165 the top three months in terms of both total rainfall amount (Fig. 4b) and average rainfall intensity (Fig. 4c). In contrast,
166 almost all of debris flow events occurred in July, the month having the largest rainfall amount (Fig. 4b) and rainfall intensity
167 (Fig. 4c) with multi-year mean values of 117 mm month⁻¹ and 0.96 mm hour⁻¹, respectively during a year. Statistical analysis
168 shows that rainfall between July and September accounts for 63.6 % of annual rainfall, while the proportions of landslide
169 and debris flow events during the three months are 98.6 % and 100 % of annual events, respectively. Obviously, the
170 landslide and debris flow hazards are seasonal hazards in Shaanxi Province and mainly occur during the rainy season. The
171 above results show that the landslide season is longer than the debris flow season.

172 We further analyzed the latitudinal distribution of annual rainfall, the number of landslides, the number of debris flows, the
173 zonal average slope, and the percentages of dominant land cover by dividing the region into four latitude bins (31° N-33° N,
174 33° N-34° N, 34° N-35° N and 35° N-36° N). As there are no reported landslide and debris flow events in the areas north to
175 36° N, we excluded these regions for analyzing the distributions of these hazards and their relations to rainfall, terrain slope,
176 and land cover in these areas. There are apparent latitudinal gradients in annual rainfall and the numbers of report landslide
177 and debris flow events, which all decrease from the south to the north (Fig. 5). The regional average terrain slope generally
178 decreases from the south to the north with the respective values of 23.4°, 23.7°, 10.7° and 11.4° in the four latitude bins (Fig.
179 5). These results suggest that more rainfall and steeper slopes in the south can explain the larger numbers of reported
180 landslides and debris flows in the south than in the north. In addition, the southern part of this province (31° N-34° N) is

181 mainly covered by forests ($\geq 78\%$), while the regions between 34° N- 35° N and between 35° N- 36° N are dominated by
182 cultivated lands (50 %) and grasslands (47.1 %), respectively (Fig. 5 and Fig. 1a). Although the southern region has a denser
183 and better preserved land cover than the middle and northern parts, the southern region still experiences more landslide and
184 debris flow hazards. This suggests that the meteorological and geomorphological factors such as rainfall and terrain slope
185 play more important roles in controlling the landslide and debris flow occurrence than land cover.

186 **4.2 Impacts of rainfall amount, intensity, and duration on the landslide and debris flow occurrence**

187 To attribute the causes of the landslide and debris flow hazards, we further analyzed the relationships between rainfall
188 characteristics (antecedent accumulated amount, duration and intensity) and the occurrence rates of the two hazards. There
189 are no apparent relationships between the antecedent rainfall amount and the number of the landslide events and between the
190 antecedent rainfall amount and the number of the debris flow events (Fig. 6a). However, the occurrence rate of debris flow
191 exponentially increases with increasing antecedent rainfall amount ($R = 0.0022\exp(1.8127P_a)$; $R^2=0.988$) (Fig. 6a).
192 Similar relationship appears between the landslide occurrence rate and antecedent rainfall amount
193 ($R = 0.0034\exp(1.6681P_a)$; $R^2=0.977$). However, the landslide occurrence rate is higher than the debris flow occurrence
194 rate when antecedent accumulated rainfall is lower than 100 mm (Fig. 6a). Once antecedent accumulated rainfall is above
195 100 mm, the debris flow occurrence rate becomes much larger than the landslide occurrence rate (Fig. 6a). This suggests that
196 triggering debris flow generally requires more rainfall than triggering landslide.

197 The occurrence rates of the two hazards also show positive exponential relationships with the rainfall duration ($R =$
198 $0.0002\exp(1.7175D)$, $R^2=0.997$ for landslide; $R = 0.00009\exp(1.9526D)$, $R^2=0.977$ for debris flow) (Fig. 6b). In
199 addition, the occurrence rates of the two hazards also show positive exponential relationships with the average rainfall
200 intensity (Fig. 6c). These results indicate that rainfall amount, duration, and intensity all play an important role in controlling
201 the landslide and debris flow occurrence in this region. In addition, the three rainfall metrics usually correlate with each
202 other to some extent. In other words, the rainfall event that has the largest accumulated rainfall usually has a long duration
203 and high average rainfall intensity.

204 In terms of the rainfall intensity, rainfall events can be classified to four classes, i.e., light rain, moderate rain, heavy rain,
205 and violent rain according to American Meteorology Society. Therefore, we also calculated the regional average occurrence
206 rates of landslide and debris flow under the four rain classes. Similar to the relationships between the occurrence rates and
207 rainfall intensity (Fig. 6c), the regional average occurrence rates of the two hazards increase largely with increasing rainfall
208 class (Fig. 7). Furthermore, Fig. 8 shows the spatial maps of landslide and debris occurrence rates under different rain
209 classes. As rain becomes severe, both landslide and debris flow occur on more grid cells (Fig. 8a-d and Fig. 8e-h). For
210 example, light rains have caused 163 landslide events and 26 debris flow events during the four-years period with average
211 occurrence rates of 0.006 % and 0.005 %, respectively. In contrast, violent rains have led to 273 landslide events and 60

212 debris flow events during the same period with average occurrence rates of 2.70 % and 8.57 %, respectively. Meanwhile, the
213 landslide occurrence rates on the grid cells that experience at least one landslide event during the four-years period increase
214 with increased rainfall intensity as well (Fig. 8a-d). As shown in Fig. 8e-h, the debris flow occurrence rates on the grid cells
215 that experience at least one debris flow event during the four-years period show a similar correlation with the rain classes (or
216 rainfall intensity classes).

