15 **Abstract**

16 In this paper, we study the impact of lightning and radar reflectivity factor data assimilation on the
17 precipitation VSF (Very Short-term Forecast, 3 hours in this study) for two relevant case studies
18 occurred in Italy. The first case refers to a moderate and localised rainfall over central Italy
19 occurred on 16 September 2017. The second case, occurred on 9 and 10 September 2017, was
20 very intense and caused damages in several geographical areas, especially in Livorno (Tuscany)
21 where nine people died.

22 The first case study was missed by several operational forecasts (from both public and private
23 sectors), including that performed by the model used in this paper, while the Livorno case was
24 partially predicted by operational models.

25 We use the RAMS@ISAC model (Regional Atmospheric Modelling System at Institute for
26 Atmospheric Sciences and Climate of the Italian National Research Council), whose 3D-Var
27 extension to the assimilation of RADAR reflectivity factor is shown in this paper for the first time.

28 Results for the two cases show that the assimilation of lightning and radar reflectivity factor,
29 especially when used together, have a significant and positive impact on the precipitation
30 forecast. For specific time intervals, the data assimilation is of practical importance for civil
31 protection purposes because changes a missed forecast of intense precipitation (≥ 40 mm/3h) in a
32 correct one.

33 While there is an improvement of the rainfall VSF thanks to the lightning and radar reflectivity
34 factor data assimilation, its usefulness is partially reduced by the increase of the false alarms,
35 especially when both data area assimilated.

36 **Keywords:** data assimilation, lightning, radar reflectivity factor, RAMS@ISAC.

37

38 **1. Introduction**

39 Initial conditions of numerical weather prediction (NWP) models are a key point for a good
40 forecast (Stensrud and Fritsch, 1994; Alexander et al., 1999). Nowadays limited area models are
41 operational at the resolution of few kilometres (< 5 km) and data assimilation of non-conventional
42 observations, as lightning or radar data, is crucial to correctly represent the state of the
43 atmosphere at local scale (Weisman et al., 1997; Weygandt et al., 2008). This is especially
44 important over the sea, where the absence of local observations and model deficiencies can
45 misrepresent convection.

46 The assimilation of radar reflectivity factor¹ is useful to improve the weather forecast considering
47 the high repetition rate (asynoptic data) and the high spatial resolution (local scale) of the radar
48 data.

49 First attempts to assimilate radar reflectivity factor are reported in Sun and Crook (1997, 1998),
50 who expanded VDRAS (Variational Doppler Radar Analysis System) to include microphysical
51 retrieval. Following these studies, several systems to assimilate radar observations, both Doppler
52 velocity and reflectivity factor, were developed (Xue et al., 2003, Zhao et al., 2006; Xu et al., 2010).
53 All these studies showed the stability and robustness of assimilating radar observations as well as
54 the improvement of weather forecast.

55 Radar data are also assimilated in WRF (Weather Research and Forecasting model, Skamarock et
56 al., 2008; Barker et al., 2012) both using 3DVar (Xiao et al., 2005, 2007; Barker et al., 2004) and
57 4DVar (Wang et al., 2013; Sun and Wang, 2012). The capability to assimilate radar data into WRF
58 was recently applied to a heavy rainfall event over Central Italy by Maiello et al. (2014). They
59 showed a notable and positive impact of the radar data assimilation on the precipitation forecast,
60 also when radar data were assimilated together with conventional data (SYNOP and RAOB).

61 In addition to direct methods, which assimilate the radar reflectivity factor adjusting the
62 hydrometeor contents, there are indirect methods adjusting other variables. In particular, the
63 method of Caumont et al. (2010) acts on the relative humidity field. It consists of two different
64 steps: a 1D retrieval of relative humidity (pseudo-profile), which depends on the radar reflectivity
65 factor observations, followed by 3D-Var assimilation of the pseudo-profile. This method has the
66 advantage to reduce the computational cost at the kilometeric scale.

¹ Throughout the paper we use the expression radar reflectivity factor, which is the quantity provided by the radar (and expressed in mm^6m^{-3} or dBz) after conversion from the received power. The radar reflectivity factor is different from reflectivity and is obtained in the special case of Rayleigh scattering. Reflectivity is not the quantity that radars usually provide and display on their screens although most of people refer to it.

67 The choice of updating the moisture field directly is motivated by its greater impact on analyses
68 and forecasts in comparison to that of hydrometeor-related quantities (e.g., Fabry and Sun, 2010).
69 Caumont et al. (2010) showed that the method improved the weather prediction of a heavy
70 precipitation event in southern France and of a eight-day long assimilation cycle experiment.
71 The method was applied in other studies (Wattrelot et al., 2014, using AEROME model; Ridal and
72 Dalbom, 2017; using HARMONIE model), or modified using 4D-Var in place of 3D-Var (Ikuta and
73 Honda, 2011; using JNoVa model) showing its capability to improve the weather forecast. The
74 method is also used in the operational context (Wattrelot et al., 2014).

75 Flashes are another important source of asynoptic data due to their ability to locate precisely the
76 convection with few temporal gaps (Mansell et al., 2007). In the last two decades, there have been
77 attempts to assimilate lightning into meteorological models both at low horizontal resolution,
78 which need a cumulus parameterization scheme to simulate convection, and at convection
79 permitting scales.

80 The first attempts to assimilate lightning in NWP models were based on relationships between
81 lightning and rainfall rate estimated by microwave sensors on board polar satellites (Alexander et
82 al., 1999; Chang et al., 2001; Jones and Macpherson, 1997; Pessi and Businger, 2009). In this
83 approach, the rainfall rate was computed as a function of lightning observations and then
84 transformed into latent heat, which was assimilated. The results of these studies showed a
85 positive impact of the lightning data assimilation on the forecast up to 24h also for fields at the
86 large scale, as sea-level pressure.

87 The study of Papadopoulos et al. (2005) used lightning to locate convection and the model water
88 vapour profile was nudged towards vertical profiles recorded during convective events.

89 Mansell et al. (2007) modified the Kain-Fritsch (Kain and Fritsch, 1993) cumulus convective scheme
90 to force convection when/where flashes are observed while the convective scheme was not
91 activated in the model simulation, demonstrating the potential of lightning to improve the
92 convection forecast. A similar approach was introduced by Giannaros et al. (2016) into WRF
93 showing the positive impact of lightning data assimilation on the precipitation forecast up to 24h
94 for eight convective events occurred over Greece.

95 Fierro et al. (2012) introduced a methodology to assimilate lightning at convection permitting
96 scales by modifying the water vapour mixing ratio simulated by the WRF according to a function
97 depending on the flash-rate and on the simulated graupel mixing ratio. The water vapour could be
98 assimilated by nudging (Fierro et al., 2012) or 3D-Var (Fierro et al., 2016).

