

Legend: blue – reviewer’s comment. Black – answers from the authors.

A marked version of the paper, highlighting the modifications with respect to the previous submission, is provided at the end of this file.

Reviewer 1

I feel that this manuscript needs to improve their structure, connection between sections (especially the last section on fragility functions), add some explanations and proper references.

We would like to thank this reviewer for the valuable comments on our manuscript. We have improved the manuscript structure and connection between sections accordingly.

General Comments

1. I think the authors should better show uniqueness of their rapid survey form, i.e. how their new rapid survey form differs to other rapid survey forms, easier/faster to fill?, can be used for various purposes, etc.

This reviewer is acknowledged for this comment. In fact, although the main features of the INSPIRE Rapid Visual Survey (RVS) are discussed in the manuscript, the comparison with other approaches and its uniqueness has been better stressed-out in the revised version of the paper. The unique features of the INSPIRE form are related to: 1) the possibility to calculate both a seismic and a tsunami index while requiring a reasonable amount of time to be filled; 2) the consideration of qualitative confidence levels for each parameter, which is particularly useful in deriving statistics, defining archetype buildings and/or numerical models (as shown in the paper); 3) with simple customisations, it can be used for other purposes (e.g., considering other types of hazards).

2. Is INSPIRE developed mainly for earthquake and tsunami or applicable to other hazards? If the later, more explanations are needed as only examples on earthquake and tsunami were demonstrated.

Currently, the INSPIRE RVS form is optimised for earthquake and tsunami. This is why the specific case study in the illustrative application (i.e., Banda Aceh) is mainly affected by such hazards. However, simple modifications of the form could be easily implemented to include other hazards (e.g., more information related to roof type/quality/connections is required when dealing with wind vulnerability). This concept has been emphasised in the revised manuscript. It is worth mentioning, however, that the multi-hazard considerations presented in Section 3.3 are still valid, and are not limited to the earthquake and tsunami hazards.

3. The newest PTVA is PTVA4 that calibrated their vulnerability based on comments and questionnaire results from experts in this field. Why don’t you use the newest one? Reference: Dall’Osso, F., Dominey-Howes, D., Tarbotton, C., Summerhayes, S., and Withycombe, G.: Revision and improvement of the PTVA-3 model for assessing tsunami building vulnerability using “international expert judgment”: introducing the PTVA-4 model, Nat. Hazards, 83, 1229–1256, 2016. Izquierdo, T., Fritis, E., and Abad, M.: Analysis and validation of the PTVA tsunami building vulnerability model using the 2015 Chile post-tsunami damage data in Coquimbo and La Serena cities, Nat. Hazards Earth Syst. Sci., 18, 1703-1716, 2018. Alternatively, you can also use or compare with previously developed tsunami fragility functions of RC buildings. Reference: Suppasri, A., Charvet, I., Imai, K. and Imamura, F. (2015) Fragility curves based on data from the 2011 Great East Japan tsunami in Ishinomaki city with discussion of parameters influencing building damage, Earthquake Spectra, 31 (2), 841-868.

The reviewer is particularly acknowledged for this comment. In the revised manuscript, the newly-calibrated PTVA4 index has been used. In the figures below, the results of the PTVA4 index (right column) for the analysed building portfolio are compared to the previously-adopted PTVA3 index (left column). The resulting vulnerability index for some of the buildings has indeed slightly changed when the new methodology is applied. However, it is worth highlighting that using the new

calibration (PTVA4) has limited-to-negligible effects on the overall multi-hazard prioritisation for the considered portfolio.

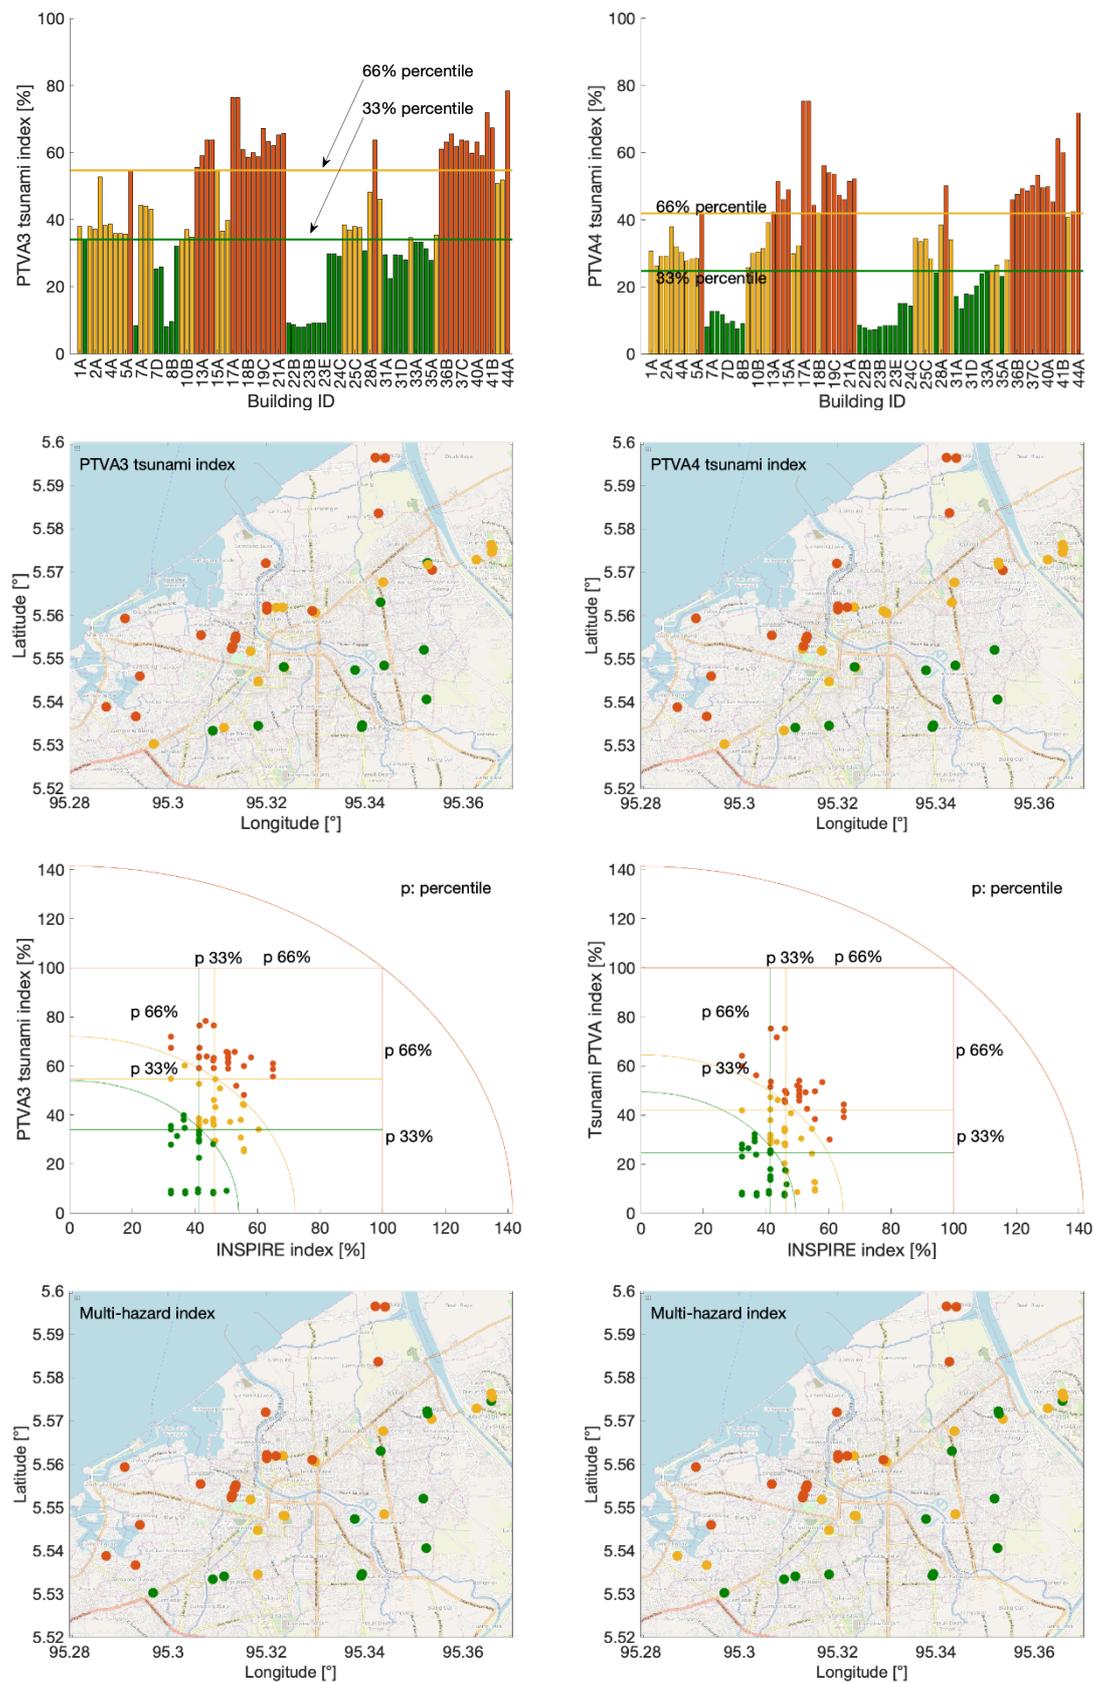

Fig. 1: comparison of the prioritisation based on the PTVA3 and PTVA4 indices.

Specific comments

1. P2 L3: Needs reference

The reference (last Italian census of 2011) has been added in the revised manuscript:

Istituto nazionale di STATistica, ISTAT (2011). 15th general census of population and housing (in Italian). <http://dati-censimentopopolazione.istat.it>.

2. Introduction section shall be rearranged for better readability. For example, grouping the literature reviews to RC building, school building and structure of INSPIRE. At present, explanations of methods and objectives are mixed up, please rearrange and make it clear (page 3).

To improve the readability of the paper, the literature review in the introduction has been rearranged as suggested from the reviewer.

3. P9 L1-2: Calibrate the baseline score to what? Why DS3 is used?

The reviewer is acknowledged for this comment. Firstly, the correct wording in this case should be “to define” rather than “to calibrate” the baseline score, and this change has been implemented in the revised manuscript. Moreover, as discussed in Section 3.1, the definition of the baseline score of the index is based on the DS3 damage state, as defined in HAZUS. This is because DS3 is deemed to be related to the Life-Safety performance objective in modern seismic codes. To further expand on this, when considering an RC member within a frame (e.g., beam or column), DS3 corresponds to the member ultimate capacity, which can be related to flexural failure (ultimate strain in concrete or steel, buckling of the reinforcement), shear or lap-splice failure. According to modern seismic codes (e.g. NZSEE 2017, ASCE 41-13, EuroCode 8), such a damage condition (for one or a few members) would define the ultimate limit state of the frame, which is “conventionally” related to the safety of people occupying the structure (i.e., Life-Safety). Such more-detailed comments have been implemented in the revised manuscript.

NZSEE: New Zealand Society for Earthquake Engineering, The seismic assessment of existing buildings - technical guidelines for engineering assessments. Wellington, New Zealand, 2017.

ASCE 41-13 (2014), Seismic Evaluation and Retrofit of Existing Buildings, American Society of Civil Engineer and Structural Engineering Institute, Reston, Virginia, USA.

EC8 (2005), ‘European Committee for Standardisation. Eurocode 8: Design of structures for earthquake resistance. Part 3: Strengthening and repair of buildings’.

4. P10 Table 3: How these weight factors obtained? If from HAZUS, how certain these values can be applied globally?

The secondary parameters are selected to account for aspects of the analysed building which are not explicitly considered in the HAZUS framework (i.e., in the baseline score). Such parameters, if present in the building, are deemed to negatively-affect its seismic performance. As mentioned in Section 3.2, the weights for such parameters (representing their relative importance) are defined according to the analytic hierarchy process, in turn based on all the possible pairwise comparisons between such parameters. At the present stage, the expert judgement that defines the pairwise comparisons is provided by the authors. However, in the future such coefficients have been updated considering the opinion of a group of experts in the field of structural and earthquake engineering. Finally, the weights of the secondary parameters are portfolio-specific, and therefore they should be calibrated differently for each analysis situation. Such concepts have been further discussed in the revised manuscript.

5. P12 Section 3.3: If there are three hazards or more, how equation 7 and Fig. 3 will be? And how to avoid such double count of subsequent damage?

This comment is particularly acknowledged. Equation 7 (Section 3.3) is defined for an arbitrary number of dimensions k . A high-dimensional Euclidean space is considered in which each

dimension represents the vulnerability/risk index for one hazard. A building subjected to k different hazards is defined as a point in this space. It is proposed to define a multi-hazard index as the distance of this point from the origin.

The second part of the comment relates to subsequent/cumulative damage. It worth mentioning that considering cumulative damage related to the different hazards is outside the scope of this prioritisation scheme. Such important concept has been discussed in the revised manuscript.

6. P14 L31: Needs reference

The reference has been added in the revised manuscript.

Seta, W.J.,: Atlas Lengkap Indonesia dan Dunia (untuk SD, SMP, SMU, dan Umum). Pustaka Widyatama. p.7, 2000.

7. P15 and/or P19: I think you should give more explanations about tsunami hazard in your study area in the past/future. How the flow depth of the 2004 Indian Ocean tsunami used in INSPIRE. I am not sure if they have measured flow depth in all buildings in your study if so, the flow depths are from model simulation?

This comment is particularly appreciated. The tsunami height (relative to the ground) related to the 2004 Indian Ocean event is based on the field-measures by Iemura et al., 2012. In this work, a correlation model between the distance from the coast and the tsunami height was developed. Such a model is adopted here to calculate, for each building in the portfolio, the expected tsunami height as a function of the distance from the coast.

Such considerations have been added in Section 4.2 of the revised paper.

Iemura, H., Pradono, M.H., Sugimoto, M., Takahashi, Y. and Husen, A.: Tsunami height memorial poles in banda aceh and recommendations for disaster prevention. *Proceedings of the International Symposium on Engineering Lessons Learned from the 2011 Great East Japan Earthquake*, March 1-4, 2012, Tokyo, Japan, 2012.

