**Abstract.** Reduction of water levels during river floods is key in preventing damage and loss of life. Computer models are used to design ways to achieve this and assist in the decision making process. However, the predictions of computer models are inherently uncertain, and it is currently unknown to what extent that uncertainty affects predictions of the effect of flood mitigation strategies. In this study, we quantify the uncertainty of flood mitigation interventions on the Dutch River Waal, based on 39 different sources of uncertainty and twelve intervention designs. The aim of each intervention is to reduce flood water levels. Our objective is to investigate the uncertainty of model predictions of intervention effect and to explore relationships that may aid in decision making. We identified the relative uncertainty, defined as the ratio between the confidence interval and the expected effect, as a useful metric to compare uncertainty between different interventions. Using this metric, we show that intervention effect uncertainty behaves like a traditional backwater curve with an approximately constant relative uncertainty value. In general, we observe that uncertainty scales with effect: high flood level decreases have high uncertainty and conversely, small effects are accompanied by small uncertainties. However, different interventions with the same expected effect do not necessarily have the same uncertainty. For example, our results show that the large-scale but relatively ineffective intervention of floodplain smoothing by removing vegetation, has much higher uncertainty compared to alternative options. Finally, we show how a level of acceptable uncertainty can be defined and how this can affect the design of interventions. In general, we conclude that the uncertainty of model predictions is not large enough to invalidate model-based intervention design, nor small enough to neglect altogether. Instead, uncertainty information is valuable in the selection of alternative interventions.

## 1 Introduction

The number of people living in areas exposed to river flooding is projected to exceed one billion in 2050 (?). Therefore, it is increasingly important that the river system is designed in such a way that flood risk is minimised. Human intervention in river systems has a long history, to a point that for some rivers human management has become the dominant factor driving

hydrological change (??). Today, the decision to change an existing river system (e.g., by leveeing a channel to protect flood-prone areas) is increasingly based on predictions made by computer models. Various software systems can be used to resolve flow conditions accurately, taking into account much of the complexity of rivers — such as terrain geometry, vegetation and hydraulic structures. However, despite increasingly available data, not all model input or model parameters can be reliably measured or represented. For example, vegetation density and vegetation height, which modify vegetation roughness (??), are variable both in time and space. This variability is neither captured on the scale of river modelling, nor by the equations that resolve vegetation roughness. Examples such as this introduce uncertainty in the modelling process and in the model output (??).

Proper understanding and communication of uncertainty is important both for scientists and decision makers (??). ? distinguished three complementary paradigms for modelling to support decision making under (deep) uncertainty: (1) using the best available knowledge, (2) quantifying uncertainty and sensitivities of key parameters and (3) exploring multiple plausible outcomes. One advantage computational models can bring to decision making for river engineering is an assessment of the impact of the planned intervention on hydraulics, such as water levels, flow velocities and the morphodynamic response of the river bed. While hydraulic effects are not the only impact of interventions (see e.g. ?, for effects on biodiversity) they are considered important: for the 39 interventions of the 2.3 billion Euro ‘Room for the River’ program in The Netherlands, the hydraulic effect as predicted by models was a precondition for any design “to be taken seriously at all” (?). ? reported that quantified, large uncertainty in flood water levels is sometimes played down when assessing effects, under the assumption that systematic errors cancel out when subtracting the intervention case from the reference case. However, it was recently demonstrated in an idealised study that uncertainty in flood water levels does not cancel out but could be significant compared to the effect, and sensitive to the specific design of the intervention (?). Therefore, uncertainty quantification of effect studies for a real-world case study is needed to assess the implications for the design of interventions.

Uncertainty quantification of impact analysis for real world solutions suffers from two compounding issues specific to intervention design studies. First, there is a practical need for sufficiently detailed models given the increasingly complicated design of interventions, which moves from traditional flood prevention (building dikes, or levees) to more holistic designs. This is in part motivated by the paradoxical ‘levee effect’ that states that flood control measures do not decrease, but increase flood risk (???) and which insight has spurred policy change away from purely flood control and towards alternative options (??). In The Netherlands, this has led to designs that focus on increasing conveyance capacity to achieve lower flood levels, while integrating multiple other (ecological, societal) objectives as well (?). Predicting the effects of such more intricate alternative approaches, like the construction of artificial secondary channels (?), requires detailed models that take into account local geometry, vegetation and other terrain features. Such models are not only computationally expensive, which both complicates Monte Carlo simulation (MSC)-based quantification methods, but also have a high number of model parameters, which complicates the use of (data-based) surrogate model approaches (?). The second issue is that the analysis relies on at least one unmeasured environmental system, namely, the river system altered by the proposed intervention. Therefore, there is no way to verify that accuracy for the proposed future state of the river. Verification of the accuracy of the current, unaltered state is likewise not necessarily available. For example, flood mitigation measures tend to be designed for a low period of return, e.g.

a one in one hundred year or even one in 1250 year flood (?), for which recent measurements are (by definition) sparse. Under such conditions, the uncertainty of model output cannot be expressed in terms of accuracy (e.g. standard deviation of model error) without additional untestable assumptions.

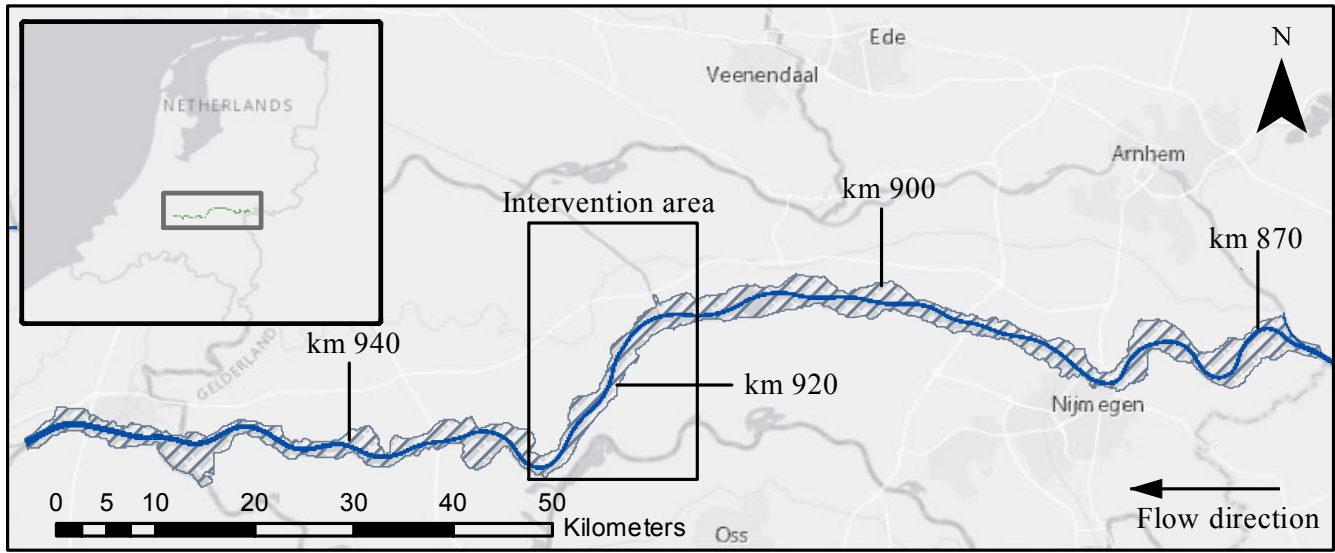

In present paper we address the lack of studies into the model uncertainty of model predictions used in impact design. Our objective is twofold. The first objective is to quantify the effect of parameter uncertainty on the predicted effect of flood mitigation measures, by implementing twelve different interventions of varying type and intensity in a section of the Dutch River Waal, using a detailed hydraulic model. To limit the computational burden we use CORAL, which is an implementation of the efficient uncertainty quantification method of ?, that does not suffer from limitations with regard to the number of model parameters. Our second objective is to explore the relationship between the expected reduction of flood levels and the uncertainty, to aid in the decision making process. To this end we will introduce the ‘relative uncertainty’ measure to facilitate inter-comparison between different intervention designs.