99 Qie et al. (2014), using WRF, extended the methodology of Fierro et al. (2012) to assimilate ice
100 crystals, graupel and snow, showing promising results for deep convective events in China.
101 Fierro et al. (2015) studied the performance of the Fierro et al. (2012) method for 67 days
102 spanning the 2013 warm season over the CONUS giving a statistically robust estimation of the
103 performance of the method. The computationally inexpensive lightning data assimilation method
104 improved considerably the short-term (≤ 6 h) precipitation forecast of high impact weather.
105 Lynn et al. (2015), Lynn (2017) also applied the method of Fierro et al. (2012) to boost the local
106 thermal buoyancy where/when lightning is observed. Results show that lightning data assimilation
107 improved lightning forecast. Importantly, Lynn et al. (2015) offer an approach to address spurious
108 convection (i.e., convection removal), which is a far more challenging problem to tackle.
109 Federico et al. (2017a) implemented the methodology of Fierro et al. (2012) in RAMS@ISAC
110 model, showing the systematic and significant improvement of the precipitation forecast at the
111 very short range (3h) for twenty case studies occurred over Italy; the impact of lightning data
112 assimilation for longer time ranges (6h-24h; Federico et al., 2017b) showed considerable impact
113 on the 6h precipitation forecast, with smaller (negligible) effects at 12 h (24 h).
114 In this paper, we study the impact of radar reflectivity factor and lightning data assimilation on the
115 very short term (3h) rainfall prediction for two case studies over Italy. We use the method of
116 Fierro et al. (2012) to assimilate lightning and the method of Caumont et al. (2010) to assimilate
117 the radar reflectivity factor. The case studies occurred in September 2017. The first case, hereafter
118 also referred to as Serano, occurred on 16 September, was characterized by moderate-intense and
119 localized rainfall. The second case, hereafter also referred to as Livorno, occurred on 09-10
120 September, was characterized by deep convection and very intense precipitation in several parts
121 of Italy. Even if the Livorno case occurred before the Serano case, we reverse the chronological
122 order in the discussion, ordering the event from the less intense to the most intense.
123 The forecast of severe events at the local scale still remains a challenge because of the multitude
124 of physical processes involved over a wide range of scales (Stensrud et al., 2009). The Serano case
125 study, being localized in space, poses challenges in forecasting the exact position and timing of
126 convection initiation; the Livorno event involves the interaction between a high impact storm and
127 the complex orography of Italy, which is difficult to simulate at the local scale. For the above
128 reasons the forecast of both events was challenging, as confirmed by the poor forecast of
129 RAMS@ISAC. The difficulty to forecast timely and accurately the precipitation field is the reason
130 for choosing them as test cases.

131 This paper presents for the first time the assimilation of the total lightning (intra cloud + cloud to
132 ground) and radar reflectivity factor in RAMS@ISAC and shows how the assimilation of the radar
133 reflectivity factor works together with total lightning data assimilation. Also, this paper shows how
134 accurate in space and time can be the forecast of the precipitation field using cloud scale
135 observations over complex terrain, contributing in this way to a number of works on the same
136 subject.

137 The paper is organized as follows: Section 2 gives details on the synoptic environment of the case
138 studies showing daily precipitation, lightning and radar observations; Section 3 gives details on the
139 meteorological model, lightning and radar data assimilation; Section 4 shows the results for three
140 very short-term forecast (VSF), one for Serano and two for Livorno; Discussion and conclusions are
141 given in Section 5. This paper has additional material where we discuss: a) how the lightning and
142 radar reflectivity factors data assimilation adjust the total water field; b) the sensitivity of the
143 results to the choice of key parameters of lightning data assimilation.

144

145 **2. The case studies**

146 *2.1 The 16 September 2017 (Serano) case study*

147 During the 16 September 2017 Italy was under the influence of a cyclone that developed to the lee
148 of the Alps. The storm crossed Italy from NW to SE leaving light precipitation over most of the
149 peninsula with moderate rainfall over Central Italy. Figure 1 shows the precipitation recorded by
150 the Italian raingauge network on 16 September 2017. Light precipitation (< 5 mm/day) is reported
151 by 1018 raingauges out of the 1666 stations measuring precipitation (≥ 0.2 mm/day) on this day.
152 Fourteen stations over Central Italy recorded more than 50 mm/day. The maximum precipitation
153 was 90 mm/day in Città di Castello (Umbria Region, Figure 1). Because the meteorological radar
154 closest to the maximum precipitation is over mount Serano (Figure 1), hereafter this event will be
155 referred to as Serano.

156 The synoptic condition during the event is shown in Figure 2. At 500 hPa (Figure 2a) a trough,
157 elongated in the SW-NE direction, extends over Western Europe and air masses are advected from
158 SW towards western Alps. The interaction between the airflow and the Alps generates a low
159 pressure to the lee of the Alps over Northern Italy.

160 The analysis at the surface (Figure 2b) shows the meteorological front represented by the
161 equivalent potential temperature gradient between air masses advected over the Mediterranean

162 Sea from NW and air masses advected from the South over the Tyrrhenian Sea. Notable is the
163 feeding of warm unstable air masses towards Central Italy.

164 Infrared satellite images (Figure 3), from 00 UTC on 16 September to 00 UTC on 17 September,
165 show the cold front structure moving slowly from NW to SE. Interestingly, at 00 UTC on 16
166 September, it is apparent the well-defined cloud system over Central Italy (red circle of Figure 3a),
167 which caused most of the daily precipitation observed between 43.50 and 45.0 N in the six-hours
168 00 UTC-06 UTC on 16 September.

169 The well-defined cloud system over Central Italy is also evident in the radar Constant Altitude Plan
170 Position Indicator (CAPPI) at 3 km above sea level at 02 UTC on 16 September (Figure 4). This
171 CAPPI is formed by interpolating all the available data from the federated Italian radar network
172 coordinated by the Department of Civil Protection (twenty-two radars, see Section 3.3 for their
173 positions) and it is also referred to as the national radar composite (hereafter also mosaic). Several
174 convective cells exceeding 35 dBz can be noted over central-northern Italy. Importantly, the cloud
175 system over Central Italy shown by the satellite infrared channel at 00 UTC (Figure 3a) and that of
176 the radar at 02 UTC have similar positions, showing that the cloud system was active for several
177 hours over Central Italy.

178 Figure 5 shows the lightning recorded by the LINET network (Betz et al., 2009) on 16 September
179 2017. More than 105.000 flashes were recorded during the day; most of them occurred during the
180 afternoon and evening, but a secondary maximum occurred in the night, from 00 UTC to 06 UTC.
181 In this phase, more than 3000 flashes were observed over Central Italy.

182

183 *2.2 The 09-10 September 2017 (Livorno) case study*

184 During the days 09 and 10 September 2017, Italy was hit by a severe storm characterised by
185 intense and widespread rainfall over the country. Figure 6a shows the precipitation on 09
186 September recorded by the Italian raingauge network. Rainfall was intense over the Alps, where
187 the maximum daily precipitation was observed (193 mm/day) and over Liguria, with precipitation
188 of the order of 30-50 mm/day. One station over Tuscany reported 90 mm/day, showing that
189 intense precipitation already started over the Region. The intensity of the storm on 09 September
190 was high because 20 raingauges reported more than 100 mm/day and 70 raingauges more than 60
191 mm/day, and, in most cases, this precipitation occurred within few hours.

192 The following day (see Figure 6b) had higher rainfall. Precipitation occurred mainly over Central
193 Italy, especially over Lazio, and over Northern Italy, in particular the North-East. In Tuscany, the

194 two stations close to the sea, in the Livorno area, recorded about 150 mm/day mostly fallen in the
195 hours between 00 and 06 UTC. The rainfall on 10 September was abundant: and 60 raingauges
196 recorded more than 100 mm/day.

197 Synoptic conditions leading to this storm are shown in Figure 7. At 500 hPa (Figure 7a) a trough
198 extends from Northern Europe towards the Mediterranean. The interaction between the air-
199 masses and Western Alps generated a depression to the lee of the Alps, which crossed the whole
200 peninsula from NW to SE. It is noted the divergent flow over Central and Northern Italy favouring
201 upward motions.

202 At the surface, Figure 7b, it is evident the equivalent temperature gradient over the western
203 Mediterranean caused by the contrast between air masses pre-existing over the sea and air
204 masses advected from France towards the Mediterranean. The pressure field at the surface
205 advects air masses from the South over the Tyrrhenian Sea. These warm and humid air masses
206 feed the cyclone during its development.

207 From a synoptic point of view, Livorno and Serano cases are similar and represent two cyclones
208 developing to the lee of the Alps (Buzzi and Tibaldi, 1978). However, the Livorno case is more
209 intense than Serano as shown by the larger rainfall occurred in the former case.

210 The notable intensity of the Livorno case is confirmed by the lightning observations (Figure 8).
211 During the evening of 9 September (after 18 UTC) about 38.000 flashes were recorded by LINET.
212 On 10 September about 290.000 flashes were recorded over Italy, following the movement of the
213 storm propagating from NW to SE. So, more than 300.000 flashes were recorded from 18 UTC on
214 09 September to 00 UTC on 11 September, which are more than three times those recorded for
215 Serano.