8. P20 Fig. 8 There should be some discussions that point out importance of considering multi-hazard scenarios. For example, buildings that became higher risk when tsunami is considered and comments on how the developed map can be used for disaster planning.

We thank the reviewer for this comment and agree on the importance of considering multi-hazard scenarios for risk prioritization. Indeed, a specific comment on this aspect has been added after Figure 8. Furthermore, a comment on how these maps can be used for disaster planning has been added. For instance, the developed maps could be used to identify “safer areas” where strategic buildings (e.g., schools or hospitals) should be located. While specific recommendations on disaster planning are outside the scope of this study, a few references to this aspect have been included in the revised paper:

Alexander D.: Disaster and Emergency Planning for Preparedness, Response, and Recovery, Oxford Research Encyclopedia of Natural Hazard Science, doi: 10.1093/acrefore/9780199389407.013.12, 2019.

9. P16 Fig. 5: Add photo taken dates

These pictures have been taken during the fieldwork carried out between 16 and 19 October 2018. This information has been added in the revised manuscript.

10. P21 Section 4.3: I feel that this section is not related to others otherwise, it should be used to compare with analysis results of other previous sections. What was the purpose of this section? Why didnt the authors use their own developed fragility functions instead of HAZUS?

As mentioned in the introduction of the paper, the INSPIRE form has multiple purposes, allowing to carry out analyses with different levels of refinement. Clearly, a prioritisation scheme can be defined according to the relative risk index. Moreover, the form provides enough data to build refined numerical models for one or more selected buildings (e.g., an “average” archetype building or the buildings with the highest relative risk index). The purpose of Sections 4.2 and 4.3 is respectively to

illustrate the above-mentioned purposes of the form. Accordingly, a more clear aim for Section 4.3 and a better link to the previous sections has been added in the revised manuscript.

It is worth noting that the structure-specific fragilities obtained with the analyses presented herein could be used to, in principle, to redefine the INSPIRE index. However, this would require the derivation of numerical fragility curves for a much larger set of archetype buildings, consistently with the building typologies identified in Table 1. Moreover, adopting the refined fragilities as an input for the INSPIRE index definition would be inappropriate. Indeed, the proposed index is defined as a quick and practical tool for seismic vulnerability prioritisation of large building portfolios (level 1 analysis). A more time-consuming fragility analysis (level 2) should instead be used to derive quantitative seismic risk estimates for one or more selected building in the database and to design structure-specific risk mitigation strategies (e.g., structural retrofitting).

Reviewer 2

General Comments

This manuscript provides a timely discussion on how to accomplish strategic prioritisation of intervention on school buildings in a transparent way using the Analytic Hierarchy Process in a multi-hazard context (earthquakes and tsunami). The approach is validated through a detailed analysis and a simplified mechanical methodology (i.e., SLAMA).

I report in the following what I consider minor comments that could improve the overall quality of the manuscript.

1. The explicit reference to Banda Aceh in the title could be removed as the methodology and approach is rather general and the case of Indonesia is a case-study

The reference to Banda Aceh in the title has been removed in the revised manuscript.

2. More discussion on the problem of “code enforcement” should be provided. The approach of classifying building according to the release of building codes is rationale, it makes sense, it refers to a widespread practice in regional analyses but a comparison with the real construction practice should be provided. In the specific case this is possible (e.g., comparison of reinforcement in figure 5e with code provisions).

This comment is particularly appreciated. The structural details of the archetype buildings for this study are defined based on Figure 5e (and other similar photos). Indeed, the simulated design approach according to the two considered seismic codes is adopted to confirm such visually-based assumptions. As it is stressed out in the revised manuscript, the amount of longitudinal reinforcement observed in the field was greater than the minimum by code. On the other hand, based on the limited visual information available for the transverse reinforcement, no joint stirrups were conservatively considered for both the Pre-2012 and Post-2012 vulnerability classes, regardless of the requirement in both codes.

3. I personally do not agree with the low weight given to soil conditions in the matrix A. Is the case study area located in a relatively firm soil area? A comparison with the Vs30 model based on slope from USGS should be provided and discussed (Allen and Wald 2009)

The authors acknowledge the comment of this reviewer. However, two considerations should be given herein. Firstly, the prioritisation is affected by the building-to-building variability in one criterion (in this case soil type), rather than the absolute values. For this particular building portfolio, the soil type is particularly uniform (shear wave velocity in the first 30 meters of soil in the range 150-250m/s). Such comment has been added in the revised manuscript. Secondly, as it has been emphasised in the revised paper, the weights of the secondary parameters should in theory be portfolio-specific, and therefore calibrated differently for each analysis situation.

4. It is not clear how and if brittle failures are accounted for in the detailed procedure presented in the second part of the work. If not, a simple approach for element classification as ductile or brittle could be attempted comparing the amount of longitudinal and transversal reinforcement ration in typical elements as done in some previous work for the L’Aquila case in Italy (De Luca and Verderame 2013).

This comment is particularly acknowledged. Both in SLAMA and the refined numerical analyses, each beam and column in the system has been characterised considering many possible failure mechanisms (i.e., flexure, bar buckling, lap-splice failure, shear), considering that the weakest will govern its behaviour. For this particular case study, the plastic mechanisms of the archetype buildings are characterised by first shear cracking and/or shear failure in the joints and flexural plastic hinges in beams and columns (Figure 11a,b,c,d). No brittle failure is registered for beams and columns. This point has been stressed out in the revised manuscript.

Specific Comments

5. Page 1 Line 10 – change Resilience with REsilience to be consistent with the acronym; Line 17 – change demonstrated with implemented on Line 30 – add a comma after the closed bracket

These editorial changes have been implemented.

6. Page 2 Line 10 – Some of the references to prioritisation programme of schools in other countries should be already cited here Line 33 – the importance of schools should be discussed including a reference form UNHDR or UN.

Three of the references in Section 2 have been moved to the introduction (page 2, line 10) as suggested by the reviewer. Moreover, a specific reference to the UN campaigns for world disaster risk reduction has been provided.

United Nations Centre for Regional Development, UNCRD,: Reducing vulnerability of school children to earthquakes. UNCDR report, 2009.

7. Page 3 Line 1 – the use of schools as shelters in crisis is highly debated can you add a reference on this topic to acknowledge this aspect? Line 14 – change representative with consistent with building codes and practice of the country.

This comment is acknowledged. According to UN, educational continuity should be prioritised in disaster conditions. Therefore, the reference to schools adopted as a shelter has been removed in the revised manuscript. Regarding the second comment, we have change representative with consistent with building codes and practice of the country.

8. Page 5 Line 33 – it should be mechanism-based and not mechanics-based

This editorial change has been implemented.

9. Page 6 Line 21 – on what basis DS3 is considered equivalent to life-safety, are you basing this on Hazus, EMS98 etc. Further specification on this is necessary

This comment is particularly acknowledged. As discussed in Section 3.1, the definition of the baseline score of the index is based on the DS3 damage state, as defined in HAZUS. This is because DS3 is deemed to be connected to the Life-Safety performance objective in modern seismic codes. To further expand on this, when considering an RC member within a frame (e.g., beam or column), DS3 corresponds to the member ultimate capacity, which can be related to flexural failure (ultimate strain in concrete or steel, buckling of the reinforcement), shear or lap-splice failure. According to modern seismic codes (e.g. NZSEE 2017, ASCE 41-13, EuroCode 8), such a damage condition (for one or a few members) would define the ultimate limit state of the frame, which is “conventionally” related to the safety of people occupying the structure (i.e., Life-Safety). Such more-detailed comments have been implemented in the revised manuscript.

EC8 (2005), ‘European Committee for Standardisation. Eurocode 8: Design of structures for earthquake resistance. Part 3: Strengthening and repair of buildings’.

10. Page 8 Table 2 – This table is too dense, try to reduce/condense the text in this table

An effort to reduce and condense the information in this table has been made.

11. Page 9 Line 13 – P_{max} and P_{min} in the equation are those indicated in Fig 2a or in Fig 2b? I assumed it is Fig 2a, if this is the case, I would remove the grey dots in Figure 2b.

$P_{HAZUS,max}$ and $P_{HAZUS,min}$ in the equation are defined based on the absolute maximum and minimum fragility values in the (selected portion of) HAZUS fragility database (Figure 2b). Therefore, the grey dots in Figure 2a have been removed in the revised manuscript.

12. Page 10 Line 2 – On what basis you assumed 25%? Do you have a reference or any evidence for this assumption? Table 3 – What is the rationale for the weights? Why unfavourable soil is so low? See general comment 3)

The performance modifier is defined in the interval [0%-50%]. Therefore, an average value of 25% is selected as a default, for simplified cases in which only the baseline is used. It is worth mentioning that any uniform value of the performance modifier will not have effects on the overall prioritisation. Such concepts have been further detailed in the revised manuscript.

13. Page 11 Table 4 – is a scoring system from 1 to 9 too granular as it is based on expert judgement?

Such a scoring system is the one defined in the original study/book introducing the AHP (Saaty, 1980). It was successfully adopted in other engineering applications available in the literature (Caterino et al., 2008, Sangiorgio et al., 2019). This is the reason why it has been adopted for this study.

Saaty, T. L.: The analytical hierarchy process: Planning, priority setting, resource allocation. London: McGraw-Hill, 1980.

Caterino, N., Iervolino, I., Manfredi, G., Cosenza, E.: Multi-criteria decision making for seismic retrofitting of RC structures. *Journal of Earthquake Engineering* 12:555-583, 2008.

Sangiorgio, V., Pantoja, J. C., Varum, H., Uva, G., & Fatiguso, F. (2019). Structural degradation assessment of RC buildings: Calibration and comparison of semeiotic-based methodology for decision support system. *Journal of Performance of Constructed Facilities*, 33(2)

14. Table 5 – again why unfavourable soil is so low

Please refer to the answer to comment 3.

15. Page 12 Line 24-27 – Asprone et al. used a similar multi-hazard index in 2013, compare differences with this approach.

In the work by Asprone et al., the authors propose to define a domain representing the capacity-to-demand ratio related to hazard j , as a function of the demand for a given value of the hazard i . This is defined for a quantitative analysis approach, therefore theoretically leading to a high number of analyses, especially if more than two hazards are considered. Contrarily, in the simplified approach proposed in this work it is assumed, rather than calculated, a shape to the multi-hazard domain. This comparison has been discussed in the revised manuscript.

16. Page 13 Line 12-16 – The 50-50 split should be assumed and changes on the basis of how suitable are Hazus typologies with respect to the building stock to the country considered. In a more general context this could be 70-30 or 30-70 if the typologies are more or less representative of the building stock. I understand this is arbitrary, but more discussion should be provided on this.

The suggestion from this reviewer is rationale and valuable. However, the authors believe that such an approach would be against the definition of the INSPIRE index. Indeed, given the assumption of relying on the HAZUS database, an effort has been made to decouple, as much as possible, the aspects of the building(s) that are covered in HAZUS, represented by the baseline score, and the ones that are not covered, represented by the performance modifier.

The selection of the appropriate fragility curves to apply for each building in the considered portfolio is an expert decision provided by the user. As stressed out in the revised manuscript, any other type of fragility curves, if deemed appropriate, can be used to define the index.

17. Page 16 Line 10 – was there any double-check of code-enforcement? Situations like Figure 5e allow this sort of discussion and this should be provided. See general comment 2).

The visually-based information on the structural details have been compared to the results of the simulated design process. The final definition of the archetype building is based on both approaches. Please also refer to the answer to comment 2.

18. Page 17 Line 6 – why you assumed modal values (and not median for example?)

In our opinion, an archetype building, being representative of a given building class, should reflect the more frequent geometric/material characteristics observed over the entire portfolio. Such a condition is achieved when distribution modal values are adopted.

19. Page 18 Line 9 – Are you referred to length of the elements or section dimensions? If this is the overall length of the elements why they increased with time?
The authors refer to the depth of the cross-section. This editorial change has been provided in the revised manuscript.
20. Page 19 Line 1 – again, did they correspond to what was prescribed by code? Table 6 – I am surprised that 2012 code was not prescribing stirrups in joints, is there again a difference between practice and code?
Based on the limited visual information available for the transverse reinforcement, no joint stirrups were conservatively considered for both the Pre-2012 and Post-2012 vulnerability classes, regardless of the requirement in both codes. Please also refer to the answer to comment 2.
21. Page 23 Line 14 – can SLAMA account for brittle failures? If not a preliminary classification of the elements as ductile or brittle could be useful, see general comment 4).
For beams and columns, SLAMA is capable to consider flexural failures, as well as lap-splice failures, rebar buckling and shear failure. Therefore, brittle failures are considered in this study. Please refer to the answer to comment 4.
22. Page 25 Line 26 – can you provide a reference for the drift thresholds?
This comment is particularly appreciated. The adopted inter-storey drift thresholds are defined according to the definitions in Kircher et al., 2006 by post processing the results of the pushover analyses. Such values are consistent with the highlighted displacements in Figure 11 and are building-specific. For this reason, no further reference is needed, since such values are directly calculated in the context of this study.
- Kircher C.A., Whitman R.V. and Holmes W.T.: HAZUS Earthquake Loss Estimation Methods”. Natural Hazard Review, 7:45-59, 2006.
23. Page 27 Line 26-28 – How did you compared the Inspire index results with results of the fragilities? A more detailed discussion should be provided right after Table 8. At the moment the comparison/validation is not very clear.
Comparing the HAZUS-based fragility curves with the refined ones derived in section 4.3 is deemed to be inappropriate. In fact, those two types of curves have a particularly-different purpose. The HAZUS-based fragilities, at least in this context, are used to define relative estimates of the seismic risk (i.e., the prioritisation scheme). Conversely, the structure-specific fragilities obtained with the analyses in Section 4.3 can be used to provide such quantitative estimates of the seismic risk. As conveyed in the revised manuscript, the purpose of Section 4.3 is not to compare/validate the adopted HAZUS fragilities. Conversely, this section shows that using the INSPIRE form allows to define refined numerical models of some selected buildings (in this case, the archetype buildings). These concepts have been added in the revised manuscript.