Our analysis proceeds in three steps. First, we set up the numerical model for the Dutch River Waal and select the uncertainty sources in section ???. Here, we also introduce the relative uncertainty measure. We then present the results of the uncertainty of the modelled water levels and reduction in water levels in section ?? and ??. In section ?? we show how uncertainty may influence decision making. In the discussion (??) we discuss reducing uncertainty in intervention design and the feasibility of probabilistic analysis for intervention design in practice. A general conclusion on the practical value of uncertainty quantification for decision making in flood mitigation strategies, and specific conclusions related to the objectives, are given in section ??.

## 2 Methods

### 2.1 Study area

The River Waal is selected as the case study for its extensive history of human intervention and good data availability. The Waal is a distributary of the River Rhine and, by discharge, the largest river in the Rhine-Meuse-Scheldt Delta, located in Western Europe. The present-day river has a main channel about 8 meters deep at bank-full discharge, a bank-full width of about 250 m and relatively narrow floodplains. Before the construction of the dikes from 1000 A.D. onward, it was a meandering river with regular over-bank deposition (?). Recorded river engineering works for flood protection as well as inland navigation dates back to at least the 18<sup>th</sup> century (e.g., see ?). In the 19<sup>th</sup> century, the river was normalised in large governmental projects, obtaining its current narrow channel, groynes (also termed *spur dikes* or *wing dikes*) and relatively straight channel (?). In present day, the river has a bed slope of approximately  $1 \cdot 10^{-4}$  m/m over a stretch of 90 km from the upstream bifurcation to the Merwede bifurcation. At the end of the 20<sup>th</sup> century, motivated by the near-disaster of 1995 (?), the large scale ‘Room for the River’ programme was enacted to reduce flood levels (??). The largest intervention in the River Waal in this programme was the Nijmegen-Lent dike relocation project, which was predicted to lower the water levels by 27 cm at a cost of approximately 350 million Euro. Most other interventions on the River Waal were projected to lower the water level by less than 10 cm.

Esri, HERE, Garmin, © OpenStreetMap contributors, and the GIS user community

**Figure 1.** The River Waal, situated entirely in The Netherlands. The study area is a stretch of about 15 km between km 913 and km 928. The hatched area shows the total extent of the model domain, which overlaps with the river and its floodplains bounded by the dikes.

90 Our study domain covers the entire Waal River (Figure ??). Distances along the river are measured using the conventional 'Rhine kilometre', which starts from km 0 at the German city of Konstanz. The Waal starts at km 867 at the Pannerden bifurcation and runs through to km 961 where it bifurcates in the Nieuwe Merwede and Boven Merwede rivers. All flood mitigation measures studied will be implemented between km 913 and km 928, depicted by the annotated rectangle in Figure ??.

95 The intervention area is characterised by a relatively straight river stretch with narrow floodplains and the strongly curved *St. Andries* river bend, which provides a known bottleneck during high discharges. Nine towns border directly on the dikes along this 17.5 km stretch. Interventions in this area to increase flood safety, considering the narrow floodplains and the populated surrounding land, present both a technical and a societal problem.

## 2.2 Hydrodynamic model & interventions

100 To simulate the hydrodynamic response of the flow to various interventions we use the Delft3D Flexible Mesh modelling system (?). Geographical information, such as land cover, bathymetry and hypsometry, as well as information on embankments and weirs, were derived from the Baseline information system (?). Our setup uses a two-dimensional unstructured numerical grid, with between 71,000 and 120,000 active grid cells. The grid size varies from 40m by 15m in the main channel to a maximum of about 120m by 120m in the floodplains. In all cases, we simulate a steady upstream discharge of  $10.165 \text{ m}^3\text{s}^{-1}$   
 105 and a constant downstream water level of 3.98 m + NAP, for 72 hours. A single model evaluation on our computer resources took about 2.5 hours. These conditions are consistent with a return period of 1250 years ( $T_{1250}$ ). Initial conditions were derived

**Figure 2.** A schematic overview of a typical cross-section of the River Waal and the flood mitigation measures studied in this paper. Figure based on ?.

from a reference run with all considered stochastic variables (see section ??) at their median values. The initial time step was set at 30s.

All interventions are modelled as changes to a reference state of the system. This reference state is the Waal River after all  
 110 interventions from the Room for the River programme, which approximately corresponds to the 2016 situation. We consider  
 twelve additional system states, each one corresponding with a particular human intervention (Figure ??). In all cases, the  
 interventions were procedurally generated by the RiverScape tool (?). We implemented six different interventions, detailed  
 below. Each intervention was implemented in a low-intensity and a high-intensity variant. Here, intensity refers to the magni-  
 115 (high-intensity). We assume that the intervention is carried out in reality exactly as it was designed. This is known as the  
 ‘*as designed*’ post-intervention state. In reality, there may be a discrepancy between the *as designed* state and the actual (*‘as  
 built’*) state. In theory, this discrepancy could be considered as an additional source of uncertainty. However, because there is  
 no literature to support any assumptions regarding such discrepancy, we do not take this into account here.

### 2.2.1 Groyne lowering (GROYNLOW)

120 Groynes (also known as *wing dikes* or *spur dikes*) are (stone) structures perpendicular to the flow. During normal conditions,  
 groynes restrict the effective channel width to promote navigable depths. However, during high flows groynes obstruct flow.  
 Prior to 2016, many groynes in the Waal were already lowered as part of the Room for the River program. The intervention as  
 implemented in this study further reduces the groynes crest-heights. Groynes were lowered to the crest-height corresponding  
 to the water levels with exceedance frequency of 150 days (low intensity) and 363 days (high intensity) per year.

### 125 2.2.2 Minor embankment lowering (MINEMBLOW)

The River Waal floodplains are compartmentalised by minor embankments, which original purpose is to prevent flooding  
 of the floodplains during minor (summer) floods. This intervention lowers the crests of these embankments to reduce their  
 obstruction during high flow. Low and high intensity lowered the crests to a water level with exceedance frequency of 50 days  
 (low intensity) and 150 days (high intensity) per year.

### 130 **2.2.3 Floodplain lowering (FLFLOW)**

Lowering or excavation of the floodplains increases the maximum water volume within the existing bounds of the river corridor, thereby increasing conveyance. In this study, we lower the level of the floodplain without changing existing vegetation or other floodplain configuration to isolate the effect of lowering. Floodplains were lowered to the corresponding water level with exceedance frequency of 20 days per year, with 5% (low intensity) and 99% (high intensity) of the terrestrial floodplain area  
135 altered.