216 Thermal infrared satellite images (channel, 10.8 micron; Figure 9) show the extension of the cloud
217 coverage every 12 hours. It is well evident the cloud system associated with the cold front over
218 Europe. More specifically, the satellite image at 00 UTC shows the cloud system over Livorno area
219 (red circle in Figure 9b), before the main precipitation event over Tuscany (00-06 UTC), while
220 Figure 9c shows the cloud system over Central Italy (orange circle), at the end of the period of
221 intense precipitation over Lazio (06-12 UTC).

222 We conclude the synoptic analysis of the case study with two CAPPI at 3 km observed by the radar
223 network of the Department of Civil Protection. The CAPPI in Figure 10a, at 00 UTC on 10
224 September, shows the cloud system over Tuscany with reflectivity factor up to 40 dBz. Other

225 clouds cause rainfall over northern Italy. The CAPPI of Figure 10a is the last assimilated by the 00-
226 03 UTC VSF on 10 September shown in Section 4.2.1.

227 Figure 10b shows the CAPPI of the national radar mosaic at 3 km above the sea level and at 06
228 UTC. The cloud system is moving towards Central Italy with reflectivity up to 45 dBz. Other cloud
229 systems are apparent over northern Italy. Figures 10a-10b well represent the movement of the
230 storm towards SE and Figure 10b shows the last CAPPI assimilated by the 06-09 UTC VSF shown in
231 Section 4.2.2.

232

233 **3.Data and Methods**

234 *3.1 RAMS@ISAC and simulations set-up*

235 The RAMS@ISAC is used as NWP driver in this work. The model is based on the RAMS 6.0 model
236 (Cotton et al., 2003) with the addition of four main features, as well as a number of minor
237 improvements. First, it implements additional single moment microphysical schemes, whose
238 performance is shown in Federico (2016): among them, the WSM6 (Hong and Lim, 2006) is used in
239 this paper. Second, it predicts the occurrence of lightning following the diagnostic method of Dahl
240 et al. (2011), the implementation being discussed in Federico et al. (2014). Third, the model
241 assimilates lightning through nudging (Fierro et al., 2012, 2015; Federico et al., 2017a). Fourth, the
242 model implements a 3D-Var data assimilation system (Federico, 2013, hereafter also RAMS-
243 3DVar), whose extension to the radar reflectivity factor is presented in this paper (Section 3.3).

244 The list of the main physical parameterisation schemes used in the simulations of RAMS@ISAC is
245 shown in Table 1.

246 Considering the domains and the configuration of the grids (Figure 11 and Table 2), two different
247 set-ups are used for Serano and Livorno. For the first case, we use the domains D1 and D2, while
248 for Livorno we use also the domain D3. The first domain covers a large part of Europe and extends
249 over the North Africa. For this domain, the horizontal resolution of the grid is 10 km (R10). The
250 second domain extends over the whole Italy and part of Europe and the grid has 4 km horizontal
251 resolution (R4). The third domain covers the Tuscany Region, has 4/3 km horizontal resolution
252 (R1), and it is used for Livorno to represent with higher spatial detail the precipitation field over
253 Tuscany. The fine structures of the precipitation field are smeared out over Tuscany using only
254 domains D1 and D2. The operational implementation of the RAMS@ISAC model uses the domains
255 D1 and D2 and no refinements for specific areas of Italy are used because Italy is a complex

256 orography country and grid refinements for a specific event can be done only a-posteriori, i.e.
257 after the occurrence of the event.

258 The resolution and the extension of the grids in the vertical direction is the same for the three
259 domains. The vertical grid covers the troposphere and the lower stratosphere. Vertical levels have
260 different spacings and are more packed close to the ground. Among the 36 levels used in this
261 paper 10 are below 1 km, 15 below 2 km and 18 below 3 km. The first vertical level is at 24 m
262 above the surface in the terrain following coordinates used by RAMS@ISAC, the level 21 is at 5200
263 m. Above 6 km the model levels are about 1000 m apart, with a maximum of 1200 m for the
264 vertical layer at the model top.

265 The vertical grid is the same as the operational setting of RAMS@ISAC and is a compromise
266 between vertical resolution and computing time. In the future, the number of vertical levels will
267 be increased to better resolve the phenomena in this direction (Planetary Boundary Layer
268 processes, vertical motions, interaction between air masses and orography etc.), nevertheless the
269 current setting was used successfully in the forecast of several heavy precipitation events over
270 Italy. The nesting between the first and second domains is one-way, while the nesting between
271 the second and the third domains is two-way.

272 VSF is implemented as shown in Figure 12. First a run with R10 configuration is performed using
273 the 0.25° horizontal resolution GFS analysis/forecast cycle issued at 12 UTC as initial and boundary
274 conditions. R10 run, which starts at 12 UTC on 16 September for Serano and at 12 UTC on 09
275 September for Livorno, lasts 36 h and doesn't assimilate neither radar reflectivity factor nor
276 lightning. The R10 run is not updated after the acquisition of new data by the analysis system and
277 this is a limitation of the results shown in this paper.

278 Starting from 12 UTC, ten VSF are performed using R4 for Serano and both R4 and R1 for Livorno.
279 The VSF lasts 9h and uses R10 simulation as initial and boundary conditions (one-way nesting). The
280 9h forecast is divided into two parts: the first six hours are the assimilation stage when
281 RAMS@ISAC simulation is adjusted by data assimilation, whereas the last three hours are the
282 forecast stage, without data assimilation. During the assimilation stage, flashes are assimilated by
283 nudging (Section 3.2), while radar reflectivity factor is assimilated every one-hour by RAMS-3DVar
284 (Caumont et al. (2010), Section 3.3).

285 It is noted that data assimilation is performed over the domain D2 (R4) only, and the innovations
286 are transferred to the domain D3 (R1), for the Livorno case, by the two way-nesting. The domain
287 D3 is used for the Livorno case to refine the resolution of the precipitation field over Tuscany and

288 to show the spatial and temporal precision of the precipitation forecast over Tuscany using data
289 assimilation. However, its usage is exceptional because, as stated above, Italy is a complex
290 orography country and grid refinements for specific areas are used only after the occurrence of
291 the event. For this reason, the domain D3 is usually not used in RAMS@ISAC and no statistics
292 about the background error are available for this grid.

293 Because lightning and radar reflectivity factor are cloud scale observations, their assimilation at
294 higher horizontal resolution by 3D-Var is foreseeable in future works.

295 The verification of the VSF for precipitation is done by visual comparison of the model output with
296 the raingauge network of the Department of Civil Protection, which has more than 3000
297 raingauges all over Italy.

298 In addition we consider the FBIAS (Frequency Bias; range $[0, +\infty)$), where 1 is the perfect score,
299 i.e. when no misses and false alarms occur), POD (Probability of Detection; range $[0, 1]$, where 1 is
300 the perfect score and 0 the worst value) and ETS (Equitable Threat Score; range $[-1/3, 1]$, where 1
301 is the perfect score and 0 is a useless forecast). Scores are computed from 2x2 dichotomous
302 contingency tables (Wilks, 2006) for different rainfall thresholds.

303

304 *3.2 Lightning data assimilation*

305 Lightning data are provided by LINET (Lightning detection NETWORK; Betz et al., 2009;
306 www.nowcast.de) which has more than 500 sensors worldwide with the greatest density over
307 Europe (more than 200 sensors). The network has a good coverage over Central Europe and
308 Western Mediterranean (from 10 W to 35 E and from 30 N to 60 N). The area of good coverage
309 includes the region considered in this paper.

310 LINET exploits the VLF/LF electromagnetic bands and provides measurements of both intra-cloud
311 (IC) and cloud to ground (CG) discharges. IC strokes are detected as long as lightning occurs within
312 120 km from the nearest sensor thanks to an optimised hardware and advanced techniques of
313 data processing (TOA-3D, Betz et al., 2004). According to Betz et al. (2009), LINET has a location
314 accuracy of 125 m for an average distance of 200 km among the sensors verified by strikes into
315 towers of known positions.