Abstract. Regional seismic risk assessment is paramount in earthquake-prone areas, for instance to define and implement prioritisation schemes for earthquake risk reduction. As part of the *Indonesia School Programme to Increase REsilience* (INSPIRE), this paper proposes an ad-hoc rapid visual survey form, allowing to 1) calculate the newly-proposed INSPIRE seismic risk prioritisation index, which is an empirical proxy for the relative seismic risk of reinforced concrete (RC) buildings within a given building portfolio; 2) calculate the Ppathoma Tsunami Vulnerability Assessment (PTVA) index, in any of its variations; 3) define one or more archetype buildings representative of the analysed portfolio; 4) derive detailed numerical models of the archetype buildings, provided that simulated design is used to cross-check the model assumptions. The proposed INSPIRE index combines a baseline score, calibrated based on fragility curves, and a performance modifier, calibrated through the Analytic Hierarchy Process (AHP) to minimise subjectivity. An attempt to define a multi-hazard prioritisation scheme is proposed, combining the INSPIRE and PTVA indices. Such a multi-level framework is implemented for 85 RC school buildings in Banda Aceh, Indonesia, the mostly affected city by the 2004 Indian Ocean earthquake-tsunami sequence. As part of the proposed framework, two archetype buildings representative of the entire portfolio are defined based on the collected data. Their seismic performance is analysed by means of non-linear static analyses, using both the analytical Simple Lateral Mechanism Analysis (SLaMA) method and numerical finite element pushover analyses to investigate the expected plastic mechanisms and derive displacement/drift thresholds to define appropriate damage states. Finally, non-linear dynamic analyses are performed to derive fragility curves for the archetype buildings. This paper demonstrates the effectiveness of the INSPIRE data collection form and proposed index in providing a rational method to derive seismic risk prioritisation schemes and in allowing the definition of archetype buildings for more detailed evaluations/analyses.

1. Introduction

Regional seismic risk assessment is paramount in highly earthquake-prone areas. In fact, in several countries around the world, a large portion of the building stock has been designed according to obsolete structural codes, which include little-to-no provisions for earthquake resistance and detailing. Several Reinforced Concrete (RC) buildings fall in this category, and they

often represent the highest share for both residential and commercial occupancy in many countries (e.g., in Italy 48% of the buildings constructed after 1971 is made of RC; [ISTAT 2011](#)). RC structural systems are also widely used in the design of critical infrastructure, such as hospitals and school facilities. Those are the focus of this paper. Clearly, it is desirable that any risk-mitigation strategy designed by governmental agencies should be based on a rational understanding of the risk of large building groups – or portfolios – at a country level (or in a smaller region). However, it is cost-ineffective to perform detailed structural simulations for a large amount of structures, given the shortage of both financial and technical/computational resources. Therefore, a multi-level approach is usually preferred, starting with a screening based on simplified and rapid methods and performing more detailed structural analyses only for selected groups of structures at higher relative risk and for which an archetype (or index) building can be identified (e.g., [FEMA P-154, 2015](#), [Benedetti and Petrini, 1984](#), [Grant et al., 2007](#)).

Common approaches for regional seismic risk assessment of RC buildings (see *Section 2* for more details) refer to typological approaches based on pre-determined building categories (e.g., [Giovinazzi and Lagomarsino, 2004](#)), or the use of Rapid Visual Survey (RVS) forms and calibrated empirical seismic vulnerability/risk indices (e.g., [Uva et al., 2013](#)). Although these approaches rely on various assumptions and usually involve some degree of subjectivity, such simplified methods provide valuable proxies to develop prioritisation schemes (i.e., performing a ranking of the buildings in a given portfolio based on vulnerability or risk-related metrics). As discussed, such simplified methods include some degree of subjectivity by the analyst, mainly reflected in the choice and the assigned relative importance of the parameters involved in the analysis. Moreover, given the low amount of information required, such methods do not allow to further refine the analysis, providing a more detailed, second-level seismic risk assessment. Finally, those methods mostly refer to seismic hazard, which in some countries might not be enough for the development of a rational multi-hazard prioritisation scheme.

Numerous evidences of previous natural hazard events have highlighted the vulnerability of school infrastructure to natural hazards and particularly to earthquake-induced ground shaking. From the structural and architectural points of view, school buildings are especially vulnerable given structural characteristics that typically include large rooms, large windows (particularly in tropical climates), and corridors, all of which may represent seismic vulnerability factors. At the same time, schools play a critical role in the education of a community's next generation, with school children being one of the most vulnerable components of the society due to their age and their developmental stage. A safer and resilient school can save valuable lives of children and help to bring normality back to society in times of disaster. These considerations set school buildings apart from their peers in terms of priority for assessment and resource allocation for structural retrofitting. In fact, some of the world disaster reduction campaigns by the United Nations International Strategy for Disaster Reduction (UNISDR) were carried out together with various partner organizations under the theme of "Disaster Risk Reduction Begins at School" (UN, 2009). Recently, the Comprehensive School Safety Framework (CSSF; [GADRRRES, 2017](#)) has proposed an integrated approach to reduce disaster risk and promote resilience in the education sector. The CSSF is funded on three pillars: "Safe Learning Facilities" (including "implementing assessment and prioritisation plans for retrofitting or replacing unsafe schools, including relocation"), "School Disaster Management", and "Risk Reduction and Resilience Education".

Based on the above discussion, a new RVS form and a seismic risk prioritisation index for RC buildings are proposed in this study to address the above-mentioned gaps. Both the RVS form and the seismic index are the first outcomes of the INSPIRE project (*Indonesia School Programme to Increase REsilience*). INSPIRE looks to develop an advanced, harmonised and science-based risk assessment framework for school infrastructure in Indonesia subjected to cascading earthquake-tsunami hazards. It also assesses the effectiveness of different soft (e.g., risk reduction education) and hard (e.g., retrofitting) mitigation measures in reducing casualties, economic loss and disruption to school infrastructure, thus increasing community resilience. The INSPIRE RVS form (Figure 1) is designed to be completed by trained engineers in approximately 20-30 minutes - depending on the size of the building - by means of a sidewalk survey. This is a one-page form including various sections related to the general identification and geolocation of the building, its geometric properties (including space for sketching the building's shape and footprint), and its structural characteristics and deficiencies, including the structural typology and the dimensions/details of the main structural members. It is also possible to assign a "confidence level" for each parameter, allowing for a better classification and weighting of the data after a campaign of RVSs. The back of the form is used to provide definition of both the parameters and the confidence levels and provides blank space that be used to register extra information. The collected data is fully compatible with both the Global Earthquake Model (GEM) Building Taxonomy (Brzev et al., 2013) and the Hazard United States (HAZUS) model (Kircher et al., 2006). The collected information allows to 1) calculate the proposed INSPIRE seismic risk prioritisation index, introduced in *Section 3*; 2) calculate the Ppathoma Tsunami Vulnerability Assessment index (PTVA4, Dall'Osso et al., 2016, in any of its variations, described in *Section 4.2*); 3) define one or more representative archetype buildings consistent with the local building codes and practice; 4) derive detailed numerical models of the archetype buildings, provided that simulated design is used to cross-check the model assumptions. The unique features of the INSPIRE form are related to: 1) the possibility of considering both seismic and tsunami while requiring a reasonable amount of time to complete the survey; 2) the consideration of "confidence levels" for the parameters, which is particularly useful in deriving statistics; 3) the possibility to be expanded to include other hazards with simple modifications/customisations.

In particular, the INSPIRE seismic risk prioritisation index (*Section 3*) aims at providing a simple method to derive a prioritisation scheme, minimising the subjectivity involved in the calculation. In fact, mechanics-based fragility functions are used to define a baseline score. A performance modifier is defined based on parameters that can jeopardise the seismic performance of a building (e.g., presence of short column, pounding potential). The weight assigned to each parameter is defined through the Analytical Hierarchy Process (AHP; Saaty, 1980), providing a mathematically-consistent and rational solution to the weighting process.

In this study, the INSPIRE RVS form and proposed multi-hazard risk prioritisation index are applied to a portfolio of 85 RC school buildings in Banda Aceh, Indonesia, highlighting the simplicity and rapidity of the whole process. Moreover, consistently with the proposed multi-level framework, a detailed analytical and numerical seismic fragility assessment is provided for the identified archetype school building, demonstrating the effectiveness of the INSPIRE RVS form in providing inputs and allowing more detailed analyses.

Provide extra information (optional)

Instructions for specific cells

- Construction Year: if unknown, provide a rough estimation and set the confidence level to Low (L)
- Building orientation (*): Orientation of the (longitudinal side of the) building with respect to the coast
- Seawall: Presence of water barriers located on the coastal point closest to the building
- Natural barriers: Presence of natural barriers to water between the coast and the building
- External brick wall: Presence of individual walls around the building (e.g. garden walls)
- Windows: Other type of openings may be considered as windows, providing average dimension.
- V₃₀ (m/s): Use the provided V₃₀ map to estimate its range, setting the confidence to High (H)
- Beam/column section: Specify average dimensions or provide more detail. High confidence should be used if all the provided dimensions rely on measurements. Medium confidence should be set if few measurements are given and the rest is visually estimated. Low confidence should be set if all dimensions are visually estimated
- Reinforcement bars: Provide this information only if, for some reason, one or more bars are visible

Vulnerability factors

- Short column: At least 20% of the columns in the same Lateral Resisting System (LRS) have a height/depth ratios less than 50% of the average height/depth ratio at that level
- Pounding: The building closer than 0.2m from an adjacent building
- Soft storey: Infills are missing at one level
- Strong Beam-Weak Column: The beams are evidently stronger than the columns to which they are connected
- Built on Slope: There is a sensible grade change from one side of the building to the other
 - The LRSs do not appear relatively well distributed in plan in either or both directions
 - Two or more LRSs are not orthogonal to each other
 - Re-entrant corners exceed 25% of the plan dimension
 - There is an opening in the diaphragm with a width over 50% of the total diaphragm width at that level
- Elevation irregularity:
 - The storey height is not sufficiently uniform
 - Vertical elements of the LRS at upper storeys are inboard of those at lower storeys
- Mass irregularity: The storey area of a given storey is substantially different from the adjacent storeys

Figure 1 INSPIRE Rapid Visual Survey form completed for building with ID 14A (Section 4.1).

2. Seismic risk prioritisation schemes: a review

Various methodologies to derive prioritisation schemes for buildings based on their relative seismic vulnerability/risk are available in the scientific literature and or international standards/guidelines. Each of these is characterised by a different underlying approach, basic assumptions and/or applicability conditions. Most of these are based on the calculation of a seismic vulnerability index for a portfolio of buildings. The results can be used to rank those building, defining a priority list of structures requiring further investigation. A comprehensive overview of this previous research is not within the scope of this paper; however, a briefing of some relevant past initiatives is presented here.

The procedure proposed in the guidelines by the Applied Technology Council (ATC 3-06, 1978) uses a strength-based approach to define an earthquake capacity ratio, comparing the ‘actual’ strength of the building to the code requirement for new ones. Adjustments are also adopted to consider in-situ material properties and insufficient detailing (compared to modern

design). Such capacity-to-demand ratio is defined as the earthquake capacity ratio, and it is calculated as the minimum of the component-by-component strength ratios.

The Alaska's Department of Education (1997), among others, has produced surveying forms to assess the structural conditions of buildings and the associated seismic vulnerability, with focus on school buildings. Such forms mainly consist of checklists
5 investigating areas of potential concerns for seismic vulnerability. On the other hand, the procedure introduced by the Federal Emergency Management Agency (FEMA P-154, 2015) is based on a Rapid Visual Screening of buildings and a two-level approach for a fast assignment of a seismic vulnerability index (which requires no mechanical calculation from the user). The companion FEMA P-155, 2015 describes the rationale behind the scoring system, which is directly connected to the probability
10 of collapse of archetype building categories. Such method is based on the HAZUS framework (and typological force-displacement curves) to define the building categories and to derive a seismic-only assessment.

The New Zealand Society for Earthquake Engineering (NZSEE) defines an Initial Evaluation Procedure (IEP) in the NZSEE guidelines of 2017, providing a broad indication of the "seismic rating" of a building based on a sidewalk survey. The score is expressed in terms of the percentage of New Building Standard (%NBS), which is the ratio of the displacement capacity of the building for the Life Safety limit state, over the minimum capacity required for a new building for the same limit state. Firstly,
15 a baseline %NBS is calculated using specifically-tabulated coefficients relating to year of design, strengthening interventions, importance of the structure, assumed ductility capacity, site hazard, presence of near-fault effects, soil type, etc. It is assumed that the capacity of the building cannot be lower than the minimum specified by the code valid for the year of design. This is only true if building codes are legally enforced. If this is not the case, the seismic vulnerability assessment may be characterised by a higher level of epistemic uncertainty. The baseline value is reduced if structural weaknesses are present (e.g., pounding
20 potential, soil characteristics, presence of vertical and plan irregularity, presence of short columns).

The Italian National Group for Earthquake Defence (*Gruppo Nazionale per la Difesa dai Terremoti*, GNDT) has also provided a seismic vulnerability index (Benedetti and Petrini, 1984, Angeletti et al., 1988) based on simple assessment forms including, among other parameters, the structural material, the typology of the Lateral-Load Resisting System (LLRS), the quality of the building materials and the overall construction, and the existing damage level (if any). The vulnerability index is based on a
25 weighted sum of such parameters and is defined in the range [0, 100] for masonry and [-25, 100] for reinforced concrete, mostly based on expert opinion. A higher value of the index indicates a higher seismic vulnerability. Interestingly, the vulnerability index by GNDT has been correlated with structural damage in past earthquakes (Grimaz et al., 1996, Zonno et al., 1999), allowing to indirectly calculate the PGA which is likely to induce collapse.

Other rapid surveying forms and rapid procedures have been proposed by different authorities and organisations, such as the
30 World Health Organisation (WHO) and the United Nations (UN), with special focus on developing countries. For instance, Dhungel et al., 2012 collected and assessed the physical condition of 1,381 school building units in Nepal. The data was collected by mobilising the school teachers; school vulnerability, calculated on the basis on the empirical weightage on different factors (e.g. structural material, number of storeys, shape of the roof), was used to estimate the possible damage/casualties/injuries for earthquakes of different seismic intensities.