### **2.2.4 Floodplain smoothing (FLPSMOOTH)**

Vegetation in the floodplain greatly contributes to resistance during high flows. Replacing existing high-friction vegetation by low-friction vegetation mitigates this problem. Here, the existing vegetation was replaced by production meadow (roughness code 1201 in table ??). Smoothing at low intensity affected the top 5% of the obstructing vegetation. At high intensity all  
140 vegetation was converted to meadow.

### **2.2.5 Dike relocation (DIKERELOC)**

In the River Waal, dikes are the primary defence against flooding. However, they also contribute to flood risk by restricting the river corridor. Dike relocation increases the floodplains and allocates more space to the river. While this is perhaps the best example of combatting problematic constriction of the river corridor, it is also the most invasive — considering human  
145 settlement near and on the dikes. At low intensity, concave dike sections of less than 700 m are replaced by straight dikes, whereas at high intensity concave sections of 7000 m are straightened, while creating small polders around existing built-up areas.

### **2.2.6 Side channels (SIDECHAN)**

Finally, the construction of secondary (side) channels within the existing corridor both increases the available volume, and  
150 decreases vegetation friction. All new channels are assigned "side channel" roughness (Code 105 in Table ??) and a trapezoidal cross sectional shape and slope of 1 to 3. The channels were implemented with widths of 10 m (low intensity) and 100 m (high intensity), and depths of 0.35 m (low intensity) and 3.5 m (high intensity) below the water level with an exceedance frequency of 363 days per year.

## **2.3 Uncertainty sources**

155 Modelling real-world rivers on the scale of nearly 100 km necessarily involves various simplifications, discretisations and parameterisations. Sources of uncertainty for this river were identified by ? using expert elicitation. The main sources were (a) boundary conditions and (b) main channel friction and to lesser extent (c) friction by vegetation, (d) geometry and (e) weir and groynes formulations. In this study we follow the design approach taken in the Room for the River program, which assumes the boundary conditions given and stationary for a certain design return rate (which is  $T_{1250}$ ) and therefore not a source of

**Table 1.** An summarised overview of the stochastic variables. A full overview is given in Table ??

Type	Number of stochastic variables
Main channel roughness	1
Floodplain roughness	
Vegetation height ( $h_v$ )	14
Vegetation density ( $n_v$ )	17
Non-vegetation roughness	6
Classification error	1
Total	39

160 uncertainty. ? considered the hydraulic roughness parameters to be the most important parameter based on literature. We adopt this assumption and take into account uncertainty of the main channel friction, vegetation parameters and classification errors in the land-use maps. The total number of stochastic variables is 39 (see Table ??).

### 2.3.1 Main channel roughness

The hydraulic roughness of the main channel is chiefly determined by the material of the bed (“grain roughness”) and the bed forms (“form roughness”). Various models have been proposed that calculate the friction factor based on the characteristics of the bed (?). Here, we adopt the approach of ? who estimated the values for Nikuradse roughness height  $k_n$  [m] for a  $T_{1250}$  event by extrapolation using a Generalized Extreme Value (GEV, Weibull variant) distribution for five roughness models. Given the GEV percentiles, we fitted a lognormal distribution at the  $T_{1250}$  return period for each roughness model. These lognormal distributions were combined into a single distribution using equal weight for each roughness model. Figure ?? shows the resulting individual and combined probability functions from the Weibull extrapolation.

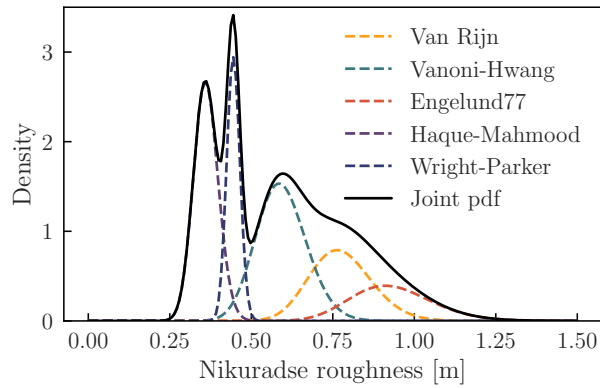

In the following we will use the joint cumulative density function of the five roughness models to sample representative roughness height  $k_n$ . The joint cumulative function is a highly asymmetrical distribution with a mean of approximately 0.58 m and 95% confidence limits at 0.31 m and 1.0 m. The sampled values of  $k_n$  will be used in the hydrodynamic model as input for the White-Colebrook model:

$$175 \quad C = 18_{10} \log \frac{12h}{k_n} \quad (1)$$

with Chézy coefficient  $C$  [ $\text{m}^{1/2}\text{s}^{-1}$ ] and water depth  $h$  [m]. The sampled  $k_n$  values are used to resolve friction for all main channel roughness classes, which cover 95.6% of the main channel area. The other 4.4% are non-erodible layers in the outer river bends which are not stochastically determined in this study.

### 2.3.2 Floodplain roughness

180 The Baseline database divides the floodplain into vegetation classes, riverbanks and water bodies. Each class is given a specific roughness code called a *trachytopes*, which is then coupled to an appropriate roughness formula and parameters specific to

**Figure 3.** The combined probability function of the main bed roughness is based in Weibull extrapolation of Nikuradse roughness height  $k_n$  to the  $T_{1250}$  return period using five different bed roughness formulas.

that formula. Spatially, the vegetation in the floodplains is discretised by polygons, which are designated by either one or a combination of distinct vegetation classes.

For vegetation, the generation of roughness by vegetation is complex, resulting from obstruction by stems and leaves and turbulent flow through the vegetation and over the canopy. The relationship between vegetation and roughness is extensively studied, leading to various models to compute hydraulic friction from vegetation traits (??). These traits often include the vegetation canopy height  $h_v$  [m], drag coefficient  $C_D$  [-], stem density  $n_v = m_v D_v$  or vegetation concentration  $\lambda = \frac{\pi D_v^2 m_v}{4}$  with number of stems per square meter  $m_v$  [ $m^{-2}$ ] and stem diameter  $D_v$  [m] (?????). ? have shown that the choice for a particular vegetation model has little influence on the outcome uncertainty compared to parameter uncertainty. Therefore, we only used the model proposed by ?, in which vegetation friction is chiefly determined by the parameters  $h_v, n_v, C_D$ . These parameter values are determined in the following way. For  $C_D$  we use fixed, deterministic values based on ?. The height and density parameters ( $h_v$  and  $n_v$ ) are assigned probability distributions based on the field campaign of ?. Based on 206 field observations, they approximated the variation in vegetation density and height for 25 homogeneous vegetation classes. Based on their estimate quantiles we fitted lognormal distributions for each class, assuming the vegetation height and density to be independent parameters. In total, the roughness of 66% of the River Waal floodplain is defined by one of the vegetation trachytopes and 2.5% is defined by combination of two vegetation trachytopes.