316 The good performance of the LINET network and its ability to detect IC strokes is shown in
317 Lagouvardos et al. (2009) for a storm in southern Germany, while the good performance over
318 Italy, including both CG and IC strokes, is discussed in Petracca et al. (2014).

319 The lightning data assimilation scheme is that of Fierro et al. (2012; 2014; 2015) and uses the total
320 lightning, i.e. intra-cloud plus cloud to ground flashes.

321 The method starts by computing the water vapour mixing ratio q_v :

$$322 \quad q_v = Aq_s + Bq_g \tanh(CX)(1 - \tanh(Dq_g^\alpha)) \quad (1)$$

323 Where coefficients are set to $A=0.86$, $B=0.15$, $C=0.30$, $D=0.25$, $\alpha=2.2$, q_s is the saturation mixing
324 ratio at the model atmospheric temperature, and q_g is the graupel mixing ratio (g kg^{-1}). X is the
325 number of total flashes (IC+CG) falling in a grid box of domain D2 (R4) in the past five minutes. The
326 mixing ratio q_v of Eq. (1) is computed only for grid points where flashes are recorded. More
327 specifically, for each grid point we consider the number of flashes falling in a grid box centred at
328 the grid point in the last five minutes. The mixing ratio of Eqn. (1) is compared with that predicted
329 by the model. If the mixing ratio of Eqn. (1) is larger than the simulated one, the latter is nudged
330 towards the value of Eqn. (1), otherwise the modelled mixing ratio is left unchanged. This method
331 can only add water vapour to the forecast.

332 The check and eventual substitution of the water vapour is performed every five minutes and it is
333 made within the mixed phase layer zone (0°C , -25°C), wherein electrification processes caused by
334 the collision of ice and graupel are the most active (Takahashi 1978, Emersic and Sounders, 2010;
335 Fierro et al., 2015).

336 The scheme of Fierro et al. (2012; 2015) was adapted to RAMS@ISAC in Federico et al. (2017a). In
337 particular, the coefficient C of Eqn. (1) was rescaled from that of Fierro et al. (2012) considering
338 the different spatial and temporal resolution of the gridded lightning data; then the coefficient C
339 was tuned (increased) by trials and errors considering two case studies of HyMeX-SOP1 (15 and 27
340 October 2012). The C constant was adapted subjectively considering two opposite requests:
341 increasing the hits and minimising false alarms. POD and ETS scores were considered as metrics
342 for this purpose. Then, Eqn. (1) was applied to twenty case studies of HyMeX-SOP1 giving a
343 statistically significant (90, or 95% depending on the rainfall threshold) improvement of the
344 RAMS@ISAC precipitation VSF (3h).

345 Nevertheless, an exhaustive statistic on the performance of rainfall VSF to nudging formulation in
346 RAMS@ISAC is missing and further studies are needed in this direction. Also, the optimal choice of
347 the coefficients A , B , C , D and α is case dependent.

348 Fierro et al (2012) applied the method using the ENTLN network, which has a detection efficiency
349 (DE) greater than 50% for IC over Oklahoma, where the ENTLN data were used. The emphasis on
350 IC flashes in the set-up of Fierro et al. (2012) is given because observational and model studies
351 have provided evidence that IC flashes correlate better than CG flashes with various measures of
352 intensifying convection (updraft strength, volume, graupel mass flux etc.; MacGorman et al. 1989;

353 Carey and Rutledge 1998; MacGorman et al. 2005; Wiens et al. 2005; Kuhlman et al. 2006; Fierro
354 et al. 2006; Deierling and Petersen 2008; MacGorman et al. 2011). For this reason methods that
355 use both IC and CG flashes performs better than those using CG only, being CG flashes correlated
356 with the descent of reflectivity cores and the onset of the demise of the storm' s updraft core
357 (MacGorman and Nielsen, 1991).

358 The analysis of the case studies shows that IC strokes are about 30% of the total number of strokes
359 reported. Also, the fraction of IC strokes to the total strokes depends on the position. For example,
360 for the Serano case, the fraction of IC strokes detected by LINET over the area hit by the largest
361 precipitation is more than 50% while over the Adriatic Sea it decreases to 10%.

362 It is also noted that DE for IC strokes cannot be reliably compared between LINET and ENTLN,
363 because the area is different and the technical details about IC detection remain unclear (type of
364 signals, VLF/LF or VHF, discrimination IC-CG).

365 For all the above reasons the application of the Fierro method to RAMS@ISAC is not
366 straightforward and it is appropriate to study the dependence of the rainfall VSF to the nudging
367 formulation. This subject is studied in the supplemental material of this paper (Section S.2) and
368 the results show that the choice of the coefficient of Eqn. (1) used in this paper is reasonable.

369 It is finally noted that despite the limitations noted above, the lightning data assimilation, as used
370 in this paper, has a significant and positive impact on RAMS@ISAC rainfall VSF (Federico et al.,
371 2017a; 2017b).

372

373

374 *3.3 Radar data assimilation*

375 The method assimilates CAPPI of radar reflectivity factor operationally provided by the Italian
376 Department of Civil Protection (DPC). Radar data are provided over a regular Cartesian grid with 1
377 km horizontal resolution and for three vertical levels (2, 3, 5 km above the sea level). The CAPPIs
378 at 2, 3, and 5km can be considered as under-sampled vertical profiles. CAPPIs are composed
379 starting from the 22 radars of the Italian Radar Network (Figure 13) 19 operating at the C-band
380 (i.e., 5.6 GHz) and 3 at X-band (i.e., 9.37 GHz). Data quality control and CAPPI composition is
381 performed by DPC. Data quality processing chain aims at identifying most of the uncertainty
382 sources as clutter, partial beam blocking and beam broadening. The radar observations are
383 processed according to nine steps detailed in Vulpiani et al. (2014), Petracca et al. (2018) and
384 references therein.

385 Radial velocity is not assimilated into RAMS@ISAC because it is not operationally processed, the
386 scan strategy being optimized for QPE purposes. Furthermore, the implementation of a radial
387 velocity data assimilation scheme is under development in RAMS-3DVAR and it is not currently
388 available for testing. For these reasons, we didn't consider the assimilation of this parameter.

389 Before entering data assimilation, the Cartesian grid is reduced to 5 km by 5 km by choosing one
390 point every five of the Cartesian grid provided by DPC in order to reduce the numerical cost of the
391 data assimilation and to reduce the effect of correlated observation errors (Rohn et al., 2001). The
392 radar grid (Figure 4, for example) is then a Cartesian grid with 5 km grid-spacing and three vertical
393 levels.

394 It is important to note the pure sampling of the data could result in implementation of errors (for
395 example reflectivity given by insects or birds) or extremes. Creating superobservations would
396 reduce this problem, the main drawback being the missing of very localised phenomena. While
397 the aim of this paper is to present the update of the data assimilation system of RAMS@ISAC and
398 its application to two challenging cases, the problem of using superobservations will be considered
399 in future studies because it impacts the results.

400 The methodology to assimilate radar reflectivity factor is that of Caumont et al. (2010), named
401 1D+3DVar, which is a two-step process: first, using a Bayesian approach inspired to GPROF
402 (Goddard Profiling Algorithm; Olson et al., 1996; Kummerow et al., 2001), 1D pseudo-profiles of
403 model variables are computed, then those pseudo-profiles are assimilated by 3DVar. Both steps
404 are discussed below.