217 **4.3 Relationship of the landslide and debris flow occurrence with slope, land cover type, and soil type**

218 Terrain, in particular terrain slope, is another important factor determining slope stability. Therefore, we grouped the 90-m
219 grid cells with at least one reported landslide or debris flow event during the study period into five slope bins, i.e., 0-2°, 2-5°,
220 5-10°, 10-20°, and >20°, and computed the respective landslide and debris flow occurrence rates. It is obvious that there are
221 strong positive correlations between the occurrence rates of the two hazards and the slope angle (Fig. 9). Once again, the
222 landslide occurrence rate is clearly larger than the debris flow occurrence rate under all of the five slope classes (Fig. 9).
223 Relative to debris flow, landslide occurrence is more sensitive to terrain slope (Fig. 9). With increasing terrain slope, the
224 landslide occurrence rate accelerates much faster than the debris flow occurrence rate.

225 We further analyzed the relationships of the hazard occurrence rates with land cover type and soil type. For debris flow, its
226 occurrence rate is higher on the cultivated lands, followed by forests and grasslands (Fig. 10a). As shown in Fig. 1b,
227 grasslands are mainly located in the north that has lower rainfall and much flatter terrain than in the south. Therefore, it is not
228 surprise to observe a lower debris flow occurrence rate on grasslands than on cultivated lands and forests. For landslide, its
229 occurrence rate is also the highest on cultivated lands, but the occurrence rates on forests and grasslands are very similar
230 (Fig. 10a). Higher occurrence rates for both landslide and debris flow on cultivated lands than on forests and grassland
231 suggest that the destruction and conversion of natural dense land cover can weaken slope stability, making these areas more
232 susceptible to landslides.

233 In this region, our analysis based on the available data does not show that soil type imposes apparent, consistent effects on
234 the occurrence rates of landslide and debris flow. For example, landslide has the highest occurrence rate in the clay soil
235 among the tree dominant soil types in this region, while the landslide occurrence rates in the loam soil and the loamy sand
236 soil are comparable (Fig. 10b). In contrast, debris flow has the highest occurrence rate in the loamy sand soil, while the
237 debris flow occurrence rates are similar in the loam and clay soils (Fig. 10b).

238 **5. Discussions**

239 Based on the survey of rainfall-induced landslide and debris flow hazards from 2009 to 2012 in Shaanxi Province, China,
240 our results show that both of landslide and debris flow occur frequently in this region and are mainly distributed in the
241 southern part of this province, which have more rainfall and steeper terrain slopes than the other areas of this province.

242 Landslide happens more frequently than debris flow. Although the number of the reported debris flow events is only one
243 sixth of the number of the recorded landslide events in this region, the debris flow-caused casualties is equal to 60 % of the
244 landslide-caused casualties. Clearly, debris flow is more destructive than landslide in this region in terms of the casualty per
245 event. Like many areas in the world, debris flow usually occurs in the areas near the stream network, which usually has
246 higher population. Moreover, debris flow usually carries more materials and travels a longer distance than landslide, making
247 it more harmful to the people and properties (Ietto et al., 2016). In fact, most of debris flow events are initialized from
248 landslide and cause more damages to the environment and society (Peng et al., 2015; Zhou et al., 2013).

249 Our results show that rainfall characteristics including rainfall amount, rainfall intensity, and rainfall duration all play
250 important roles in controlling the occurrence of landslide and debris flow. Relatively speaking, rainfall amount and rainfall
251 duration have higher impacts on the occurrence of landslide and debris flow than average rainfall intensity in this region.
252 This is because a rainstorm with higher average rainfall intensity does not necessary last for a long duration and lead to
253 larger accumulated rainfall amount. In addition, one has to note that the three rainfall characteristics do not necessary
254 correlate with each other. The previous studies have pointed out that different types of landslides and debris flows have
255 different critical rainfall conditions for failure considering the different geologic and geomorphologic conditions (Zeze et
256 al., 2015; Guzzetti et al., 2008). For example, rapid debris flows are typically triggered by very intense showers concentrated
257 in a few hours, while shallow translational soil slips are usually triggered by intense precipitation falling within a few days
258 (Zeze et al., 2015). In contrast, deep-seated landslides of rotational, translational and complex types are related to long
259 periods (weeks to months) of nearly constant rainfall (Zeze et al., 2015; Chen et al., 2013). In general, rainfall with long
260 duration and large rainfall amount is more likely to trigger landslide and debris flow (Saito et al., 2014).