Six trachytopes are associated with water bodies or riverbanks, accounting for about 27% of the total areal. We model the friction for these 6 classes with the Manning formula

$$C = h^{1/6} n^{-1} \quad (2)$$

with Manning coefficient  $n$  [ $sm^{-1/3}$ ]. The  $n$  values for these trachytopes are modelled as triangular probability functions with the minimum, maximum and mean values based on ?. All parameters of the vegetation parameter distributions are summarised

in Table ???. The remaining 4.5% of floodplain area, which is given deterministic roughness values, is mostly (3.7%) covered by buildings which are excluded from flow computations, revetment and pavement.

### 2.3.3 Classification error matrix

205 Available vegetation maps are likely to contain ‘impurities’ (?) or classification errors, that have significant impact on model output uncertainty (?). The probabilities of one class being in reality another is encoded in a confusion matrix (we use Table 1 in ?). Following this matrix it is found, for example, that "Willow plantation" was, in all cases, found to be "Softwood forest" instead. An overview of the various vegetation classes is given in the Appendix. Following these probabilities we generated an ensemble of 2000 pre-intervention trachytopes maps. Each map was then given a fixed index number. We sample from these  
 210 maps by picking a number from a discrete uniform distribution and finding the corresponding map by index number. In this way, each map is assigned the same probability.

## 2.4 Quantification of model output uncertainty

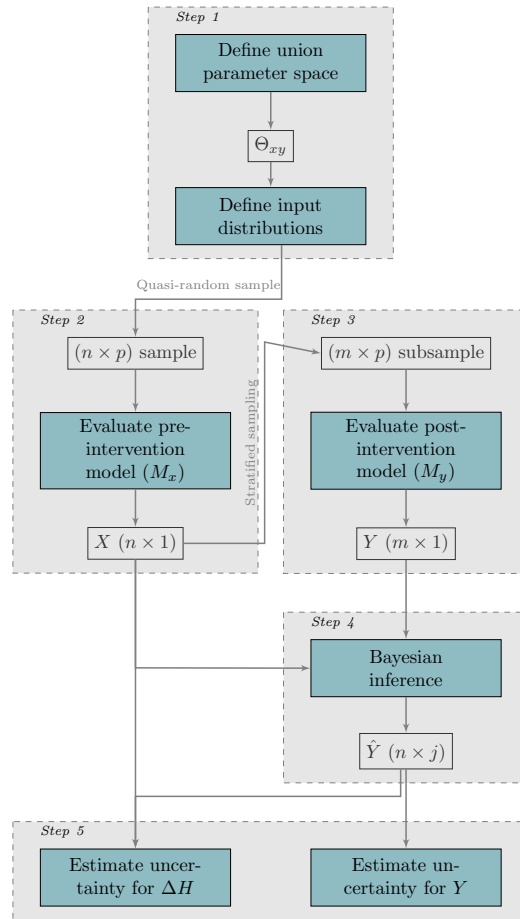

### 2.4.1 Estimation method

In this study we focus on prediction of the maximum flood levels (see Figure ??) in the reference state (denoted by  $X$ ),  
 215 the maximum flood levels in the various interventions (denoted by  $Y$ ) and the difference between these two (denoted by  $\Delta H$ ). Due to the uncertainties in model input discussed in section ??,  $X$ ,  $Y$  and  $\Delta H$  are stochastic. To analytically compute differences between these two (stochastic) states of the river system, we would need to obtain both the model output probability distributions, as well as the covariances between the two distributions (?). This problem is analytically intractable, but can be solved numerically by Monte Carlo simulation (MCS; ??). In the numerical approach, covariances are not explicitly computed.

220 However, MCS is not always practically feasible or desirable. Although MCS has been applied for estimation of flood level uncertainty before (?), the added task of performing a separate MCS for each intervention puts a severe strain on computational resources. Therefore we follow the approach of ?, schematically depicted in Figure ??, which is computationally more efficient. We refer to this method as ‘correlated output regression analysis’ (CORAL). The key feature of CORAL is that the stochastic intervention output  $Y$  is not directly solved by MCS, but instead an estimator  $\hat{Y}$  is computed using the reference state and a  
 225 correlation model. This correlation model is defined within a Bayesian framework and is probabilistic as well. We use the same linear model as ?:

$$\hat{Y} = \alpha(X - c) + \beta + \epsilon + c \tag{3}$$

with  $\epsilon \sim \mathcal{N}(0, \sigma_\epsilon)$  and transformation constant  $c$ . The constant is introduced to shift data to the origin, which facilitates faster inference, and is defined as  $c = \min(X)$ . In the Bayesian framework, the regression parameters  $\theta = \{\alpha, \beta, \sigma_\epsilon\}$  are considered  
 230 stochastic variables themselves and estimated via a Markov Chain Monte Carlo (MCMC) algorithm, trained by a limited subsample of simulations from  $Y$ . We use a subsample of  $m = 20$  for all intervention states. To estimate the distribution of the reference state (step 2) we use a quasi-random MCS sample ( $n = 1000$ ) with the Sobol’ low-discrepancy sequence. The

**Figure 4.** Schematic overview of the efficient uncertainty estimation method CORAL for post-intervention model output and impact analysis. In this figure:  $n$ : MCS sample size;  $m$ : subsample size;  $p$ : number of stochastic parameters;  $X$ : pre-intervention model output;  $j$  the number of draws from the posterior predictive model;  $Y$ : post-intervention model output;  $\hat{Y}$ : estimated post-intervention model output;  $\Delta H$ : intervention effect. Figure adapted from (?).

linear model was demonstrated to be applicable to similar intervention studies by ?, and (visual) inspection of the correlation between the reference state and the intervention models shows this holds for our cases as well.

235 The main advantage of this approach is a significant decrease of required computational resources by reducing the number of model evaluations. The total number of hydrodynamic model evaluations was 1240, divided over thirteen model states (the reference plus 12 interventions). This is a decrease of computational effort of more than 90% compared to direct MCS with all states, which would have totalled 13.000 model evaluations. It is important to state that the consequence of having a probabilistic correlation model, is that the intervention state estimator  $\hat{Y}$  is stochastic for each individual draw from the

240 reference state ( $X$ ). Since  $X$  is stochastic itself, this can be thought of as the ‘uncertainty of the uncertainty’ or the estimation uncertainty.

To maintain correlation between the  $X$  and  $Y$ , a union stochastic parameter space is constructed (step 1 in figure ??). Practically, this means that each corresponding member in the reference and intervention model ensembles has identical values for their stochastic variables, with the noticeable exception where those were altered by the intervention. For example, we  
 245 assume that a tree with a height of 8 m in the reference case still has a height of 8 m after intervention, unless this tree was removed or otherwise affected by the intervention. This is straightforward to implement for parameter values, but requires an additional step for the classification uncertainty. To be able to draw from the confusion matrix (see section ??) a large number of trachytopo maps was generated for the reference case. To maintain correlation, the same number of maps is generated for  
 250 each intervention in such a way that every map is identical to the corresponding reference map with the same index, except in areas where the intervention has altered the trachytopo. For example, an area which was classified as ‘willow plantation’ in the reference state will still be classified as ‘willow plantation’ after the intervention, unless that area has been reclassified as part of the intervention.

## 2.4.2 Uncertainty metrics

As a data reduction step, we summarise the results using the following metrics based on the water level reduction effect  $\Delta H$ .