405 The first step computes a pseudo-profile of relative humidity weighting the model profiles of
406 relative humidity around the radar profile (Bayesian approach). The pseudo-profile is computed
407 by:

$$408 \quad z_o^p = \frac{\sum_i RH_i W_i}{\sum_j W_j} \quad (2)$$

409 Where RH_i is the RAMS@ISAC vertical profile of relative humidity at a grid point inside a square of
410 $50*50 \text{ km}^2$ centred at the radar vertical profile, W_i is the weight of each profile and z_o^p is the
411 relative humidity pseudo-profile. The summation is taken over all the grid points inside a square of
412 $50*50 \text{ km}^2$ around the observed profile and the denominator is a normalisation factor. The
413 weights are determined by the agreement between the simulated and observed reflectivity factor:

414
$$W_i = \exp \left\{ -\frac{1}{2} [\mathbf{z}_o - h_z(x_i)]^T \mathbf{R}_z^{-1} [\mathbf{z}_o - h_z(x_i)] \right\} \quad (3)$$

415 Where h_z is the forward observation operator, transforming the background column \mathbf{x}_i into the
 416 observed reflectivity factor. The forward radar observation operator is taken from the RIP
 417 (Read/Interpolate/Plot) software ([https://dtcenter.org/wrf-](https://dtcenter.org/wrf-nmm/users/OnLineTutorial/NMM/RIP/index.php)
 418 [nmm/users/OnLineTutorial/NMM/RIP/index.php](https://dtcenter.org/wrf-nmm/users/OnLineTutorial/NMM/RIP/index.php), last access 03 March 2019) and is given in the
 419 supplemental material of this paper (Section S4). It assumes a Marshall-Palmer hydrometeors size-
 420 distribution, Rayleigh scattering, and depends on the mixing ratios of rain, graupel and snow.

421 The matrix \mathbf{R}_z in Eqn. (3) is diagonal and its value is $n\sigma^2$, where σ is 1 dBz and n is the number of
 422 available observations in the vertical profile (from 1 to 3). In this way, we give more weight to
 423 vertical profiles containing more data.

424 The error of radar data is assumed small (1dBz) for two reasons: a) reflectivity data are carefully
 425 checked by the Civil Protection Department; b) the performance of control simulation, not
 426 assimilating any data, is rather poor for the case studies. This setting, however, could not be
 427 optimal for cases when the control forecast performs better.

428 It is important to point out that the 50 km length-scale of the above step doesn't represent the
 429 horizontal correlation length-scale of the background error, which determines the horizontal
 430 spread of the innovations in the 3D-Var data assimilation (the latter length-scale is between 14
 431 and 25 km depending on the level). The 50 km length-scale is used to set a square for computing
 432 the pseudo-profile of relative humidity (Eqn. (2)). This profile is given by a weighted average
 433 whose weights are determined by the agreement between the simulated and observed reflectivity
 434 factor. The larger the agreement the larger the weight. This distance is appropriate because the
 435 spatial error of meteorological models in simulating meteorological features, for example fronts,
 436 can be of this order. The control simulation of the two events considered in this paper confirms
 437 this choice.

438 The method is not able to force convection when the model has no rain, snow or graupel in a
 439 square around (50*50 km²) a radar profile with reflectivity factor greater than zero. In this case,
 440 the pseudo-profile of relative humidity is assumed saturated above the lifting condensation level
 441 and with no data below (Caumont et al., 2010).

442 It is also noted that the method is able to reduce spurious convection when the reflectivity factor
 443 is simulated but not observed, because the pseudo-profile of relative humidity gives more weight
 444 to the drier relative humidity profiles simulated by RAMS@ISAC inside the 50*50 km² square

445 centred at the radar profile. Of course, the ability to reduce spurious convection depends on the
 446 availability of dry model profiles around the specific radar profile (see the example below). Finally,
 447 if the observed profile is dry and the profile simulated by RAMS@ISAC is dry too, the pseudo-
 448 profile is not computed.

449 In summary, pseudo-profiles are computed for each profile of the radar grid whenever reflectivity
 450 is observed or simulated.

451 The pseudo-profiles computed with the procedure introduced above, are then used as
 452 observations in the RAMS-3DVar data assimilation (Federico, 2013), minimising the cost-function:

$$J(\mathbf{x}) = \frac{1}{2} (\mathbf{x} - \mathbf{x}_b)^T \mathbf{B}^{-1} (\mathbf{x} - \mathbf{x}_b) + \frac{1}{2} (\mathbf{z}_o^p - h(\mathbf{x}))^T \mathbf{R}^{-1} (\mathbf{z}_o^p - h(\mathbf{x})) \quad (4)$$

453
 454 Where \mathbf{x} is the state vector giving the analysis when J is minimized, \mathbf{x}_b is the background, \mathbf{B} and \mathbf{R}
 455 are the background and observations error matrices, \mathbf{z}_o^p is the pseudo vertical profile computed by
 456 Eqn. (2) and h is the forward observation operator transforming the state vector (RAMS@ISAC
 457 water vapour mixing ratio) into observations. The cost function in RAMS-3DVar is implemented in
 458 incremental form (Courtier et al., 1994) and its minimization is performed by the conjugate-
 459 gradient method (Press et al., 1992). No multi-scale approach is used.

460 The background error matrix is divided into three components along the three spatial directions
 461 (x , y , z). The \mathbf{B}_x and \mathbf{B}_y matrices account for the spatial correlation of the background error. The
 462 correlations are Gaussian with length-scales between 14 and 25 km, depending on the vertical
 463 level. These distances are computed using the NMC method (Barker et al., 2012) applied to the
 464 HyMeX-SOP1 (Hydrological cycle in the Mediterranean Experiment – First Special Observing Period
 465 occurred in the period 6 September-6 November 2012; Ducroq et al., 2014) period. It is again
 466 stressed that the spread of the innovations along the horizontal spatial directions in the 3D-Var
 467 analysis is determined by the length scales of \mathbf{B}_x and \mathbf{B}_y matrices and varies between 14 and 25 km,
 468 depending on the level.

469 The \mathbf{B}_z matrix contains the error for the water vapour mixing ratio, which is the control variable
 470 used in RAMS-3DVar. This error is about 2 g/kg at the surface and decreases with height. In
 471 particular, it is larger than 0.5 g/kg below 4 km, and less than 0.2 g/kg above 5 km. The vertical
 472 decorrelation of the background error depends on the level and can be roughly estimated in 500-
 473 2000 m. The observation error matrix \mathbf{R} in Eqn. (4) is diagonal and observations' errors are
 474 uncorrelated. This choice is partially justified by under sampling the radar reflectivity factor
 475 observation by choosing one point every five grid points in both horizontal directions of the radar

476 Cartesian grid. However, correlation observations errors have significant impact on the final
477 analysis, as shown for example in Stewart et al. (2013), and different choices of the matrix \mathbf{R} will
478 be considered in future studies.

479 The value of the elements on the diagonal of \mathbf{R} depends on the vertical level and are 1/4 of the
480 diagonal element of the \mathbf{B}_z matrix at the corresponding height. By this choice, we give more credit
481 to the observations than to the background and analyses strongly adjust the background towards
482 observations. The background error matrix is computed using the NMC method (Parrish and
483 Derber, 1992; Barker et al. 2004) applied to the HyMeX-SOP1 (Hydrological cycle in the
484 Mediterranean Experiment – First Special Observing Period occurred from 6 September to 6
485 November 2012; Ducroq et al., 2014). This choice is motivated by the fact that HyMeX-SOP1
486 contains several heavy precipitation events over Italy and the background error matrix is
487 representative of the convective environment of the cases considered in this paper. In particular,
488 10 out of 20 declared IOP (Intense Observing Period) of HyMeX-SOP1 occurred in Italy (Ferretti et
489 al., 2014). On the contrary, the period of September 2017, especially before the events selected in
490 this study was characterized by fair and stable weather conditions over Italy and the background
491 error matrix for September 2017 is less representative of the convective environment that
492 characterise the events of this paper.