Finally, a broader perspective is provided in the work by Grant et al., 2007 which proposes a four-level prioritisation framework focused on school buildings, filtering the buildings with increased level of detail, allowing the policy-makers to choose the filtering thresholds based on the available resources. The idea is to firstly check the code-based demand deficit of the buildings, comparing the new structural code demand to the code appropriate for the year of construction, in terms of PGA. For the buildings with a deficit above a given threshold, the GNDT index is calculated. The buildings with the highest rating are assessed with a simplified mechanics-based procedure, and finally the most critical ones are assessed with structural models providing full details.

3. Definition of the INSPIRE seismic risk index

The INSPIRE index (I_V) is an empirical proxy for the relative seismic risk of various buildings within a given building portfolio. The index is specifically defined for RC buildings, although its definition can be extended to other building types, and it consists of two parts: the baseline score (I_{BL}) and a performance modifier (ΔI_{PM}), which are summed up to obtain the final index (Eq. 1). In its current version, the baseline score is based on the fragility curves available in the HAZUS MH4 framework (Kircher et al., 2006), which allows to have a transparent and consistent fragility estimation for a wide range of structural typologies. HAZUS fragilities are defined by three “primary” parameters: RC Basic Structural System (BSS: Frame, Infilled frame or Wall), building height (Low-rise, Mid-rise or High-rise) and seismic design criteria (Pre-, Low-, Moderate- or High-code). On the other hand, the performance modifier is based on the score of the building regarding eight “secondary” parameters (preservation condition, plan shape, storey height uniformity, added storeys, infills at ground storey, short columns, pounding, unfavourable soil), which, if present, are deemed to jeopardise the performance of the building. It is worth mentioning that the selection of the appropriate fragility curves (HAZUS category) for each building in the portfolio is an expert decision provided by the analyst. However, as further discussed below, any other type of fragility curves, if deemed appropriate, can be used to re-define the INSPIRE index according to the proposed methodology.

$$I_V = I_{BL} + \Delta I_{PM}$$

1

3.1. Baseline score

The HAZUS MH4 framework provide, among other information, an extensive set of fragility curves representing the seismic performance of archetype buildings which are classified based on four parameters: material (*Mat*), BSS, building *Height* and seismic *Code* level (defined according to the Uniform Building Code 1997, UBC 1997). Adopting the HAZUS fragility database as a reference is further motivated by the fact that several countries around the world have adopted seismic provisions which are, to different extents, consistent with the recommendations of the UBC 1997. For each archetype building category, four fragility functions are provided in HAZUS, respectively for the Slight, Moderate, Extensive and Complete Damage States (DS), or limit states. The fragility functions are defined as lognormal Cumulative Distribution Functions, or CDF (Eq. 2), in

terms of different Intensity Measures, among which the Peak Ground Acceleration (PGA). The curves are defined by a median PGA (μ) and a dispersion term (β).

$$P(DS \geq DS_i | Mat, BSS, Code, Height, PGA) = \Phi\left(\frac{\ln(PGA/\mu)}{\beta}\right), i = 1: 4 \quad 2$$

For the scope of this paper, the HAZUS fragility database has been filtered to consider only the curves related to RC buildings (namely, categories C1, C2, C3). Moreover, only the fragility curves corresponding to the Extensive Damage limit state (DS3) have been considered, which are mainly related to the Life Safety performance objective according to modern seismic codes (e.g., [ASCE 7-10](#), [Eurocode 8](#), [NZSEE 2017](#)). The selected fragility curves are reported in Table 1. Details of the involved parameters is provided in Table 2.

Table 1 Selected fragility curves from HAZUS MH4 framework (Kircher et al., 2006).

Table 2 Description of the HAZUS MH4 categories involved in the INSPIRE index (modified after Kircher et al., 2006).

	Description
C1 Concrete Moment Frame	These buildings have a frame of reinforced concrete columns and beams. Some older concrete frames may be proportioned and detailed such that brittle failure of the frame members can occur in earthquakes leading to partial or full collapse of the buildings. Modern frames in zones of high seismicity are proportioned and detailed for ductile behaviour and are likely to undergo large deformations during an earthquake without brittle failure of frame members and collapse.
C2 Concrete Shear Wall	The vertical components of the lateral-force-resisting system in these buildings are concrete shear walls that are usually bearing walls. In older buildings, the walls often are quite extensive and the wall stresses are low but reinforcing is light. In newer buildings, the shear walls often are limited in extent, generating concerns about boundary members and overturning forces.
C3 Concrete Infilled Frame	These buildings are made of reinforced concrete columns and beams and unreinforced masonry infill walls. In these buildings, the shear strength of the columns, after cracking of the infill, may limit the semi-ductile behaviour of the system.
Building height for C1, C2, C3	Low Rise 1:3 storeys Mid Rise 4:7 storeys High Rise 8+ storeys
Damage State 3 (DS3): Extensive Damage [C1]	Some of the frame elements have reached their ultimate capacity indicated in ductile frames by large flexural cracks, spalled concrete and buckled main reinforcement; nonductile frame elements may have suffered shear failures or bond failures at reinforcement splices, or broken ties or buckled main reinforcement in columns which may result in partial collapse.
Damage State 3 (DS3): Extensive Damage [C2]	Most concrete shear walls have exceeded their yield capacities; some walls have exceeded their ultimate capacities indicated by large, through-the-wall diagonal cracks, extensive spalling around the cracks and visibly buckled wall reinforcement or rotation of narrow walls with inadequate foundations. Partial collapse may occur due to failure of nonductile columns not designed to resist lateral loads.
Damage State 3 (DS3): Extensive Damage [C3]	Most infill walls exhibit large cracks; some bricks may dislodge and fall; some infill walls may bulge out-of-plane; few walls may fall partially or fully; few concrete columns or beams may fail in shear resulting in partial collapse. Structure may exhibit permanent lateral deformation.
Pre Code	Gravity-dominated structures. No seismic design/detailing is available. Such structures are likely built prior to the introduction of seismic codes.
Low Code	According to the provisions in UBC1994 (seismic zone 1), such buildings can sustain a base shear at most equal to 7.5% of the total weight (assuming an elastic design, no importance factor and stiff soil). The real lateral capacity is likely to be lower than this maximum value.
Moderate Code	According to the provisions in UBC1994 (seismic zone 2b), such buildings can sustain a base shear at most equal to 20% of the total weight (assuming an elastic design, no importance factor and stiff soil). The real lateral capacity is likely to be lower than this maximum value.
High Code	According to the provisions in UBC1994 (seismic zone 4), such buildings can sustain a base shear at most equal to 40% of the total weight (assuming an elastic design, no importance factor and stiff soil). The real lateral capacity is likely to be lower than this maximum value.

To define the baseline score of the INSPIRE index, for each considered archetype building category, and its corresponding fragility curve, the probability to exceed DS3 (Extensive Damage) is calculated (Figure 2a) for three levels of PGA, 0.1g, 0.25g, 0.4g, respectively corresponding to low, moderate and high seismicity levels. The analyst will select the seismicity level appropriate for the considered building portfolio/geographic area. It is worth noting that, in modern seismic codes, DS3 is related to the Life Safety performance objective. The process above is repeated for each archetype building category in the

HAZUS database, such that it is possible to map the building basic parameters to the exceeding probability of the DS₃ conditional to the considered PGA value ($P_{HAZUS} = P(DS \geq DS_3 | Mat, BSS, Code, Height, PGA)$). The baseline score of the risk index is set to be proportional to such exceeding probability, after a re-scaling in a range [1%, 50%] based on the minimum/maximum DS3 exceeding probability in the complete (non-filtered) HAZUS database and calculated according to Eq. 3. In such equation, $P_{HAZUS,max}$ and $P_{HAZUS,min}$ are the maximum and minimum DS3 exceeding probability in the HAZUS database for the chosen levels of PGA (indicated with dots in Figure 2b), while P_{HAZUS} is the DS3 exceeding probability of the considered building, for the chosen level of PGA.

10 **Figure 2 a) Example baseline score for a given archetype building typology. b) HAZUS fragility curve database related to the Extensive Damage limit state for RC buildings.**

$$I_{BL} = \left(\frac{50 - 1}{P_{HAZUS,max} - P_{HAZUS,min}} \right) (P_{HAZUS} - P_{HAZUS,min}) + 1 \quad 3$$

3.2. Performance modifier

Eight secondary parameters are used to define the performance modifier, which are deemed not explicitly considered in the HAZUS framework (and therefore in the baseline score) but at the same time, if present, can jeopardise the seismic performance of a given building. Firstly, based on Table 3, a score is assigned for each secondary parameter ($SCORE_i$ in the range [0%, 100%]). Therefore, the performance modifier (ΔI_{PM}) is defined as a weighted sum of each of these scores (Eq. 4, where w_i is the weight of parameter i), finally scaling the result in the range [0%, 50%]. It is worth mentioning that, according to this definition, the performance modifier can only increase the baseline score, therefore denoting an increase in seismic fragility. For a more simplified utilisation, it is also possible to calculate the INSPIRE index considering the baseline score only. In such case, a default performance modifier equal to 25% is assigned (average of 0% and 50%). It is worth mentioning,

however, that any uniform value of the performance modifier will not have effects on the overall prioritisation, since it will shift all the calculated indices by the same amount.

$$\Delta I_{PM} = \frac{1}{2} \sum_{i=1}^8 w_i SCORE_i \quad 4$$

Table 3 Secondary parameters: definition, available alternatives, related scores and weights.

Secondary parameter	Scores	Alternatives	Weight
Preservation condition and/or existing damage	100	Significantly affecting performance	0.0939
	50	Moderately affecting performance	
	0	Not affecting performance	
Plan shape	100	L-shape or irregular	0.0826
	50	C-shape	
	0	Rectangular or regular	
Storey height uniformity	100	Significantly non-uniform (more than 0.5m difference)	0.0470
	50	Moderately non-uniform (difference between 0 and 0.5m)	
	0	Uniform	
Added Storeys	100	Yes	0.0470
	0	No	
Infills at ground storey	100	No	0.3039
	0	Yes	
Short column	100	Yes	0.1817
	0	No	
Pounding	100	Pronounced (less than 0.1m gap)	0.1817
	50	Moderate (gap between 0.1m and 0.2m)	
	0	None (more than 0.2m gap)	
Unfavourable soil	100	Yes (very soft soil. Liquefaction is not explicitly considered)	0.0621
	0		
		No	

5 The secondary parameters defining the performance modifiers are deemed to complement the information in the HAZUS fragility curves. The idea is that the baseline score (HAZUS fragility database) provides the (conditional) seismic risk of a given building class, while the secondary parameters are related to building-specific vulnerability factors. The secondary parameters have been selected based on the fundamental rules of seismic design (e.g., Paulay and Priestley, 1992) and the commonly observed post-earthquake damage on RC structures (e.g., Elnashai and Di Sarno, 2008, Palermo et al., 2017, De Luca et al., 2018). For each of them, Table 3 provides guidance on the selection of the alternatives. The score for each alternative has been defined based on a uniform partitioning of the range [0%, 100%].

Clearly, the secondary parameters defining the performance modifier do not have the same influence on the overall vulnerability and risk. For example, the absence of infill walls at the ground storey can lead to a soft-storey mechanism, which in turn can result in local or global collapse. On the other hand, the addition of storeys to a building can increase its risk to a lower extent, considerably less likely leading to collapse. Therefore, the weight of the former parameter should be higher than
15 the latter, to reflect such a different effect on the overall seismic risk.

To this extent, the Analytic Hierarchy Process (AHP), originally proposed by Saaty (1980) is used to calibrate the weights in the proposed procedure. This allows to have a rational and mathematically-consistent assignment of the weights which is based on pairwise comparisons between the secondary parameters and eigenvalues theory. Hence, the selected weights can reflect the relative importance of each parameter with respect to the others in the determination of the performance modifier. It is worth mentioning that such approach has been successfully adopted in other earthquake engineering applications, such as the selection of the optimal seismic retrofitting strategy for case-study buildings (Caterino et al., 2008). Also, it is worth mentioning that, in its current version, the expert judgement defining the weights adopted in the procedure is provided by the authors. However, such weights can be further updated considering the opinion of a group of experts in the field of structural and earthquake engineering.

After the definition of the parameters involved in the analysis, the first step of the process consists of expressing an expert opinion about every possible pairwise comparison of those parameters. Given two parameters P_i and P_j , the relative importance of P_i over P_j is expressed with the coefficients a_{ij} , defined according to Table 4. For the calibration proposed in this paper, the pairwise comparisons are performed considering the relative influence of the secondary parameters on the Life Safety performance objective. The related judgement matrix $[A]$ containing the 27 pairwise comparisons is given in Table 5. As an example, the presence of infill walls at the ground storey has been considered extremely more important than the presence of unfavourable soil, given its implications on Life Safety. Therefore, the related a_{ij} parameter is set to 9.

Table 4 Scale of relative importance of the secondary parameters (Saaty, 1980).

Relative importance (a_{ij})	Description
1	Parameters P_i and P_j are equally important
3	Parameter P_i is moderately more important than P_j
5	Parameter P_i is essentially more important than P_j
7	Parameter P_i is demonstratedly more important than P_j
9	Parameter P_i is extremely more important than P_j
2, 4, 6, 8	Intermediate values between the two adjacent judgements
Reciprocal of the above	If criterion i compared to j gives one of the above, then j, when compared to i, gives its reciprocal

Once the pairwise comparisons have been performed, the vector $\{w\}$ containing the weights of the secondary parameters is found by solving the eigenvalue problem $Aw = \lambda_{max}w$, where λ_{max} is the largest eigenvalue. The principal right eigenvector of the $[A]$ matrix is the vector of the weights $\{w\}$, after normalisation with respect to its sum. Using such approach allows to measure the consistency of the pairwise comparisons, therefore minimising the chance to have a random prioritisation of the parameters. In fact, if the pairwise comparisons are performed in a perfectly consistent manner, the $[A]$ matrix has only one eigenvalue equal to its rank, and the coefficients a_{ij} are equal to the ratio w_i/w_j of the weights related to the parameters P_i and P_j . Practically, the comparisons are unlikely to be perfectly consistent, and the first eigenvalue of the $[A]$ matrix will be slightly different than its rank, while the other eigenvalues are close to zero.