255 Confidence intervals measure the distance between two percentiles (e.g. the 10% and 90%) of a cumulative density function (cdf). We refer to the confidence intervals of the stochastic variables  $X$ ,  $Y$  and  $\Delta H$  as the model uncertainty confidence interval or MCI. For example, the MCI of  $\Delta H$  is defined as:

$$\text{MCI}_{\Delta H} = |\hat{F}_{\Delta H}^{-1}(p_u) - \hat{F}_{\Delta H}^{-1}(p_l)| \quad (4)$$

The MCI of  $\hat{Y}$  is derived in the same way. Here,  $\hat{F}^{-1}$  is the inverse cumulative density function, also known as the *quantile* or  
 260 *percent point* function and  $p_l$ ,  $p_u$  the lower and upper quantiles. Here, these quantiles are always symmetric around the median. We use a limited subset of quantiles (consistent with the 10%, 20%, 50%, 80% and 90% confidence intervals) to summarise the data. Additionally, we calculate the exceedance probability  $P(\Delta H < z) = \hat{F}_{\Delta H}(z)$ .

It is important to note that  $\text{MCI}_{\hat{Y}}$  and  $\text{MCI}_{\Delta H}$  are stochastic — resulting from the estimation method. Therefore, each value belonging to an arbitrary quantile  $p_z$  may be expressed in terms of the expected value  $E(\hat{F}_{\Delta H}^{-1}(p_z))$  and variance  
 265  $\text{Var}(\hat{F}_{\Delta H}^{-1}(p_z))$ . This uncertainty may be referred to as the estimation uncertainty. A more detailed account of this can be found in ?.

To compare the uncertainty of interventions we calculate the *relative uncertainty*, i.e. the uncertainty relative to the expected effect. For this, we use an adapted version of the coefficient of variation, defined as:

$$U_{r;90} = \frac{\text{MCI}_{90,\Delta H}}{E(\Delta H)} \quad (5)$$

270 where  $\text{MCI}_{90,\Delta H}$  is the 90% confidence interval for  $\Delta H$  and  $E(\Delta H)$  the average of  $\Delta H$ . We use  $U_{r;90}$  instead of the coefficient of variation (which is defined as the standard deviation on the expected value) to directly express the size of the largest used

confidence interval in percentages of the expected effect. Therefore, a  $U_{r;90}$  of 100% means that the 90% MCI is as large as the average effect. Since both  $MCI_{90,\Delta H}$  and  $E(\Delta H)$  are stochastic,  $U_{r;90}$  is stochastic as well.

### 3 Results

#### 275 3.1 Pre-intervention uncertainty

**Figure 5.** Middle panel: Confidence levels of design water levels, normalised by the average water levels at each location. The water flow is from left (upstream) to right (downstream). The black line indicates km 893. Right panel: the histogram of the (not normalised) water levels at km 893.

Figure ?? shows the uncertainty in the water levels along the River Waal before any intervention has taken place, normalised by the average water levels. The average confidence intervals over the entire stretch range from 55.4 cm for the 90% interval to 5.7 cm for the 10% interval. However, the intervals are not uniform along the river. At the downstream boundary the intervals collapse to zero due to the fixed boundary condition. Upstream from the boundary, there is a noticeably smaller interval, approximately between km 885 and km 925. This is attributed to the relatively wider floodplains in this part of the river, which reduces flow through the main channel (?). The right hand panel of Figure ?? shows the histogram at km 893, which enables visual comparison with Figure 6 in ?, who performed their analysis with the WAQUA modelling system for the 1995 River Waal and slightly higher upstream boundary discharge. They reported a 95% confidence interval of 68 cm (13.99 m + MSL to 14.66 m + MSL) at km 893. Our results also show a 95% confidence interval of 68 cm, although at slightly higher water levels (14.05 m + MSL to 14.73 m + NAP). This provides confidence in the model results. However, we highlight two differences with respect to the study of ?. First, we did not include the vegetation roughness model as a source of uncertainty, but we added vegetation parameter uncertainty. This change does not seem to have affected the output uncertainty of flood levels significantly. Second, the increase in flood levels with respect to the study of ? was not expected, given that between 1995 and 2015 a large scale flood mitigation programme (called ‘Room for the River’) was carried out aimed at reducing flood levels.

290 However, given the different modelling systems and assumptions, this comparison cannot be used to judge the effectiveness of that programme.

### 3.2 Uncertainty of along-channel flood level decrease

**Figure 6.** The expected lowering of flood levels for side channel construction (a, SIDECHAN), and floodplain smoothing (b, FLPSMOOTH), both high intensity and flow direction from left to right. The colours in this chart convey identical confidence levels as shown in Figure ?? . The location of the maximum expected effect is indicated by the dashed line and annotation  $x_m$ .

The primary objective of the flood mitigation measures is to lower flood levels during a given design discharge. In deterministic approaches, this effect is typically communicated with an along-channel diagram showing the difference (i.e., before and after the intervention) in flood levels (see e.g. Figure 3 in ?). Figure ?? shows a similar diagram, augmented with information on the uncertainty of the prediction. The expected effect follows the general trend as a deterministic approach. Starting from the downstream end of the intervention (around km 932), water levels gradually decrease due to the local increase of conveyance compared to the reference state. From km 912 upstream, water levels gradually return to the reference equilibrium. The gradual relaxation to equilibrium levels both over and upstream from the intervention, i.e. backwater curves, is explained through basic sub-critical flow theory. We note that the length of the backwater curves spans tens of kilometres resulting in a residual water level decrease of approximately 5 cm near the upstream boundary (km 868). In theory, this could affect the distribution of discharge at the bifurcation of the River Waal with the Pannerden Canal. This secondary effect is not accounted for in this study.

The novelty of Fig. ?? results is mainly found in the uncertainty, visualised through the confidence intervals. These intervals follow the movement of the average; going down when the average decreases and relaxing toward the reference equilibrium upstream from the location of maximum effect ( $x_m$ ). This shows that taking into account parameter uncertainty does not

fundamentally change established typical effects of flood mitigation measures. However, the movement with the average is not accompanied by parallelity: the range of the intervals is not constant along the river. Instead, the range of the intervals scale with the expected effect: the ranges are small for small effects, and increase with increasing effect. Consequently, uncertainty is largest at the maximum effect. Downstream from the intervention the confidence bands tend to zero, since for a steady computation, there is no difference between the pre- and post-intervention models and no backwater effects. Upstream from the intervention the confidence intervals reduce to zero along with the backwater curve effect.