261 Terrain slope is another important factor influencing the slope stability since gravity makes these slopes with higher slope
262 angles more vulnerable (Nourani et al., 2014; Dehnavi et al., 2015). In addition, terrains with steep slopes make plants harder
263 to establish and grow. Furthermore, the vegetation roots are hard to reach the sliding surface if the slope is steep (usually
264 exceed 1.5 m) (Ocakoglu et al., 2002; Cammeraat et al., 2005). In this case vegetation biomass may increase the weight of
265 landslide body and promote the occurrence of landslides (Nilaweera and Nutalaya, 1999; Collison and Anderson, 1996). The
266 terrain and vegetation can interact with each to create complex hydrological and mechanical effects on the slope stability.
267 Benefits from vegetation are conditional on the geological and geomorphological conditions (Nilaweera and Nutalaya,
268 1999; Collison and Anderson, 1996).

269 Land cover type is another factor that impacts the slope stability. As show in our results (Fig. 10), cultivated lands have
270 higher landslide and debris flow occurrence rates than forests in the same climatic zone. The similar findings were also
271 reported in the previous researches, showing that conversion of natural vegetated lands, in particular forests, to cultivated
272 lands or the early-stage abandonment of cultivated lands can largely weaken slope stability by increasing surface water

273 runoff, intensifying erosion processes, and increasing soil instability (Begueria, 2006; Lopez-Saez et al., 2016; Persichillo et
274 al., 2017). Besides, the slopes with woody vegetation are more stable than those with herbaceous vegetation because woody
275 vegetation has deeper roots than herbaceous vegetation and can draw down soil moisture, making the slopes more stable
276 (Kim et al., 2017; Begueria, 2006). In addition, some studies also show that the stand age, structure and composition of
277 vegetation can influence the slope stability (Turner et al., 2010).

278 In this region, soil type does not appear to impose apparent, consistent effects on the occurrence rates of landslide and debris
279 flow based on the available data. These results suggest that soil type is not the dominant factor influencing the slope stability
280 in this region. As shown in the other studies, soil types and their physical properties such as cohesion, saturated hydraulic
281 conductivity, porosity and friction angle have impacts on the slope failure and stability (Antinoro et al., 2017; van Asch and
282 Malet, 2009; Zhang et al., 2016; Pasculli et al., 2017; Milne et al., 2012).

283 **6. Conclusions**

284 In this paper, we analyzed the spatiotemporal distributions, occurrence rates, and resultant casualties of rainfall-triggered
285 landslide and debris flow based on a survey from 2009 to 2012 in Shaanxi Province, China. Our results show that landslide
286 has a higher occurrence rate and more extensive distribution than debris flow in Shaanxi Province, while both of the two
287 hazards are concentrated in the south of this region with ample rainfall and relatively steep terrains. Debris flow is more
288 destructive than landslide in terms of the casualties per event. Both landslide and debris flow show a clear seasonality,
289 corresponding to the rainy season in this region. Debris flow mainly occurs in July, whereas landslide usually takes place
290 between July and September.

291 The characteristics of rainfall events including accumulated rainfall amount, duration and intensity and terrain slope show
292 the strongest impacts on the slope stability and the occurrence rates of landslide and debris flow. The landslide and debris
293 flow occurrences have exponential relationships with all of the above four factors ($P < 0.1$). When accumulated rainfall
294 amount and intensity are on the low and intermediate levels, landslide has a higher occurrence rate than debris flow. On the
295 contrary, the debris flow occurrence rate is much higher than the landslide occurrence rate when accumulated rainfall
296 amount and intensity are on the high level. Responses of the landslide and debris flow occurrence rates to rainfall duration
297 do not differ much between each other. The occurrence of both landslide and debris flow also largely depends on the terrain
298 slope, but landslide has a higher sensitivity to terrain slope than debris flow does. Our results also show that land cover also
299 influences the occurrence of the two hazards to some extent in this region. In particular, both landslide and debris flow has
300 lower occurrence rates on the natural vegetated land than on the cultivated lands. However, the study does not find an
301 apparent relationship between the occurrence rates of the two hazards and soil type. In summary, we compiled an important
302 inventory data of the rainfall-triggered landslide and debris flow hazards in Shaanxi Province, China based on a four-years

303 survey and revealed the spatiotemporal distributions and characteristics of these events and the impacts of rainfall
304 characteristics, topography and soil texture on the occurrence of landslide and debris. This study not only provides an
305 important inventory data for understanding the formation mechanisms and characteristics of the landslide and debris flow
306 hazards but also add valuable information for modeling and predicting the rainfall-triggered landslide and debris flow
307 hazards to improve preparedness for and enhance resilience to these hazards in this region and the other similar areas.

308 **Author contribution:** K.Z. designed the study; S.W. and K.Z. conducted this study; K.Z. and S.W. wrote this paper; H.B.