493 Because it is the first time that we show the assimilation of radar reflectivity factor in
494 RAMS@ISAC, it is useful to discuss an example of analysis. We select the analysis of Livorno case
495 study at 06 UTC. The observed CAPPI at 3km above sea level is shown in Figure 10b. The
496 corresponding CAPPI simulated by the background is shown in Figure 14a. In general, the
497 comparison between simulated and observed reflectivity factor shows the difficulty of the model
498 to represent convection properly. In particular, the model is able to represent the convection over
499 Northern Italy but it has poor performance over Sardinia, south of Sicily and over Central Italy. The
500 difference between the analysis and background relative humidity after and before the analysis is
501 shown in Figure 14b (absolute values less than 1% are suppressed in the figure for clarity). Both
502 positive (convection enhancing) and negative (convection suppressing) adjustments are found.
503 Over Central Italy, Sardinia and South of Sicily relative humidity is increased because the model
504 doesn't simulate the observed reflectivity (Figure 10b). Over northern Italy the model is partially
505 dried for two different reasons: over northwest of Italy because RAMS@ISAC simulates
506 unobserved reflectivity, over north and northeast of Italy because the model simulates larger
507 values of reflectivity factor compared to the observations. The RAMS-3DVar is able to dry the

508 relative humidity field north of Corsica island, where the RAMS@ISAC predicts unobserved
509 reflectivity, while RAMS-3DVar didn't suppress the unobserved convection west of Sardinia
510 because the pseudo profiles computed over this area weren't appreciably drier than the
511 background.

512 Cross correlations among different variables of the data assimilation system are neglected in this
513 study and the application of the RAMS-3DVar affects the water vapour mixing ratio only. Cross
514 correlations among different variables can improve the performance of data assimilation system,
515 and an example of their impact in the RAMS-3DVar is shown in Federico (2013). Nevertheless, the
516 impact of cross correlations among different variables in the precipitation VSF will be explored in
517 future works.

518 Because also lightning data assimilation adjusts the water vapour mixing ratio, it follows that the
519 data assimilation presented in this study adjusts only this parameter.

520 Lightning and radar data assimilation may produce sharp gradients in vertical direction caused by
521 the addition of water vapour to specific layers. In the case of lightning, the water vapour is added
522 by nudging to reduce sharp gradients. However, radar data assimilation, which accounts for the
523 largest mass of water added to RAMS@ISAC (see Section S.1 of the supplemental material),
524 directly adjusts the water vapour into the model. Our experience with RAMS@ISAC, however,
525 shows that results are reliable and the sudden addition of water vapour doesn't cause shocks to
526 the model simulation, despite the notable gradients of specific humidity.

527 It is finally noted that the data assimilation increase/decrease the water vapour into the model
528 depending on the cases. The eventual increase/decrease of the forecasted rainfall depends on the
529 physical and dynamical processes occurring into the meteorological model, without any specific
530 tuning.

531

532 **4. Results**

533 In this section, we discuss the most intense phase of the Serano case, 03-06 UTC on 16 September,
534 and two VSF forecasts, 00-03 UTC and 06-09 UTC on 10 September, for the Livorno case. The two
535 VSF for Livorno correspond to the most intense phase of the storm in Livorno and to a very intense
536 phase over Lazio region, Central Italy. The aim of the section is to show the notable improvement
537 given by the lightning and radar reflectivity factor data assimilation to the VSF.

538 We consider four types of VSF (Table 3): a) CTRL, without radar reflectivity factor and lightning
539 data assimilation; b) LIGHT, assimilating lightning but not radar reflectivity factor; c) RAD,

540 assimilating radar reflectivity factor but not lightning; d) RADLI, assimilating both lightning and
541 radar reflectivity factor.

542 In order to avoid excessive length two specific topics are considered in the supplemental material
543 of this paper; specifically, we study: a) the relative contribution to the total water mass given by
544 lightning and radar reflectivity factor data assimilation (Section S.1); b) the sensitivity of the
545 precipitation VSF to the nudging formulation (Section S2). Also, the supplemental material gives
546 different plots of Figures 15-17 (Section S3) and the forward radar operator used in RAMS-3DVar
547 (Section S4).

548

549 *4.1 Serano: 03-06 UTC on 16 September 2017*

550 In this period, an intense and localised storm hit central Italy, while light precipitation occurred
551 over northern Italy (Figure 15a). Considering the storm over central Italy, 10 raingauges observed
552 more than 30 mm/3h, 6 more than 40 mm/3h, 3 more than 50 mm/3h and 1 more than 60
553 mm/3h, the maximum observed value being 63 mm/3h.

554 The CTRL forecast, Figure 15b, misses the storm over central Italy and considerably
555 underestimates the precipitation area over Northern Italy, giving unsatisfactory results.

556 The assimilation of the radar reflectivity factor improves the forecast, as shown in Figure 15c. In
557 particular, RAD forecast shows localized precipitation (30-35 mm/3h) close to the area where the
558 most abundant precipitation was observed. However, the maximum precipitation is
559 underestimated. Also, the RAD forecast better represents the precipitation over Northern Italy
560 compared to CTRL.

561 The rainfall forecast of LIGHT, Figure 15d, shows some improvements compared to CTRL because
562 the precipitation over central Italy has a maximum of 25-30 mm/3h, close to the area where the
563 maximum precipitation was observed. LIGHT, however, has a worse performance compared to
564 RAD because it underestimated the precipitation area over northern Italy. Also, similarly to RAD,
565 LIGHT underestimates the maximum precipitation in central Italy.

566 RADLI forecast, Figure 15e, has the best performance. The precipitation over central Italy is well
567 represented because the maximum rainfall (40-45 mm/3h) is in reasonable agreement with
568 observations, and also because the area of intense precipitation (> 25 mm/3h) is elongated in the
569 SW-NE direction in agreement with raingauge observations, giving a much better idea of the real
570 storm intensity compared to RAD and LIGHT, as well as CTRL. The precipitation over northern Italy
571 is well represented by RADLI.

572 Table 4 shows the ETS and POD scores for selected rainfall thresholds for different neighbourhood
573 radii. Different radii are considered to account for the well-known double penalty error (Mass et
574 al., 2002; Mittermaier et al., 2013) caused by displacement errors of the detailed precipitation
575 forecast in convection allowing grids. CTRL was unable to predict rainfall larger than 6 mm/3h. The
576 comparison between RAD and LIGHT shows that assimilating radar reflectivity factor performs
577 better than assimilating lightning. This behaviour, however, is not general and sometimes the
578 assimilation of lightning has a better performance than assimilating radar reflectivity factor (see
579 section 4.2.1).

580 RADLI forecast has the best performance among all model configurations. In particular, it is the
581 only forecast having positive scores for thresholds larger than 30 mm/3h.

582 In conclusion, for this VSF, the assimilation of lightning and radar reflectivity factor acted
583 synergistically to improve the precipitation VSF and the simulation assimilating both data performs
584 considerably better than simulations assimilating either lightning or radar reflectivity factor.

585

586 *4.2 Livorno*

587 The Livorno case study lasted for several hours starting at 18 UTC on 9 September 2017 and
588 ending more than a day later. The most intense phase in Livorno and its surroundings was
589 observed during the night between 9 and 10 September. In the following, we will show two
590 representative VSF (3h), including the most intense phase in Livorno.

591

592 *4.2.1 Livorno: 00-03 UTC on 10 September 2017*

593 This period represents the most intense phase of the storm in Livorno. In particular, the raingauge
594 close to the label A (Figure 16a) reported 151 mm/3h (Collesalveti), while the one close to the
595 label B measured 82 mm/3h. Among the 518 raingauges reporting valid data, 75 observed more
596 than 10 mm/3h, 31 more than 20 mm/3h, 17 more than 30 mm/3h, 9 more than 40 mm/3h, and 6
597 more than 50 mm/3h.

598 The CTRL precipitation forecast is shown in Figure 16b. The forecast is poor because it misses the
599 precipitation swath from the coast towards NE. A precipitation swath is forecasted about 50 km to
600 the North of the real occurrence, but it is less wide compared to the observations.