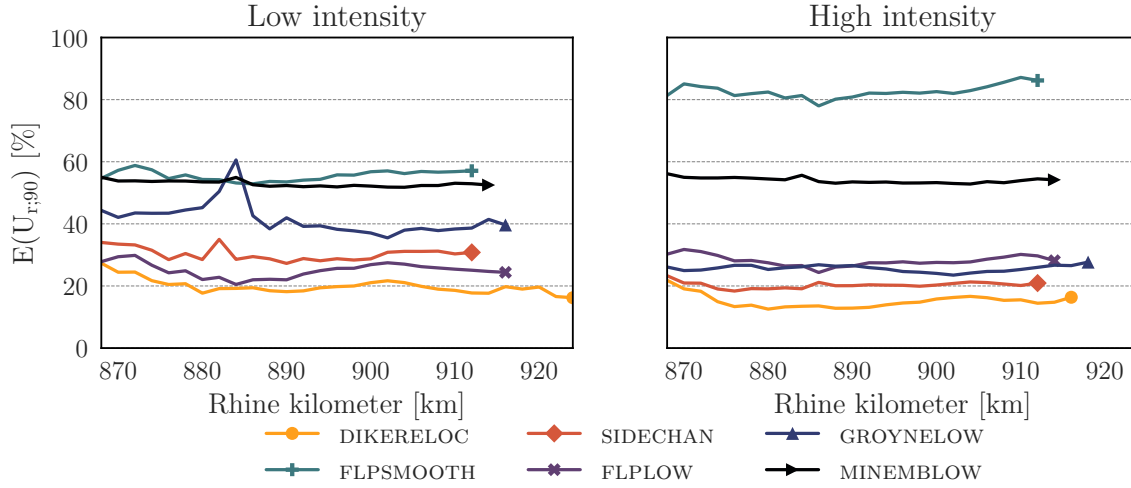

Next, we compute the relative uncertainty ( $U_{r;90}$ ) for each intervention and intensity. We first marginalise the uncertainty in  $U_{r;90}$  due to CORAL by calculating the expected value ( $E(U_{r;90})$ ) for each point along the river (Fig. ??). Figure ??, as well as the relatively small standard deviations in Table ??, show that values for  $E(U_{r;90})$  are fairly constant over the river length up to the location of the maximum flood level decrease ( $x_m$ ) for all interventions. A notable exception is the peak at approximately km 885 for low-intensity GROYNLOW. This is attributed to small inaccuracies in the estimation of the expected effect. Since  $U_{r;90}$  is a ratio, its value is sensitive to small values of the denominator, which is the expected effect (see Eq. (??)). GROYNLOW has a very minor effect (maximum of 1 cm at low intensity), so small inaccuracies in estimation will greatly affect  $U_{r;90}$ . For this same reason, we do not compute  $U_{r;90}$  upstream from the maximum effect, as the flood level decrease will rapidly return to and cross zero, which will lead to rapidly exploding  $U_{r;90}$  values. From the fact that we do not observe such peaks much more often, we gain confidence that the chosen estimation method is suitable for this type of analysis even at very small-scale effects. In general, the constant values for  $E(U_{r;90})$  shows that it is a useful parameter to characterise the uncertainty of an intervention, as the increase in uncertainty with the effect, observed in Figure ?? is sufficiently summarised by a single  $U_{r;90}$  value.

It is interesting to note that in theory, the adaptation length (i.e. the length scale of the backwater curve) is affected by the equilibrium water level and can therefore result in converging or diverging confidence intervals. Since  $E(U_{r;90})$  is relatively constant along the river, the adaptation lengths (i.e. the length scale of backwater effects) are not significantly affected by the intervention. Therefore, we see that all uncertainty is generated over the length of the intervention and subsequently diminishes upstream as water levels return to their equilibrium. In other words, if the adaptation lengths are known, the uncertainty upstream of  $x_m$  can be readily estimated from the relative uncertainty at  $x_m$ .

A comparison of all interventions (Table ??) shows that small effects ( $E(\Delta H)_{x_m}$ ) are accompanied by small uncertainties ( $E(\text{MCI}_{90})_{x_m}$ ). This shows that even small changes to rivers can be predicted, even when the absolute uncertainty in water levels (see figure ??) is an order of magnitude larger than the expected effect.

### 3.3 Inter-comparison between interventions

A straightforward way to compare differences between the effect of two or more interventions is to look at the backwater figures. In Fig. ?? we see two diagrams of interventions that result in flood level decrease within the same order of magnitude, but with very different uncertainty. The uncertainty of FLPSMOOTH is much higher than that of SIDECHAN, as represented by the wider confidence intervals.

**Figure 7.** The expected values for the relative uncertainty ( $U_{r;90}$ ) along the river, from the upstream boundary at km 868 to the location of maximum effect  $x_m$  indicated by the marker, showing relatively constant values upstream from  $x_m$ .

**Table 2.** Summarised results for each measure. H=high intensity; L=low intensity;  $x_m$ = location in Rhine kilometre (km) where maximum effect occurs;  $E(\Delta H)_{x_m}$ = expected effect at  $x_m$ ;  $E(\text{MCI}_{90})_{x_m}$ =expected 90% uncertainty at  $x_m$ ;  $E(\widehat{U_{r;90}})$ = Expected relative uncertainty along the river (average  $\pm$  the standard deviation). The rows are sorted from highest expected effect (top) to lowest expected effect (bottom).

Intervention		$x_m$	$E(\Delta H)_{x_m}$	$E(\text{MCI}_{90})_{x_m}$	$E(\widehat{U_{r;90}})$
DIKERELOC	H	916	-1.08	0.176	15 $\pm$ 2.2%
	L	924	-0.21	0.034	20 $\pm$ 2.3%
FLFLOW	H	914	-0.80	0.224	28 $\pm$ 1.7%
	L	916	-0.10	0.024	25 $\pm$ 2.3%
SIDECHAN	H	912	-0.36	0.076	20 $\pm$ 1.0%
	L	912	-0.02	0.007	30 $\pm$ 2.1%
FLPSMOOTH	H	912	-0.28	0.239	82 $\pm$ 1.9%
	L	912	-0.04	0.023	55 $\pm$ 1.6%
GROYNLOW	H	918	-0.04	0.012	26 $\pm$ 0.9%
	L	916	-0.01	0.004	42 $\pm$ 5.1%
MINEMBLOW	H	914	-0.03	0.014	54 $\pm$ 0.9%
	L	914	-0.03	0.013	53 $\pm$ 0.9%

**Figure 8.** Probability densities of the relative uncertainty ( $U_{r;90}$ ) at the location of maximum effect ( $x_m$ ), for all interventions, showing that FLPSMOOTH is significantly more uncertain than other interventions. Most interventions show similar distributions for the low intensity (left, light coloured) and high intensity (right, dark coloured) variants.

340 To systematically compare interventions we compute the relative uncertainty  $U_{r;90}$  at the location of the maximum effect for each intervention (Figure ??). Since  $U_{r;90}$  is stochastic, we visualised the kernel density estimation of their probability distributions. In general we observe that (i) FLPSMOOTH and MINEMBLOW are more uncertain than the other four interventions. This can be seen by their higher values for  $U_{r;90}$ , especially for the high-intensity variants. We also observe that overall, the low-intensity variants have similar distributions compared to their high-intensity variants, both in shape and location. Even in the

345 cases where the high-intensity variant distribution is clearly different from the low-intensity variant (DIKERELOC, GROYNLOW and FLPSMOOTH), the distribution still overlap. This shows that the intensity of an intervention is not a deciding explaining factor for  $U_{r;90}$ , even though it is evidently important in explaining the absolute uncertainty ( $MCI_{90}$ ) and the expected effect. The latter follows from the earlier observation that the absolute uncertainty scales with the expected effect following a (constant) relative uncertainty. For decision making, it may be useful to estimate how much uncertainty is expected for a given expected

350 effect. When considering different flood mitigation measures, the choice may depend on the level of acceptable uncertainty.