Table 5 Judgement matrix adopted for the calibration of the weights.

	Preservation condition	Plan shape	Storey height uniformity	Added Storeys	Infills at ground storey	Short column	Pounding	Unfavourable soil
Preservation condition	1	1	2	2	1/3	1/2	1/2	2
Plan shape	1	1	2	2	1/3	1/2	1/2	1/2
Storey height uniformity	1/2	1/2	1	1	1/6	1/4	1/4	1
Added Storeys	1/2	1/2	1	1	1/6	1/4	1/4	1
Infills at ground storey	3	3	6	6	1	2	2	6
Short column	2	2	4	4	1/2	1	1	4
Pounding	2	2	4	4	1/2	1	1	4
Unfavourable soil	1/2	2	1	1	1/6	1/4	1/4	1

Therefore, the consistency of the pairwise comparison is measured by calculating the Consistency Index (CI) using Eq. 5, where n is the rank of the matrix. The CI is compared to the Random Consistency Index (RCI), which is the average Consistency Index of a large number of randomly-generated reciprocal matrices using the scale (1/9, ..., 1, ..., 9). According to Saaty, 1980, for 8x8 matrices the Random Consistency Index is equal to 1.41. According to the same study, if the CI is smaller than 10% of the RCI (Eq. 6), the final choice of the weights is logically sound and not a result of random prioritisation. In general, if such criterion is not satisfied for the performed pairwise comparisons, the whole process should be repeated until acceptable consistency is achieved. For the pairwise comparisons in this paper, the consistency index is equal to 2.1%, which is considered acceptable.

$$CI = \frac{\lambda_{max} - n}{n - 1} \quad 5$$

$$\frac{CI}{RCI} \leq 0.1 \quad 6$$

3.3. Multi-hazard considerations

In many common situations, it is very likely that seismic considerations alone are not enough to define a robust prioritisation scheme for the decision-making process by a governmental agency or the owner of a large building portfolio. To deal with such scenario, this paper presents a simple methodology to include other hazards in the prioritisation scheme.

Simplified analytical indices are available for the estimation of the vulnerability of buildings to natural hazards different than seismic hazard, such as Tsunami (e.g., [Dall'Osso et al., 2016](#)), Flood (e.g., Stephenson and D'Ayala, 2014, Pazzi et al., 2016, Nassipour et al., 2018), Wind (e.g., Womble et al., 2016), etc. Once the desired single-hazard vulnerability indices (I_k) are

computed, a combined, multi-hazard index can be defined as the multi-dimensional distance from the origin of the system of reference (Eq. 7). Although this concept is applicable regardless of the number of considered hazards, a two-dimensional example is presented in Figure 3. Supposing that both “hazard 1 and 2” are defined over a range [1%, 100%], the combined index will be defined on the range [1%, 141.4%]. However, this can be re-scaled in any other desired range without affecting the prioritisation list of the considered building portfolio. It is worth mentioning that cumulative damage related to subsequent hazards are outside the scope of such a simplified multi-hazard index.

$$I_{multi} = \sqrt{\sum_k I_k^2}$$

7

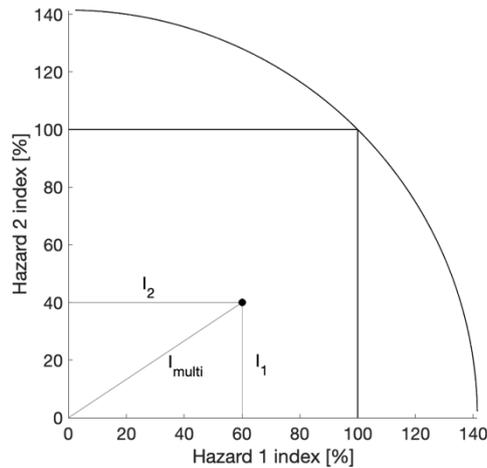

Figure 3 Definition of a two-dimensional ($k = 2$) multi-hazard index.

3.4. Dealing with subjectivity

- 10 According to the definition of the seismic risk prioritisation index given in *Section 3*, it appears evident that a degree of subjectivity is always involved in the calculation. In particular:
- 1) The baseline score is based on the fragility functions available in the HAZUS MH4 guidelines. Although such model is largely based on numerical analyses of building models, the results are provided for a limited number of structural categories. The user should carefully select the category that best matches with the characteristics of the considered buildings, with special reference to the “Code level” parameter;
 - 15 2) The weights needed for the calculation of the performance modifier are based on a subjective set of pairwise comparisons between the secondary parameters, although this is derived in a mathematically-consistent and rational way that allows to minimise the chance of having randomly-assigned weights;

3) The ratio between the maximum possible baseline score and the maximum possible performance modifier is “arbitrarily” set to unity, i.e. $I_{BL,max} = 50\%$ and $\Delta I_{PM,max} = 50\%$.

It is worth noting that the subjectivity is an intrinsic component of any simplified vulnerability index, including the INSPIRE index. Therefore, rather than assessing a single building, these methods should only be used to derive a proxy for the relative vulnerability (or risk) of buildings in a given portfolio, and to define a prioritisation scheme for possible risk mitigation actions. However, in this section some measures are proposed to control and minimise the subjectivity involved with the definition of the index. An example of such measures is given in *Section 4*, in relation to a real building portfolio application.

It is virtually impossible to perfectly match the considered buildings with the archetype buildings in HAZUS. However, a careful examination of the characteristics of the considered buildings should be carried out, to better select the appropriate HAZUS categories. Characteristics such as the presence of strong beams vs weak columns should be considered, which can lead to a Pre-Code classification, or documented structural retrofit measures, which can lead to higher “Code level” classification. A review of the (history of the) structural/seismic codes appropriate for the considered buildings can considerably reduce the level of subjectivity. These can be compared to the different provisions in UBC1994, defining “equivalence relationships”. Any information related to the year of construction (or design) of the considered buildings is fundamental in such process. Overall, it is deemed that the assignment of the HAZUS categories to the considered buildings should reflect their expected differences in their seismic performance, rather than perfectly match the properties of the archetype in the HAZUS category definition.

As an alternative to the HAZUS definition, the baseline score can be re-defined adopting, if available, a portfolio-specific set of fragility curves. To this aim, the OpenQuake platform (open-source, <https://storage.globalquakemodel.org/openquake>), by the Global Earthquake Model (GEM) foundation, might be used. Among other capabilities, such platform contains large databases of empirical and numerical fragility/vulnerability models appropriate for many structural typologies and many regions of the world.

An illustrative set of weights needed to calculate the performance modifier is given in this paper. However, a case-specific AHP, for instance involving groups of local experts, can be performed to derive new weights that match the characteristics of the considered building portfolio. Such a procedure cannot remove the subjectivity related to the performance modifier but provides the user with a tool to reduce it and have a close match between the analysed building portfolio and the adopted weights.

Finally, the subjectivity related to the ratio between the maximum possible baseline score and performance modifier can be tested through a sensitivity analysis. For a given building portfolio, the idea is to repeat the calculation of the seismic index with different values of the maximum possible performance modifier. This allows to check the reliability of the priority list to this assumption. If slight modifications in the maximum possible performance modifier lead to high differences in the resulting priority list, engineering judgement should be adopted to justify the final choice.

4. Illustrative application: school building portfolio in Banda Aceh, Indonesia

4.1. Description of the case-study portfolio and definition of an archetype building

The case study portfolio selected for this study consists of 85 RC buildings belonging to 44 school compounds located in Banda Aceh, the capital and largest city in the province of Aceh, Indonesia (Figure 4). Banda Aceh is located in the island of Sumatra and, according to the 2000 census, has a population of 219,070 people (Seta, 2000). The city was severely affected by the 26 December 2004 Indian Ocean earthquake (Moment magnitude, $M_w=9.1$), being the closest major city to the event location. Due to the effects of the following devastating tsunami, the city suffered from 167,000 deaths and catastrophic damage to structures and infrastructures. It is worth noting that Indonesia suffered a 4.5bln\$ economic loss for this event (Pomonis et al., 2006). In the Aceh region, 45,000 students and 1,870 teachers died and 2,065 education facilities were damaged, 100,000 (BAPPENAS, 2006).

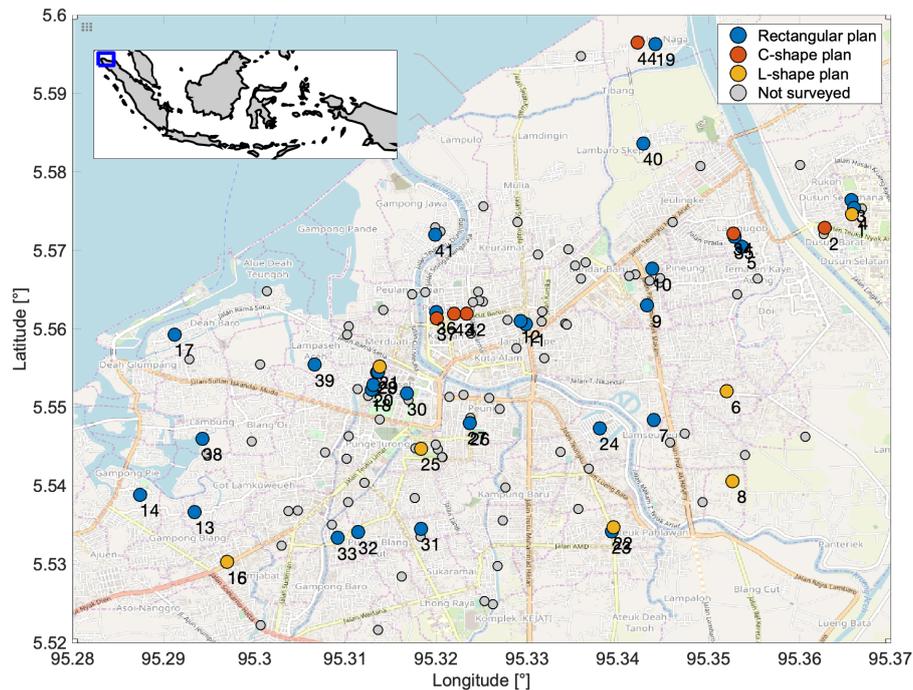

Figure 4 Map of the school buildings in Banda Aceh, including non-surveyed ones.

A RVS campaign through the INSPIRE form (Figure 1) was carried out to collect administrative, geometric and mechanical data related to the investigated buildings. The RVS campaign (Figure 5) was conducted by three teams composed of one experienced engineer and two final-year (one undergraduate and one postgraduate) local engineering students working for four days. The surveys were conducted in all the suburbs of Banda Aceh (Figure 6a), to obtain a clear overview of the construction practice in the city. For all the surveyed buildings, the BSS is a reinforced concrete frame with infills. The majority (81%) of the buildings in the portfolio has a rectangular plan, with the remaining 19% composed of L-, C- or T-shaped plans (Figure 6b). 68% of the surveyed buildings is two-storey high, while one- and three-storey buildings represent 15% and 16% of the

portfolio, respectively (Figure 6c). The year of construction for each building was retrieved from the school signboard, registry or by interview of the school principal. Figure 6d shows that few buildings (18%) survived the 2004 earthquake-tsunami sequence; hence, the majority of the portfolio (57%) was constructed between 2005 to 2011, while the remaining 25% was built from 2013 onwards.

5

Figure 5 Sample photos of the building portfolio (taken on 16-19 October 2018).

The accurate knowledge of the year of construction is essential for the structural characterisation of the portfolio. In fact, such information can be coupled with the history/evolution of the available structural and/or seismic codes to derive minimum-by-law dimensions of the structural members, reinforcement detailing, level of considered vertical and lateral forces in the design, etc. In this specific case, the appropriate structural code for the whole portfolio is the SKBI 1.3.53.1987 (SNI, 1987). The first seismic code appropriate for the region is the SNI 1726:2002 (SNI, 2002), which is inspired to the American Uniform Building Code 1997 (UBC 1997), which also facilitates the compatibility with the HAZUS framework. Stricter seismic provisions were adopted when the seismic code was updated in the SNI 1726:2012 (SNI, 2012), which fully consistent with the American ASCE 7-10 (ASCE, 2010). Therefore, apart from a minority (12) of buildings constructed before 2002, approximately half of the buildings are constructed according to the SNI 1726:2002 (lower) standards while the other half refers to the updated SNI 1726:2012, with nominally better nominal seismic performance.