601 The RAD forecast, Figure 16c, shows that the assimilation of radar reflectivity factor gives a clear
602 improvement to the forecast. The largest precipitation in the coastal part of the swath (we
603 searched for the maximum in the area with longitudes between 10.20E and 10.70E and latitudes

604 between 43.10N and 43.60N) is 94 mm/3h. Another local maximum is in the southern part of the
605 domain (label B of Figure 16a). The maximum location is well represented, but the forecast value
606 (55 mm/3h) underestimates the observed maximum (82 mm/3h).

607 An improvement, compared to both CTRL and RAD, is given by the assimilation of lightning (Figure
608 16d). Also for this simulation there is a precipitation swath from coastal Tuscany to the Apennines,
609 but the shape of the swath better resembles that observed. The maximum value close to Livorno,
610 i.e. in the coastal part of the swath, is 158 mm/3h.

611 LIGHT simulation shows the local maximum in the southern part of the domain (about 50 mm/3h),
612 but the amount is underestimated.

613 Figure 16e shows the RADLI rainfall forecast. The precipitation swath from coastal Tuscany
614 towards NE is more apparent compared to LIGHT and RAD. The maximum rainfall accumulated
615 close to Livorno is 186 mm/3h. Also, the second precipitation maximum in the southern part of
616 the domain reaches 70 mm/3h in good agreement with observations (82 mm/3h). RADLI is the
617 only run giving a satisfactory precipitation VSF over the south-eastern Emilia Romagna (north-
618 eastern part of the domain), to the lee of the Apennines. It is also noted that the main
619 precipitation swath forecasted by RADLI is too broad in the direction crossing the swath compared
620 to the observations. This is confirmed by the FBIAS of RADLI (not shown), which is more than 3 for
621 thresholds larger than 42 mm/3h.

622 The analysis of the scores (Table 5) confirms the results outlined above. CTRL has the lowest
623 performance and the improvement given by the data assimilation to the VSF is apparent for POD
624 and ETS for all thresholds and neighbourhood radii considered. For this specific VSF, lightning data
625 assimilation gives a better improvement to rainfall forecast compared to RAD. RADLI has the best
626 performance, especially for 25 km and 50 km neighbourhood radii, nevertheless it over forecast
627 the precipitation field. Because ETS penalises false alarms, the value of this score for RADLI is
628 sometimes lower than that of LIGHT.

629

630 *4.2.3 Livorno: 06-09 UTC on 10 September 2017*

631 In this period, the most intense precipitation occurred over the coastal part of Lazio (Figure 17a).
632 More in detail, among the 2695 raingauges reporting valid data over the domain of Figure 17a,
633 307 reported more than 10 mm/3h, 132 more than 20 mm/3h, 86 more than 30 mm/3h, 66 more
634 than 40 mm/3h, 49 more than 50 mm/3h and 35 more than 60 mm/3h. Among the 35 raingauges

635 measuring more than 60 mm/3h, 33 were over Lazio, showing the heavy rainfall occurred over the
636 Region.

637 Some precipitation persisted over Tuscany but the rainfall is much lower compared to previous 6h
638 (the rainfall over Tuscany between 03 and 06 UTC was very intense, not shown). Other notable
639 precipitation areas are over the NE of Italy (moderate to low amounts), over central Alps
640 (moderate values) and over the whole Sardinia (small amounts).

641 Figure 17b shows the rainfall simulated by CTRL. The forecast is unsatisfactory, mainly for the
642 following two reasons: a) heavy precipitation is simulated over Tuscany (> 75 mm/3h), also close
643 to the Livorno area; b) few millimetres of precipitation are forecasted over central Italy. The
644 rainfall over NE Italy is well represented in space, but overestimated.

645 Considering the evolution of CTRL forecast for the two VSF of Livorno, we conclude that it was
646 able to predict abundant rain over Livorno, but the rainfall forecast was delayed compared to the
647 real occurrence. A similar behaviour was found in Ricciardelli et al. (2018) using the WRF model,
648 showing that the results of this paper for Livorno are likely not tied to the specific model used.

649 The rainfall simulated by RAD (Figure 17c) clearly improves the forecast compared to CTRL. First,
650 the precipitation over Lazio is very well predicted and the rainfall values are up to 65 mm/3h, so
651 RAD forecast well represents the main precipitation spot over Italy for this VSF. Second, the
652 precipitation over Tuscany is less than for CTRL, showing the ability of radar reflectivity factor data
653 assimilation to dry the model when it predicts reflectivity that is not observed. This is confirmed
654 by the inspection of the analysis of Figure 14b, the last analysis used before this VSF, which gives a
655 decrease of the relative humidity over most of Tuscany and over the sea in front of Livorno. Third,
656 the precipitation over central Alps is represented, even if located about 30 km to the East. It is
657 noted, however, that the area of intense rainfall (>60 mm/3h) is overestimated by RAD, showing a
658 wet forecast. This is confirmed by the wet frequency bias of the RAD simulation, which is greater
659 than 3 between 14 and 44 mm/3h. The wet bias of the RAD forecast is apparent in the
660 representation of the rainfall VSF shown in the supplemental material of this paper (Figure S5).

661 LIGHT forecast, Figure 17d, shows a worse performance compared to RAD for this time period. The
662 precipitation forecast is mainly over Tuscany, where it is overestimated, with a small precipitation
663 spot over Lazio.

664 The precipitation forecast of RADLI, Figure 17e, represents very well the precipitation over Lazio,
665 and the rainfall amount is better predicted compared to RAD. The precipitation over Sardinia is

666 well represented by RADLI as well as the precipitation over Central Alps, giving the best results
667 among all VSF.

668 The analysis of the scores confirms the above results (Table 6). CTRL has a poor performance as
669 shown by the POD and ETS values, close to zero, for all thresholds above 30 mm/3h and for all
670 neighbourhood radii. The simulations assimilating radar reflectivity factor performs better than
671 LIGHT, the difference being larger for higher rainfall thresholds and for smaller neighbourhood
672 radii.

673 It is also notable the good performance of RADLI forecast for the nearest neighbourhood radii
674 (ETS=0.43, POD=0.92) for the 50 mm/3h threshold.

675

676 **5. Discussion and Conclusions**

677 In this paper, we showed the impact of lightning and radar reflectivity factor data assimilation on
678 the very short term precipitation forecast (3h) for two case studies occurred in Italy. We used
679 RAMS@ISAC model, whose 3DVar extension to the assimilation of radar reflectivity factor is
680 shown in this paper for the first time.

681 The first case study occurred on 16 September 2017 and it is a moderate case with localised
682 rainfall over central Italy. It was chosen because the control forecast, i.e. without radar reflectivity
683 factor or lightning data assimilation, missed the event. The second event, occurred on 9-10
684 September 2017, was characterised by exceptional rainfall over several parts of Italy. This event
685 was partially represented by the control forecast. In particular, the forecast of the event was
686 incorrect because: a) the control forecast was delayed compared to the observations; b) the
687 control forecast missed the rainfall over central Italy (Lazio Region).

688 It is important to recall that the impact of the lightning data assimilation on the precipitation
689 forecast of RAMS@ISAC was already studied for the HyMeX-SOP1 period (Federico et al., 2017a,
690 2017b), and a robust statistic is already available. The results of this study confirm the important
691 role of the lightning data assimilation on the rainfall forecast for other two case studies. However,
692 considering the assimilation of radar reflectivity factor, and its combination with lightning data
693 assimilation in RAMS@ISAC, the results of this paper are new.

694 Because we analysed only two case studies, no definitive conclusions can be derived on the
695 performance of RAMS@ISAC for radar reflectivity factor data assimilation. There are, however,
696 few points worth of mention.