By linearly interpolating between the expected values of the low and high intensities, we obtain a first approximation of the uncertainty for a given expected effect for each intervention (Figure ??). For example, consider that the objective of a planned flood mitigation measure is 25 cm. We see from figure ?? that this can be accomplished by four different interventions (FLPSMOOTH, FLFLOW, SIDECHAN and DIKERELOC), within the bounds marked by the low- and high intensities. The confi-

355 dence intervals differ markedly between those choices. Under the assumption of linear interpolation between the two intensities, the 90% confidence intervals for an expected decrease of 25 cm are estimated at 4 cm (DIKERELOC), 5 cm (SIDECHAN), 7 cm (FLFLOW) and 21 cm (FLPSMOOTH). These intervals may or may not be acceptable.

**Figure 9.** The expected effect ( $E(\Delta H)$ ) at  $x_m$  against the 90% confidence interval, linearly interpolated between the low and high intensities. The relationship between the two is described by the relative uncertainty  $U_{r,90}$ , here shown as dashed grey lines. The error bars depict the estimation uncertainty (90% interval). The right hand panel (b) displays a zoomed-in part of the left-hand graph.

Instead of looking at the expected effect, the confidence intervals can be marginalised by designing for a given exceedance probability of the effect. The desired effect is related to the expected effect through the exceedance probability. To illustrate how the exceedance probability can be used to guide intervention design, we linearly interpolated between the low-intensity and high-intensity variants as function of the expected effect (Figure ??). In this figure, the estimation uncertainty is not taken into account. Given that we only have two points (low and high intensity), a linear transformation is the only model we can support. Although we acknowledge that other models are possible, we included this as a first approximation, because it illustrates information available for decision makers.

The high-intensity variant of FLPSMOOTH has an expected flood level decrease of 28 cm. However, the likelihood that the decrease is smaller (or higher) than that number is only approximately 50%. This means that the expected effect of 28 cm is as likely as not to be met by the proposed intervention. In contrast, the 90% exceedance probability for the high-intensity variant is 18.7 cm. This means that it is "very likely" (following IPCC terminology, see ?) that the flood level decrease is larger than 18.7 cm.

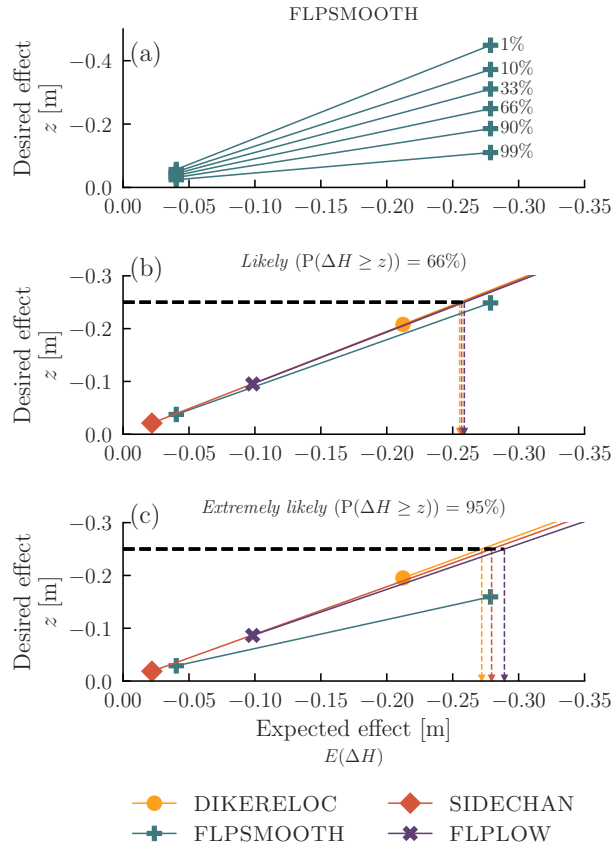

This approach can be applied to the earlier example of a planned mitigation measure with a 25 cm flood level decrease objective. In figure ?? (b), we see that at an exceedance probability of 66% ("Likely"), all four possible interventions can be implemented. However, to meet this likelihood all interventions have to be "over-designed", i.e. to meet a larger expected

flood level decrease than the given objective. For example, floodplain smoothing needs to be designed for an expected effect of 28 cm for a 66% likelihood of reaching the objective of 25 cm. The amount by which the measure needs to be over-  
375 designed depends on the uncertainty of that measure and the exceedance probability. Higher exceedance probabilities such as a 95% likelihood ("Extremely likely") can also preclude some flood mitigation measures (Figure ?? (c)). With this level of confidence, FLPSMOOTH can no longer be considered: none of the computed examples reach an 'extremely likely' flood level decrease of 25 cm within the limits of the considered interventions. In this case, there is a physical limit to an even higher intensity FLPSMOOTH, since there is simply no more available land within the study area to turn into meadow. Extrapolation  
380 beyond the given limits is therefore not possible, although a higher effect could be obtained by simply enlarging the study area. Within the given limits, the three remaining interventions (DIKERELOC, SIDCHAN and FLPLOW) can still be used. They would need to be designed for an expected effect of -0.27m , -0.28m and -0.29m, respectively. For perspective, it is worthwhile to point out that one of the greatest interventions on the River Waal in the past decades, the Nijmegen-Lent dike relocation project, has (deterministically) predicted effect of -27 cm, at an estimated cost of more than ten million Euro per cm flood level  
385 decrease.

#### 4 Discussion

Our results show that some interventions are inherently more uncertain than other interventions. Given the complexity of high-detailed modelling of floodplains, it is not straightforward to explain these differences. The statistical causes of uncertainty are discussed in detail by ?. They observed that the removal of existing stochastic elements (e.g., a vegetation polygon) in  
390 exchange for new ones greatly increased the unexplained variance ( $\epsilon$  in (eq. ??)) and therefore increases effect uncertainty. We see that here as well: FLPSMOOTH, which removes high-friction vegetation in exchange for meadow, is by far the most uncertain intervention. However, in this study we have argued that the relative uncertainty ( $U_{r;90}$ ) is a more useful parameter than the absolute uncertainty (MCI). In that context, a large absolute uncertainty can be offset by a large expected flood level decrease. This is evidenced by both DIKERELOC and FLPLOW, which both have a large absolute uncertainty at high intensity  
395 but a relatively low relative uncertainty. A reduction in relative uncertainty could therefore be achieved by minimising the amount of change to existing floodplains while optimising the expected flood level decrease. This general observation is likely applicable to other rivers and case studies.

A lack of computational resources is often named as the main obstacle that motivates the use of deterministic approaches over probabilistic approaches. The analysis performed in this study is nonetheless feasible due to the CORAL approach, which  
400 reduces the required computer resources by reducing the number of model evaluations. An additional advantage of this method is that the uncertainty of the estimation is known and can be explicitly incorporated in analyses. In this study, we show that the relative uncertainty  $U_{r;90}$  can be estimated to a sufficient precision (Fig. ??) to draw conclusions, even with a relatively low number of model runs (20 for each intervention). It is possible to decrease the estimation uncertainty by increasing the number of model runs with the post-intervention models (?), if (computational) resources allow.