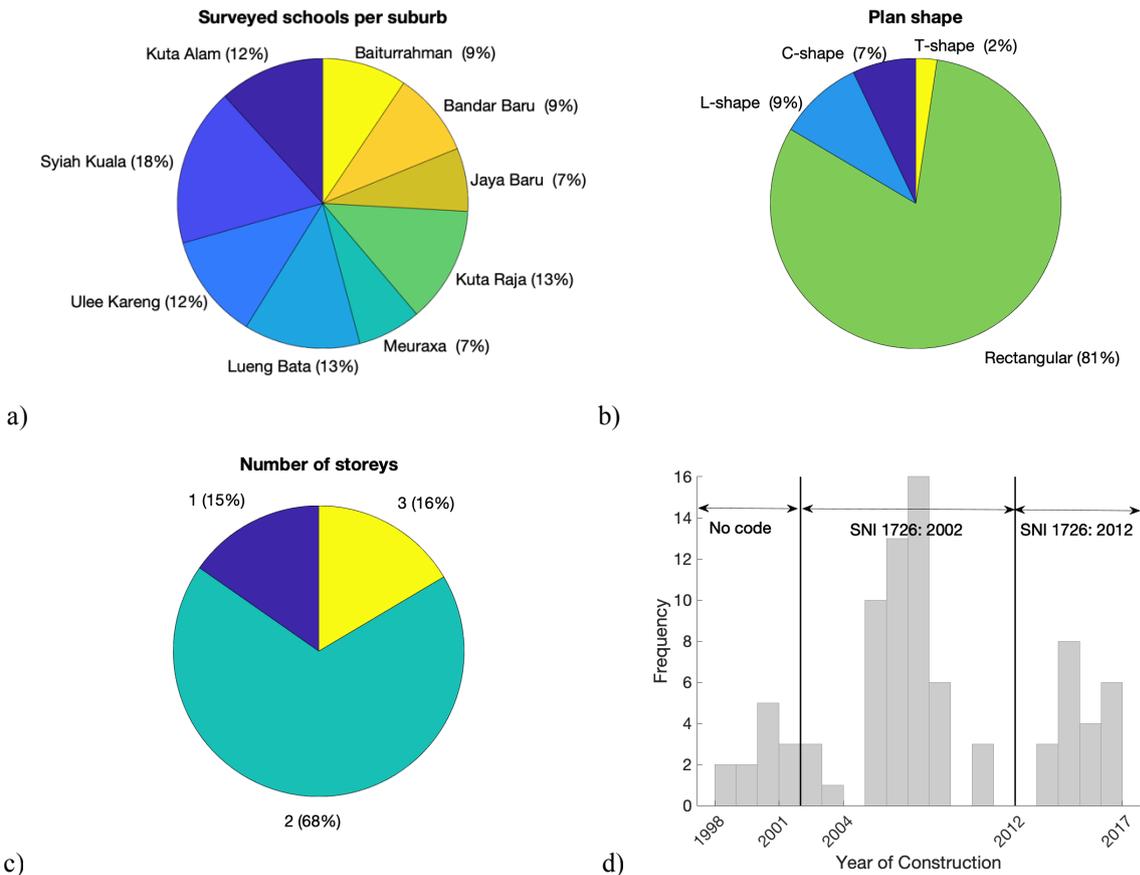

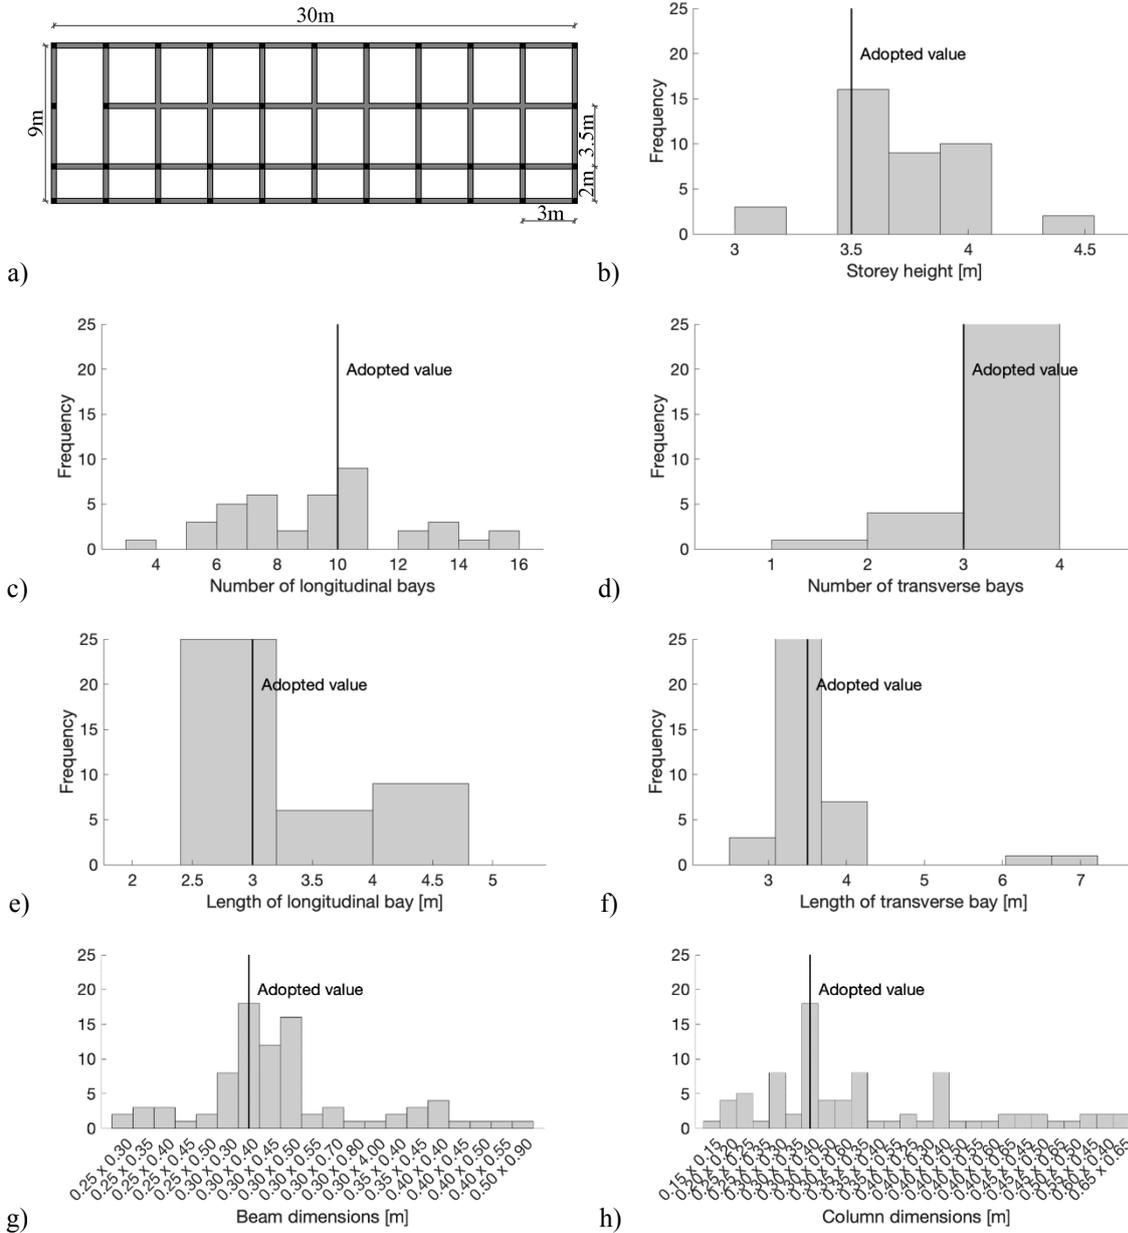

Figure 6 Statistics for the 85 surveyed school buildings.

The analysis above, based only on the information of the INSPIRE forms, allows to identify an archetype building which represents the construction practice for school building in Banda Aceh. The archetype building is a two-storey, rectangular RC building. Figure 7 shows the geometrical characteristics of the archetype building geometry, which are based on the modal (most frequent) values of the empirical distributions (histograms) considering only the rectangular, 2-storey buildings in the portfolio (69). The archetype has 10 bays in the longitudinal direction (one for the staircase, three for each classroom). In the transverse direction there are two 3.5m bays and a 2m corridor bay. The storey height is equal to 3.5m. 0.4x0.3m columns are adopted, except for the corridor columns, whose dimensions are 0.3x0.3m. Finally, the dimensions of the typical beams are 0.3x0.4m. The dimensions of beams and columns are validated with simulated design approaches according to the above-mentioned codes.

5 **Figure 7 Two-storey, rectangular buildings: geometry trends and adopted values for the archetype building. a) plan view of the archetype building; b-h) histograms of the geometric parameters.**

Considering the same geometry, two different sets of structural details are provided, to reflect the SNI2002 and SNI2012 seismic codes. Table 6 provides examples of structural reinforcement for typical members. It is worth mentioning that, for the Post-2012 archetype structure, the cross-section height of beams and columns are respectively 5cm and 10cm bigger than the corresponding members in the Pre-2012 archetype structure. The reinforcement of the structural members is selected by cross-

10

checking visual information (see Figure 5) with the outcome of both gravity-based and seismic-based simulated design according to the SNI codes. To this aim, acting loads are calculated considering permanent dead loads (according to the suggested material properties in SNI1987) and live load equal to 5kPa (1kPa for the roof). Gravity axial load on columns is calculated based on a tributary area approach. This cross-checking exercise has shown that the real observed amount of longitudinal reinforcement is greater than the minimum by code. On the other hand, based on the limited visual information available for the transverse reinforcement, no joint stirrups are conservatively considered for both the Pre-2012 and Post-2012 classes, regardless of the requirement in both codes.

Table 6 Typical structural details for the archetype building(s).

	Materials (mean values)	Typical beam	Typical column	Typical joint
Pre-2012	Concrete $f_c = 21.5\text{MPa}$	3 ϕ 16 top	3 ϕ 16 top	No stirrups
	Long. Steel $f_y=400\text{MPa}$	3 ϕ 16 bottom	3 ϕ 16 bottom	
	Tran. Steel $f_y=240\text{MPa}$	ϕ 10@150mm stirrups	ϕ 10@200mm stirrups	
Post-2012	Concrete $f_c = 24\text{MPa}$	3 ϕ 16 top	3 ϕ 16 top	No stirrups
	Long. Steel $f_y=400\text{MPa}$	3 ϕ 16 bottom	3 ϕ 16 bottom	
	Tran. Steel $f_y=240\text{MPa}$	ϕ 10@150mm stirrups	ϕ 10@100mm stirrups	

Note: f_c is the concrete compressive cylinder strength; f_y is the steel yield stress.

10 4.2. Prioritisation scheme

Based on the data collected with the forms, the INSPIRE seismic risk prioritisation index is calculated for the whole portfolio. Moreover, the Tsunami PTVA4 index (Dall’Osso et al., 2016) is calculated, finally combining these results to derive a multi-hazard index. It is worth mentioning that the resulting indices values are arbitrarily categorised in three groups, respectively “green, yellow and red tags” by defining two threshold values for the various indices. The definition of such thresholds is essentially a subjective (often political) choice that shapes the prioritisation scheme, based for instance on resources availability. For a governmental agency, those can be calibrated estimating the average structural retrofit (or relocation) cost per building and defining the amount of available public funding in two or more-time windows (e.g. one and five years) to obtain specified risk-reduction objectives. As a proof of concept, in this paper the thresholds are selected to be equal to 33% and 66% for the calculated seismic, tsunami or multi-hazard indices.

20 The PTVA index, similarly to the proposed INSPIRE index, allows to derive the relative tsunami vulnerability of a building. It is calculated as a weighted sum of two parameters: the “structural vulnerability” and the so-called “water vulnerability”. The first parameter depends on three factors: the type of the lateral resisting system, the depth of the flood water at the building location, and the degree of external protection (e.g. presence of seawalls). The “water vulnerability” depends on the ratio of the inundated-to-total number of storeys. It is worth mentioning that this parameter is calculated using the inundation data from the 2004 Indian Ocean Tsunami. In particular, Iemura et al., 2012 provide 85 field-measurements of the tsunami height (from the ground) for the city of Banda Aceh. For the purpose of this paper, a linear regression ($R^2=0.66$) is performed to define a linear relationship between distance from the coast and tsunami height. The calculation of the final risk-related index is dependent on scoring parameters assigned according the number of storeys of the building, its material, the percentage of

openings (e.g. windows), foundation type, impacting objects, orientation and shape of the building, and its position with respect to a building row. It is worth mentioning that, although the name refers to vulnerability, the PTVA index somehow refers to tsunami risk, since the expected hazard is also considered. This facilitates the compatibility with the INSPIRE index.

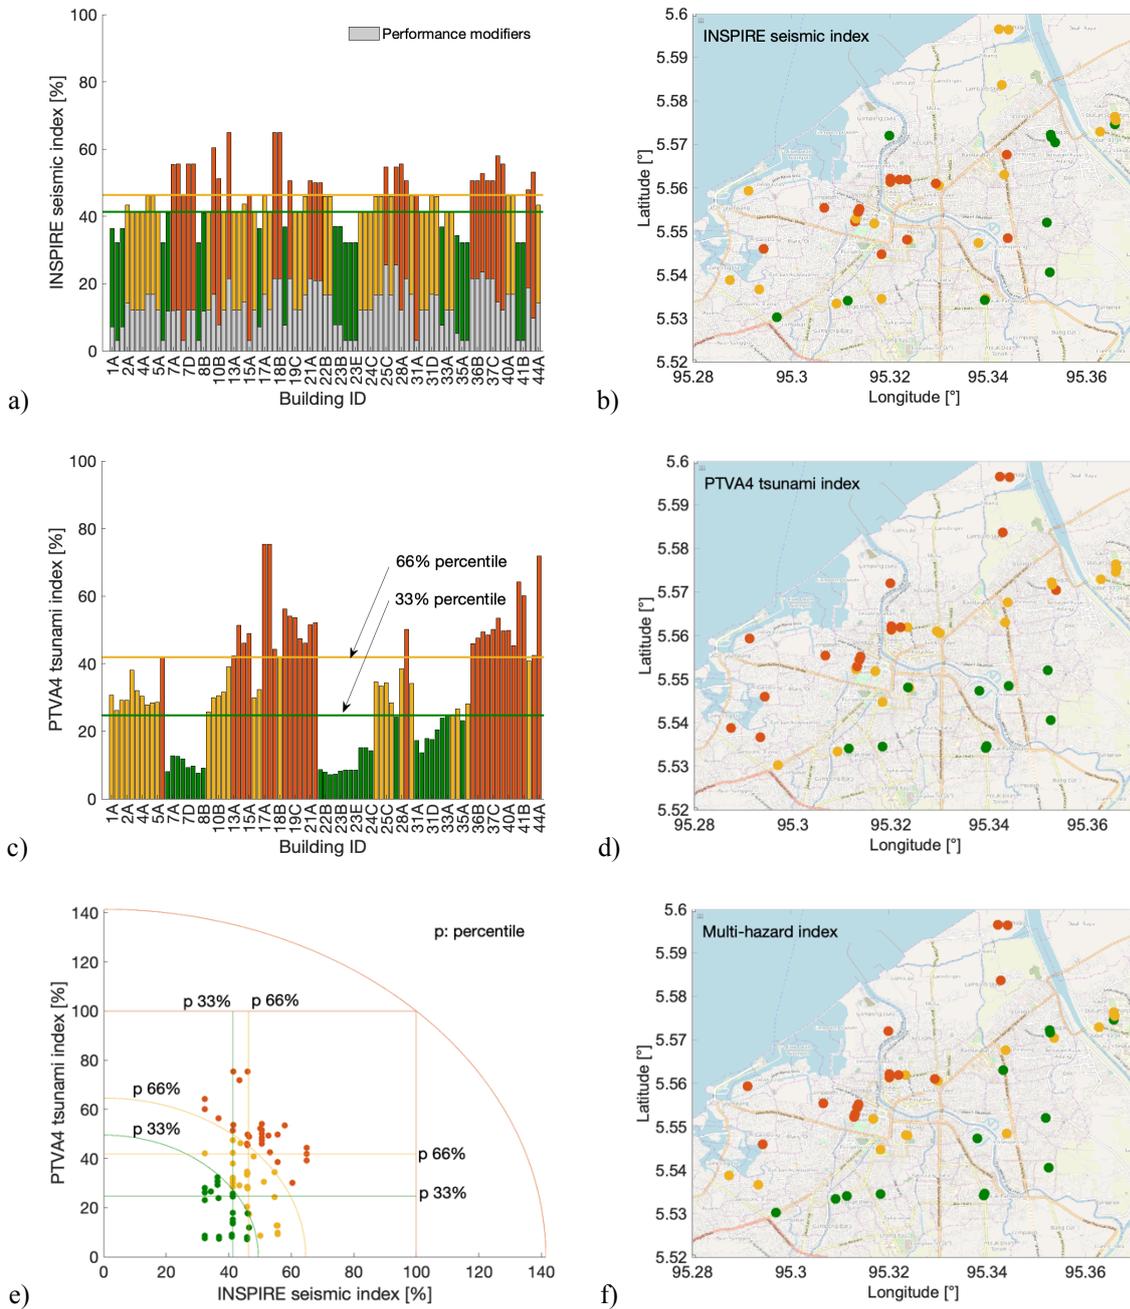

Figure 8 Application to the seismic and tsunami indices to 85 RC school buildings in Banda Aceh, Indonesia.