697 The VSF performance of RAMS@ISAC is systematically improved by the assimilation of radar
698 reflectivity factor. This improvement is of paramount importance for some specific VSF (for
699 example for the 00-03 UTC of Livorno), when the control forecast missed the event while it was
700 correctly predicted by radar reflectivity factor data assimilation. Sometimes the improvement of
701 reflectivity factor data assimilation has a lower impact on the precipitation forecast, as for the
702 period 18-21 UTC on 9 September 2017 (Livorno, not shown, see the discussion paper Federico et
703 al. (2018) for a description of this VSF). This suggests that there is space for improvement for all
704 components of the VSF: observations, data assimilation, meteorological model.

705 Lightning and radar observations are different and both add value to the VSF. In particular, flashes
706 are recorded when deep convection develops, while radar reflectivity factor is observed also for
707 light stratiform rain. Flashes of ground based network, as LINET, are available over the open sea,
708 even if with a reduced detection efficiency, while radar reflectivity factor is confined to the range
709 of coastal radars in the network. Lightning has a seasonal dependence over Italy, with the
710 maximum in summer and fall, while radar reflectivity factor is available in all seasons.

711 For the above reasons, the impact of the two kinds of data on the rainfall VSF is expected
712 different. Some examples have been shown: the light precipitation over Northern Italy for Serano
713 is well forecasted assimilating radar reflectivity factor, while it is not simulated assimilating flashes
714 because they are too few in this area to force convection; lightning data assimilation is able to
715 better represent the deep convection occurring during the intense phase of the Livorno case (00-
716 03 UTC), especially because it is able to force convection where it occurs, reducing false alarms.
717 The ability of lightning data assimilation to reduce false alarms compared to RAD and RADLI it is
718 shown by the fact that the ETS score for LIGHT is sometimes the best among all simulations (see
719 also the section S2 of the supplemental material of this paper). These results show also that the
720 influence of different observations depends on the meteorological situation.

721 The model configuration assimilating both radar reflectivity factor and lightning (RADLI) is able to
722 retain important features of both data assimilation. For example, the simulation of the Livorno
723 case in the phase 06-09 UTC was able to simulate the heavy precipitation over Lazio thanks to the
724 radar reflectivity factor data assimilation and the precipitation over Sardinia, as well as the
725 moderate precipitation over central Alps, thanks to lightning data assimilation.

726 The property of RADLI to retain the precipitation features of both RAD and LIGHT it is shown by
727 the POD score, which is the best, for most cases and thresholds, for RADLI.

728 Another interesting feature is the considerable improvement of the POD of RADLI compared to
729 CTRL for the lowest thresholds.

730 It is also underlined that the data assimilated, both lightning and radar reflectivity factor, are
731 available in real time and could be used for an operational implementation of the VSF.

732 All the above features are promising and deserve future studies to better understand the role of
733 radar reflectivity factor and its interaction with lightning data assimilation to improve the
734 precipitation forecast.

735 There are, however, less satisfactory aspects of assimilating both radar reflectivity factor and
736 lightning data. In particular, the wet bias of RAD and RADLI forecast is the main drawback of the
737 results of this paper. To reduce the moisture added by radar and lightning data assimilation
738 further research is needed and different approaches are possible (Fierro et al., 2016). In particular:
739 a) assimilating for a shorter time (0-6h in this paper); b) reducing the length-scales of the 3D-Var in
740 the horizontal directions to limit the spreading of the innovations, or assuming an innovation
741 equal to zero for grid points without lightning and with zero reflectivity factor; c) reducing the
742 amount of water vapour added to the model (for example reducing the values of A and B
743 constants for lightning data assimilation or relaxing the request of saturation when radar
744 reflectivity is observed in areas where the model has zero reflectivity); d) adding moisture to a
745 shallower vertical layer.

746 It is also noted that a combination of heating and moistening could provide the same buoyancy
747 with less water vapour addition (Marchand and Fulberg, 2014) and this approach could be used in
748 future studies.

749 In addition to the acquisition of more case studies, there are two directions of future development
750 of this work. The lightning data assimilation can be formulated by 3DVar, using a strategy similar
751 to the radar reflectivity factor in which pseudo-profiles of relative humidity are first generated
752 where flashes are recorded, and then those profiles are assimilated by 3DVar. This methodology
753 was already reported in Fierro et al. (2016). The assimilation of both radar reflectivity factor and
754 lightning using RAMS-3DVar will be explored in future studies.

755 Another important point to study is how long the innovations introduced by data assimilation lasts
756 in the forecast. While in this study we consider the VSF at 3h, future studies must explore longer
757 time ranges. This kind of study was performed for lightning data assimilation (Fierro et al., (2015);
758 Federico et al., 2017b; Lynn et al. (2015) among others) and for radar data assimilation (Hu et al.
759 (2006); Jones et al. (2014), among others), using a rationale similar to that used in this paper.

760 In general, the performance of the forecast and the impact of lightning and radar data assimilation
761 decrease with forecasting time because of the propagation of boundary conditions inside the
762 domain and because of model errors growth. Improving the data assimilation system also
763 contributes to a longer resilience of model performance. The studies cited above showed that
764 lightning and radar data assimilation can have an impact up to 24h depending on several factors
765 (meteorological model, data assimilation, quality of the data, meteorological conditions, initial and
766 boundary conditions).

767 A study considering both radar reflectivity factor and lightning should be performed to understand
768 the resilience of the innovations introduced by data assimilation.

769

770 **ACKNOWLEDGMENTS**

771 This work is a contribution to the HyMeX program. Part of the computational time used for this
772 paper was granted by the ECMWF (European Centre for Medium Weather range Forecast)
773 throughout the special project SPITFEDE. LINET data were provided by Nowcast GmbH
774 (<https://www.nowcast.de/>) within a scientific agreement between H.D. Betz and the Satellite
775 Meteorological Group of CNR-ISAC in Rome.

776 This work was partially funded by the agreement between CNR-ISAC and the Italian Department of
777 Civil Protection.

1039 **TABLES**

1040 Table 1: List of physical parameterisations used for RAMS@ISAC in this paper.

Physical parameterization	Selected scheme
Parametrized cumulus convection	Modified Kuo scheme to account for updraft and downdraft (Molinari and Corsetti, 1985). The scheme is applied to R10 only.
Explicit precipitation parameterization	Bulk microphysics with six hydrometeors (cloud, rain, graupel, snow, ice, water vapour). Described in Hong and Lim (2006).
Exchange between the surface, the biosphere and atmosphere.	LEAF3 (Walko et al., 2000). LEAF includes prognostic equations for soil temperature and moisture for multiple layers, vegetation temperature and surface water, and temperature and water vapour mixing ratio of canopy air.
Sub-grid mixing	The turbulent mixing in the horizontal directions is parameterised following Smagorinsky (1963), vertical diffusion is parameterised according to the Mellor and Yamada (1982) scheme, which employs a prognostic turbulent kinetic energy.
Radiation scheme	Chen-Cotton (Chen and Cotton, 1983). The scheme accounts for condensate in the atmosphere.

1041

1042 Table 2: Basic parameters of the RAMS@ISAC grids (R10, R4 and R1, corresponding, respectively, to the domains D1,
 1043 D2 and D3). NNXP is the number of grid points in the WE direction, NNYP is the number of grid-points in the NS
 1044 direction, NNZP is the number of vertical levels, DX is the size of the grid spacing in the WE direction, DY is the grid
 1045 spacing in the SN direction. Lx, Ly, and Lz are the domain extensions in the NS, WE, and vertical directions. CENTLON
 1046 and CENTLAT are the coordinates of the grid centres.

1047

	R10, D1	R4, D2	R1, D3
NNXP	301	401	203
NNYP	301	401	203
NNZP	36	36	36
Lx	3000 km	1600 km	~270 km

1091 Figure 1: Daily precipitation (P) [mm] over Italy on 16 September 2017. Only raingauges observing at least 0.2 mm/day
1092 are shown. The first number in the figure title within brackets represents the available raingauges, while the second
1093 number represents raingauges observing at least 0.2 mm/3h. The lowest precipitation class is represented by smaller
1094 dots, the largest by a red square. The locations of Città di Castello and Mount Serano are indicated.