**Figure 10.** (a) The relationship between the expected effect  $E(\Delta H)$  and the exceedance level  $z$  for various exceedance probabilities. (b) Inter-comparison of a 66% exceedance probability for four interventions. The dashed black line indicates a  $z$  of 25 cm, and the coloured dashed lines indicate which expected level belong to that  $z$ , given the exceedance probability (see text). (c) same as (b), but for an exceedance probability of 99%. Note that all lines show the expected value of the exceedance level; the estimation uncertainty is not depicted.

405 Our study focused on providing uncertainty estimations for many different interventions, not to provide an optimal interven-  
tion for the given case study. Following this approach we made several simplifications, that must be resolved when an optimal  
intervention design is pursued. The linear interpolation between low intensity and high intensity interventions in figures ?? and  
?? was used to obtain a first approximation of the uncertainty for interventions at different intensities. These figures are useful  
to illustrate how confidence levels and differences in relative uncertainty between interventions affect the expected effect but  
410 should not replace new calculations in intervention design – in part because our study provides only two support points, which  
is insufficient to either support or oppose the assumption of linearity. Rather, they may help to provide a starting point for a  
new set of calculations. Second, we marginalised the estimation uncertainty in figure ?? by averaging, to show how model  
uncertainty implicates intervention design. Practical use of exceedance levels should include estimation uncertainty of those  
levels — which can be reduced by increasing the number model evaluations if necessary. Finally, the interventions studied  
415 in this paper are single archetypes, while in reality designs would likely be a combination of multiple archetypes (e.g. side  
channel combined with lowering of the surrounding floodplain). Our study does not provide support for claims regarding such  
compound interventions, which would require further study.

Our approach is a form of forward uncertainty analysis: the quantification of model output uncertainty based on uncertainty  
in model assumptions without taking into account historical evidence of the goal variable (i.e., water level measurements).  
420 We justify choosing this approach based on the assumption that no historical information can be used to infer or narrow the  
distributions of the uncertain parameters, because (a) such information does not exist for our study case and (b) measurements  
after the intervention will never be available *ex ante*. The results of our analysis are therefore conditional on our assumptions  
about the validity of the model, the selection uncertainty sources and the probability distributions of these sources. We have  
taken care to select the stochastic variables, and their distributions, based on previous research specific to our study case.  
425 Forward uncertainty analysis is contrasted (e.g., see ?) with so-called inverse methods, such as GLUE (?), DREAM (?) or  
deterministic calibration, that use historical evidence to potentially narrow the uncertainty bands of input variables. However,  
the potential use of historical data to constrict uncertainty faces complex challenges which will have to be met. Chief among  
them are extrapolation to unmeasured conditions and dealing with the large number of uncertain variables (here, 39) which may  
not be uniquely identifiable (?). In any case, like traditional deterministic approaches, the assumptions underlying probabilistic  
430 approaches should be readily available, transparent, and open to discussion.

Models can play a role in decision support under (deep) uncertainty and the uncertainty quantification is an important step to  
model the future (?). However, too much focus on quantifiable uncertainty should be avoided. ? documented several examples  
where too much focus on quantifiable (also “statistical” or “technical”) uncertainty resulted in knowledge creation that did not  
contribute to the policy process (“superfluous knowledge”). A key idea is that other uncertainties exist that cannot be reduced by  
435 more data or simply cannot be quantified. Examples of these include ‘social uncertainty’: fundamental disagreement between  
experts, lack of trust in scientific results, ambiguity and diverging narratives based on the same empirical basis (???) Coping  
with such uncertainties may require adaptive river management (?) and exploration of multiple alternate futures (See the third  
paradigm of ?, and references therein). Given these considerations, there are several probabilistic frameworks of flood risk  
adaptation strategies to which explicit quantification of model uncertainty is a natural and required extension (e.g. ??). In this

440 paper, we demonstrated that model predictions of human intervention in rivers are sensitive to uncertainty and can substantially influence design decisions. Therefore, we argue that trusting only on the best available knowledge and, by extension, prediction by the best-available models, is not sufficient for planning interventions in river systems. Finally, our study was limited to the effect of interventions with respect to water level lowering. We did not consider other indicators, such as economic, ecological or societal costs and benefits, as was done by ? (albeit without addressing uncertainty). Multidisciplinary and multisectoral as-  
445 sessment of interventions including uncertainty is recommended to determine trade-offs in river management. CORAL provides a computationally effective method to do so.

## 5 Conclusions

In general, our study shows that explicitly quantifying the uncertainty of predicted flood mitigation measures provides valuable information to decision makers and modellers. On the one hand, results show how taking into account uncertainty can lead  
450 to different design choices. On the other hand, even small effects on flood levels can be quantified, because small effects are accompanied by small uncertainties. This shows that model uncertainty does not invalidate model-supported decision making in river management, but enriches it.

Our first objective was to quantify the effect of parameter uncertainty on the predicted effectiveness of flood mitigation measures. Based on previous studies, we quantified the parameter uncertainty for 39 variables and estimated the uncertainty of  
455 model output. Results show that the absolute uncertainty of the predicted effect of flood level decrease is highly dependent on the type of intervention and location along the river. However, we found that the confidence bounds of flood level decrease along the river can be adequately described by a single "relative uncertainty" metric, defined as the ratio between the 90% confidence interval and the expected effect. This ratio remains relatively constant along the river and between intensities of intervention types, and enables us to make some general observations. First, all uncertainty is 'generated' where the intervention has  
460 modified the river system. Upstream from there, the uncertainty gradually diminishes upstream with a constant rate following typical backwater curves. Second, a higher expected flood level decrease lead to a higher uncertainty, and a small flood level decrease was accompanied by a small uncertainty. The ranges of the expected relative uncertainty varied between 15% and 40% for most interventions, which means that the size of the 90% confidence bounds of those interventions is less than half of the expected flood level decrease.

465 The second objective was to explore the relationship between the expected effect and its uncertainty, to aid in the decision making process. We observe that interventions of different types may reach the same expected flood level decrease, but having different uncertainty. Specifically, a large-scale but relatively ineffective intervention such as floodplain smoothing (by removing high-friction vegetation) has a high relative uncertainty compared to alternative interventions. The intensity of an intervention (e.g. total area of vegetation smoothed) may be increased to reach a higher effect. Our results show that higher  
470 intensity also leads to a higher uncertainty, while the relative uncertainty remains approximately constant. This relationship was then used to show how explicit uncertainty quantification and differences in relative uncertainty between various interventions may affect design choices, depending on the level of acceptable uncertainty. For a fixed level of acceptable uncertainty (i.e.,

by a given exceedance probability), we graphically demonstrated that interventions need to be designed for a larger expected flood level decrease than the given objective.

475 *Code availability.* In this article we used the following code and software. For the hydraulic modelling we used Delft3D Flexible Mesh (FM) version 1.1.261.52670. Delft3D FM is available from (<https://oss.deltares.nl/web/delft3dfm>). For the generation of the various flood mitigation measures we used the Python tool RiverScape (for availability see ?). The uncertainty quantification method CORAL is available from GitHub (<https://github.com/kdberends/coral>).