Figure 8a,b show the application of the INSPIRE seismic risk prioritisation index to the considered portfolio. To calculate the baseline scores, the HAZUS fragility curves related to the C1 category “Concrete Moment Frame” are used. Since the infills of the investigated frames are made of a single layer of poor-quality clay bricks, their presence is neglected. According to the analysis of the year of construction and the history of the structural/seismic codes in Indonesia, the categories Pre-Code and Low-Code are adopted for the Pre-2012 and Post-2012 buildings, respectively. Given the particularly small differences in the characteristics of the buildings, the INSPIRE index is particularly similar for the whole portfolio [32%, 64%]. The slight differences in the value of the index are due to the performance modifiers, mainly governed by short columns and/or pounding for the majority of the schools. This is a further confirmation of the uniformity of the construction practice for school buildings in Banda Aceh, also observed in other countries (e.g., Nassirpour et al., 2018, Zhou et al., 2018). It is worth mentioning that, for this particular portfolio, soil condition is not influencing the performance modifier, since the “unfavourable soil” parameter is set to “yes” for all the buildings. On the other hand, the results for the PTVA tsunami index (Figure 8c,d) show a larger variability [7%, 75%] and a clear correlation between the distance from the coast and the relative tsunami risk. This result, although preliminary, might suggest that the distance from the coast can be used as a very simple proxy for the “water vulnerability” parameter in the tsunami PTVA index.

Given the above-mentioned trends, the combination of the seismic and tsunami indices (Figure 8e,f) clearly indicates that the tsunami hazard play a substantial role in determining the prioritisation scheme for the school buildings in the city of Banda Aceh. Indeed, the overall trend of the multi-hazard results is practically equal to the trend of the tsunami index results. For instance, the developed maps could be used to identify “safer areas” where strategic buildings (e.g., schools or hospitals) should be located, increasing the awareness of vulnerabilities that could be integrated in emergency planning for critical infrastructure disruption (e.g., Pescaroli and Alexander 2016).

To control the role of the subjectivity in calculating the INSPIRE seismic index, a sensitivity study is conducted. The seismic index is applied to the entire portfolio four times (Figure 9), by considering that the maximum value of the performance modifier is equal to 20%, 30%, 40%, and 50%. Clearly, the maximum value of the baseline score is respectively equal to 80%, 70%, 60%, and 50%.

The results of the seismic index are ranked in descending order of risk. The results clearly show that, for this portfolio, the overall priority list is rather insensitive to the maximum baseline-to-performance modifier ratio. Indeed, a small number of “swaps” in the priority list is sought and, with the same definition of the thresholds for the tags, the number of building in each category has a negligible dependency on the ratio above.

4.3. Analytical/numerical seismic fragility analyses for the archetype building(s)

As discussed above, the INSPIRE form provides enough data to build refined numerical models for one or more selected buildings, in a multi-level approach. While the previous sections illustrate the portfolio-level approach (relative-risk prioritisation), this section illustrates a possible structure-specific application of the proposed framework. To this aim, the archetype building(s) defined in Section 4.1 are further analysed by means of non-linear static and non-linear dynamic analyses

to derive structure-specific fragility curves. Those are derived considering a two-dimensional representation of the longitudinal and transverse frames that compose the archetype building. As discussed above, due to their small thickness and poor quality, infills are not considered in the models. Both the Pre-2012 and the Post-2012 archetype buildings are analysed, leading to four different computational models.

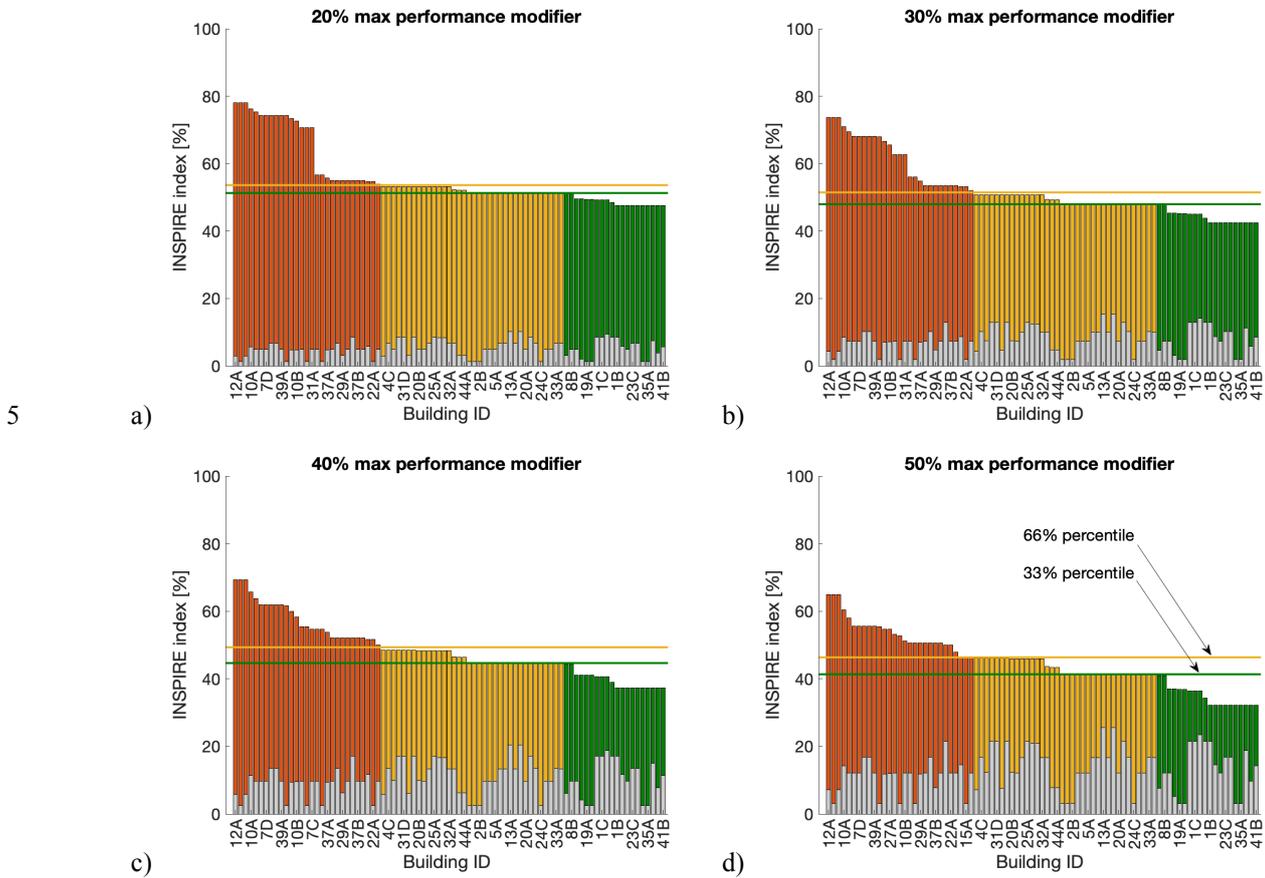

Figure 9 Sensitivity analysis for the baseline-to-performance modifier ratio.

The Simple Lateral Mechanism Analysis (SLaMA) is firstly used to obtain a first estimation of the non-linear force-displacement curve of the building. SLaMA (NZSEE 2017, Gentile et al., 2019a,b,c,d) is a tool to derive both the expected plastic mechanism and the capacity curve of RC frame, wall and dual-system buildings by using a “by-hand” procedure (i.e., using an electronic spreadsheet). This allows to identify potential structural weaknesses in the lateral resisting mechanism and allows to test the reliability of numerical computer models in capturing the most probable behaviour of a structure. It is worth mentioning that, each beam and column in the system is characterised considering many possible failure mechanisms (i.e., flexure, bar buckling, lap-splice failure, shear), considering that the weakest link will govern the overall structural behaviour.

The results of SLaMA are compared to refined numerical pushover analyses carried out with the FEM software Ruaumoko (Carr, 2016). The adopted modelling strategy, previously validated on experimental results (Magenes and Pampanin, 2004), is

based on a lumped plasticity approach and is resumed in Table 7 and Figure 10. The characterisation of the structural members is consistent to the approach adopted for SLAMA. It is worth mentioning that P-Delta effects are not modelled, given that the building is just two-storey high and made by RC. Fully fixed boundary conditions are considered at the base and floor diaphragms are modelled as rigid in plane. A uniform force profile is adopted.

5 **Table 7 Numerical modelling strategy.**

	Modelling approach	Mechanical characterisation model	Notes
Beams	Mono-dimensional Giberson elements (Sharpe, 1976) with Moment-Curvature characterisation of end sections	Moment-Curvature analysis and 50% increase in negative moment capacity due to flange effect (NZSEE 2017)	Software CUMBIA (Montejo and Priestley, 2007, Gentile, 2017) for Moment-Curvature
Columns	Mono-dimensional Giberson elements (Sharpe, 1976) with Moment-Axial load characterisation of end sections	Moment-Axial load interaction diagram analysis	Software CUMBIA for Moment-Axial load
Joints	Rigid ends in the beam-column intersections which are connected with non-linear moment-rotation springs	Behaviour of the springs follows the Equivalent Column Moment vs Drift curve (NZSEE 2017)	Drift limits for joint panels based on exp. Tests (NZSEE 2017)

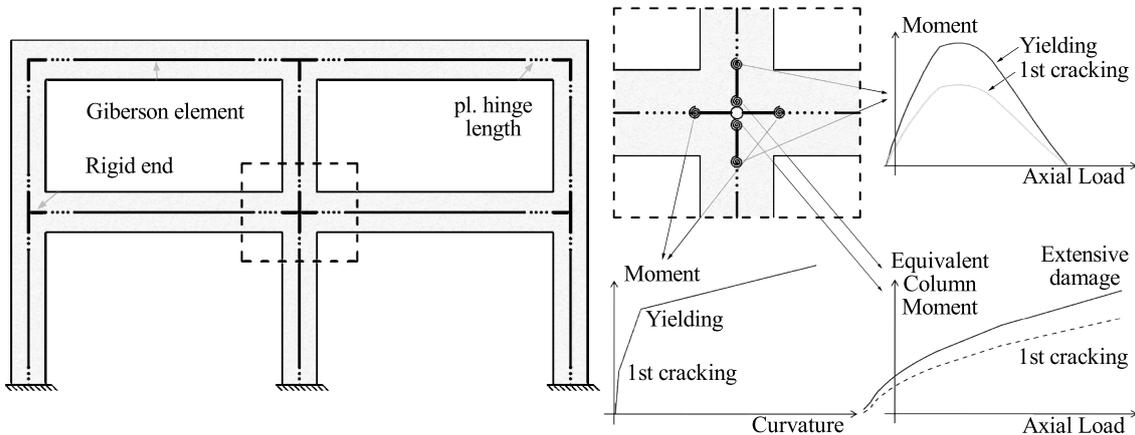

Figure 10 Numerical modelling strategy (from Gentile et al., 2018a).

Figure 11 shows the results of the non-linear static analyses. Firstly, the fundamental period of such frames in the transverse and longitudinal directions are equal to 0.55s and 0.47s for the Pre-2012 archetype, and 0.5s and 0.44s for the Post-2012 one.

10 The plastic mechanism (numerically-based) of the Pre-2012 archetype frames is very similar to the one related to the Post-2012 ones, in both the transverse and longitudinal directions. In the transverse direction, the plastic mechanism, calculated at the onset of the Extensive Damage State (DS3) is characterised by the development of plastic hinges for the roof beams and base columns, and joint shear hinges at the first storey (Mixed-Sway mechanism). No brittle shear failure is registered for beams and columns (both considering SLAMA and the pushover analysis). The beam causing DS2 (yielding) is highlighted in a blue circle in Figure 11a, while the joint panel causing DS3 is highlighted with a red circle. In the longitudinal direction, the DS3 plastic mechanism is characterised by a soft-storey at the first storey, with one internal column causing DS2, but the DS3

15

displacement of the structure is limited by the ultimate drift in the beam-column joint highlighted with a red circle in Figure 11b,d. According to the similarities in the plastic mechanism, the capacity curves for the Pre-2012 and Post-2012 archetype frames are particularly consistent. It is worth mentioning that, the DS3 base shear for the Post-2012 archetype building is 16% and 19% greater than the Pre-2012 archetype, respectively in the transverse and longitudinal directions.

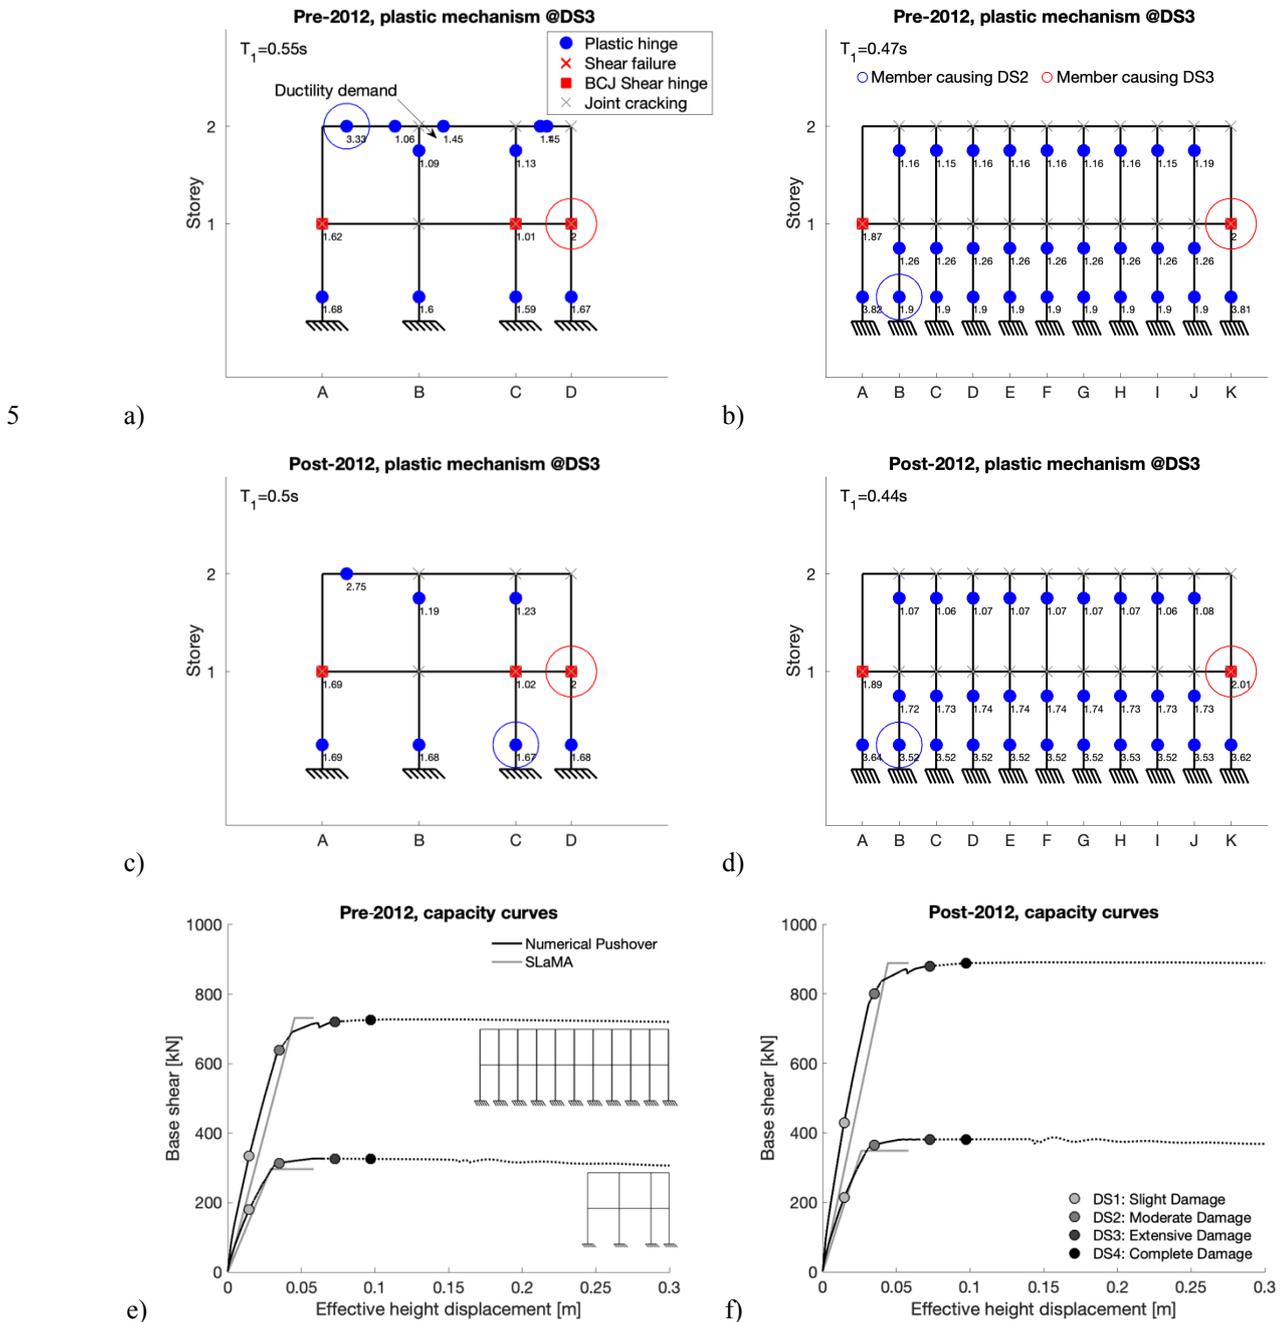

Figure 11 Non-linear static analyses results for the archetype building.

On the other hand, negligible differences are recorded for the displacement at DS3, for both the Pre- and Post-2012 archetypes and both transverse and longitudinal directions. This is because, in all four cases, the failure of one joint panel causes the attainment of such damage state. The displacement in the force-displacement curves is calculated at the effective height (Priestley et al., 2007), which is approximately equal to 5.50m. It is evident that the structure has a particularly-low displacement capacity, since this is limited by the low drift capacity of the joint panels. Finally, there is a satisfactory agreement between SLaMA and the numerically-based pushover, especially considering that the ultimate displacement in the SLaMA curves represents DS3.

The same two-dimensional models are analysed by means of a Cloud Analysis (Jalayer and Cornell, 2009), which consists in a series of non-linear time history analyses considering a large database of unscaled ground-motion records. For this application, the SIMBAD database (Selected Input Motions for displacement-Based Assessment and Design, Smerzini and Paolucci, 2013, Smerzini et al., 2014) is adopted. SIMBAD includes a 467 tri-axial accelerograms, generated by 130 worldwide seismic events (shallow crustal earthquakes with moment magnitudes ranging from 5 to 7.3 and epicentral distances ranging from 6 to 35 km). A subset of 150 records is considered here to provide a statistically significant number of strong-motion records of engineering relevance for the applications presented in this paper. As in Rossetto et al., 2016, these records are selected by first ranking the 467 records in terms of their PGA values (by using the geometric mean of the two horizontal components) and then (arbitrarily) keeping the component with the largest PGA value (for the 150 stations with highest mean PGA). This record selection strategy is compatible with the adopted cloud analysis procedure and with the lack of specific, freely-available, ground-motion databases for the considered case-study region. A rigorous site-specific, hazard-consistent record selection could be used for alternative non-linear demand estimation methods for probability-based seismic risk assessment (Jalayer and Cornell, 2009), such as multiple-stripe analysis. The models used for the numerical pushover analysis are also adopted for the cloud analysis. The hysteretic behaviour of beams and columns is characterised by the revised Takeda model (Saiidi and Sozen, 1979), with the columns having a thinner loop. On the other hand, the hysteretic behaviour of the beam-column joints is modelled using the Modified Sina model (Saiidi and Sozen, 1979), which is able to capture their pinching behaviour.

The results of the dynamic analyses (150 non-linear time history simulation for each of the four models), are used to plot a cloud of points in the plane inter-storey drift (chosen as Engineering Demand Parameter, EDP) vs pseudo-spectral acceleration at the first fundamental period (T_1) of each frame and for a 5% damping, i.e., $S_a(T_1)$, chosen as Intensity Measure, IM. The linear least square method is applied on those pairs in order to estimate the conditional mean and standard deviation of EDP given IM and derive the commonly-used power-law model $EDP = aIM^b$, where a and b are the parameters of the regression. The derived probabilistic seismic demand model is used to define a set of four fragility curves, one for each DS. Such curves are represented in the form of Eq. 2, but using $S_a(T_1)$ as intensity measure of the earthquake intensity. An average fundamental period (given the actual periods in Figure 11), equal to 0.5s, is chosen as a representative period of the considering building class. Although this might cause a small decrease in the efficiency of the IM (e.g., Minas and Galasso, 2018), such choice allows for a comparison between the different fragility curves for different buildings. This curve represents the probability of exceeding a given threshold of inter-storey drift threshold (corresponding to a given DS), conditioned on a value of the

earthquake IM. Figure 12 represents the fragility curves for the Pre-2012 and Post-2012 archetype structures, both for the longitudinal and transverse directions. The adopted inter-storey drift thresholds are defined according to the definitions in Kircher et al., 2006 by post processing the results of the pushover analyses. Those are equal to 0.25%, 0.6%, 1.25%, and 1.67% respectively for DS1, DS2, DS3, and DS4. Such values are consistent with the highlighted displacements in Figure 11, and respectively correspond to the cracking in the first member in the system, the full onset of the plastic mechanism, the attainment of 75% and 100% of the ultimate drift in the first member.

The results show that the seismic fragility of the Post-2012 structures is reduced with respect to the Pre-2012 ones (Table 8). On average, the fragility median of the Post-2012 frames are 5.6% and 4.3% higher than the Pre-2012 ones, respectively in the transverse and longitudinal directions. The related dispersion is reduced, on average, by 16.1% and 14.3% for transverse and longitudinal directions.

	DS2	0.5260	0.4429	0.5506	0.3885
	DS3	1.0873	0.4429	1.1000	0.3885
	DS4	1.4428	0.4429	1.4552	0.3885

- 5 It is worth noting that the structure-specific fragilities obtained with the analyses presented herein could be used to, in principle, to redefine the INSPIRE index. However, this would require the derivation of numerical fragility curves for a much larger set of archetype buildings, consistently with the building typologies identified in Table 1. However, adopting the refined fragilities as an input for the INSPIRE index definition would be inappropriate. Indeed, the proposed index is defined as a quick and practical tool for seismic vulnerability prioritisation of large building portfolios (level 1 analysis). A more time-consuming
- 10 fragility analysis (level 2) should instead be used to derive quantitative seismic risk estimates for one or more selected building in the database and to design structure-specific risk mitigation strategies (e.g., structural retrofitting).

5. Concluding remarks

This paper introduces the INSPIRE index, which is an empirical proxy for the relative seismic risk of buildings within a given building portfolio and allows to define prioritisation schemes for risk mitigation measures. The definition of such index represents the first step of the wider framework of the *Indonesia School Programme to Increase Resilience* (INSPIRE), which aims to develop an advanced, harmonised and science-based risk assessment framework for school infrastructure in Indonesia subjected to cascading earthquake-tsunami hazards.

To this aim, a data collection form used for the rapid visual inspection of RC buildings is first developed and presented. Such form allows to calculate the INSPIRE seismic risk prioritisation index, the Tsunami PTVA index (in any of its variations), to obtain a level of geometrical/mechanical information sufficient to define one or more archetype buildings (representative of the portfolio) and/or to build refined numerical models, provided that simulated design is adopted to cross check the available information.

The INSPIRE index is specifically calibrated for RC buildings, and consists of two parts: a baseline score and a performance modifier. The baseline score is based on the HAZUS MH4 fragility curves, while the performance modifier is based on the score of the building with regard to eight “secondary” parameters, which, if present, are deemed to jeopardise the building

performance. To minimise subjectivity, the relative weight of the secondary parameters is defined according to the Analytic Hierarchy Process. This allows to have a rational and mathematically-consistent assignment of the weights which is based on pairwise comparisons between the secondary parameters and eigenvalues theory.

5 The INSPIRE form and seismic risk prioritisation index are adopted for the analysis of 85 RC school buildings in the city of Banda Aceh, Indonesia, which is located in the Sumatra Island, the area mostly affected by the 2004 Indian Ocean earthquake-tsunami sequence. The joint application of the INSPIRE seismic risk prioritisation index and the PTVA tsunami index allow to define a clear and transparent rationale behind any prioritisation schemes for school buildings in Banda Aceh. In fact, the relative seismic risk of the considered buildings is particularly similar, while the relative tsunami risk shows, clearly, a strong dependence with the distance from the coast. Indeed, the results show that a multi-hazard-based priority list is mostly governed
10 by the tsunami risk for the case-study portfolio.

The advantages of using the INSPIRE form are further demonstrated by defining two archetype buildings, representative of the portfolio, based on the RVS results. The seismic performance of the archetype buildings are firstly analysed by means of non-linear static analyses, both analytically using the Simple Lateral Mechanism Analysis (SLaMA), and numerically using refined finite-element models. Finally, the archetypes are analysed by means of cloud analysis, performing non-linear dynamic
15 analyses using 150 unscaled natural ground motions and deriving fragility curves.

The results in this paper demonstrate the effectiveness of both the INSPIRE RVS form and INSPIRE seismic risk prioritisation index in providing a rational method to derive a prioritisation scheme, which can be extended including multi-hazard considerations, and in allowing the definition of an archetype building for more detailed evaluations/analyses.

This study represents a first step toward a comprehensive framework for earthquake and tsunami vulnerability and risk
20 assessment and the selection of optimal retrofitting strategies for school facilities in Indonesia, through a to a multi-criteria decision-making analysis. Future research will investigate the numerically-based tsunami fragility of the archetype buildings adopting different approaches (e.g., Petrone et al., 2017) and a full seismic loss analysis considering non-structural components, which often represent the highest share of the seismic losses.
