Abstract. Although many studies have explored the effect of teleconnection patterns on flood, few investigations have focused on the assessment of expected flood damages under such large-scale atmospheric signals. This study aims at determining the effect of the most emblematic teleconnection, El-Niño, on the expected damages of floods with low return periods in Kan River basin, Iran. To determine the flood damage costs, the median of annual precipitation changes during El-Niño condition was firstly estimated, although the annual precipitation change factor cannot necessarily be transferred to extreme values. Then, the flooded area was then determined under increased rainfall due to El-Niño for 5-, 10- and 50-year return period. The results showed that El-Niño increases the precipitation amount by 12.2% in average. Flood damage assessment using damage-elevation curves showed that the expected increase percentile in flood damage for smaller return periods, which is more frequent, is much more than that for larger return periods. In general, 12.2% increase in the precipitation would result in 1671% and 176% damage increase respectively for the return periods of 5- and 10- year. However, for the 50-year rainfall this increase amount will be about 52%. These results indicate the importance of small flood events in flood management planning during El-Niño.

25

1 Introduction

In recent decades, the frequency of flood events and the resultant damages have been increasing dramatically in Iran. Reviewing the recorded flood events in the past decades shows an increasing trend. According to the available reports, the number of flooding events happened in any parts of Tehran over four decades had grown up from 12 cases in 1951 to 54 cases in 1991 (Farsnews 2015; Saghafian et al. 2017). Climate change, approaching to floodplain, land use changes, diversion of the waterways, population increase and destructive effects of human activities, degradation of forests and

pastures, construction of dysfunctional and vulnerable hydraulic structures can be mentioned as the reasons for increasing flood risks (Wang et al. 2019; Tang 2020).

The magnitude and frequency of flood events in each region depends on several factors: (i) physiographical features of the catchment such as shape, slope, and rivers network density, (ii) hydrological features such as precipitation, storage and initial losses, evapotranspiration, and permeability, (iii) human activities, (iv) large-scale atmospheric signals and (v) climate change (Ward et al. 2014; Alizadeh-Choobari and Najafi 2017; Hooshyaripor and Yazdi 2017; Hooshyaripor et al. 2017; Saghafian et al. 2017; Hao et al. 2018). These factors affect the occurrence frequency and intensity of the flood and consequently the amount of damage costs. Identifying these factors will help to manage the flood and reduce the risks. In recent years, the effects of teleconnection phenomena have been more and more discussed and has tried to identify their impact on the local climate.

Prediction of teleconnection indicators helps to reduce the flood damages by implementing the necessary practical measures (Schöngart and Junk 2007). Sun et al. (2015) showed that parts of North and South America, South and East Asia, South Africa, Australia and Europe are affected by El-Niño Southern Oscillation (ENSO). Grieco and DeGaetano (2018) concluded that the occurrence of El-Niño in the winter reduces the frequency of high waves in the east of the Ontario Lake, while there was no meaningful relationship in the conditions of La-Niña. Azmoodehfar and Azarmsa (2013) showed that the south-east of Iran during the years with the event of La-Niña experienced a higher-than-normal maximum and minimum temperature. Schöngart and Junk (2007) showed that there is a strong correlation between ENSO and Amazon River flood such that the river water level decreases in the warm episode of the ENSO (El-Niño) and increases in its cold episode (La-Niña). In a global study, Ward et al. (2014) showed the impact of ENSO on the daily peak discharge of some important rivers.

In addition, many studies have shown the effect of ENSO on the climate variability in Iran. Saghafian et al. (2017) showed that in the Dez and Karoun basins (located in the west and southwest of Iran) during March and April the El-Niño increases the probability of occurrence of maximum annual flood and vice versa in the case of La-Niña. Their results showed that the maximum annual flood variation during El-Niño events is much greater than that during La-Niña events. Gholizadeh (2015) investigated the effect of El-Niño on the rainfall events between 1973 and 2012 and concluded that the El-Niño phenomenon increases the annual rainfall of Iran while its severity reduces from south to north of country. Hooshyaripor et al. (2019) investigated the impact of different teleconnection indices on Iran rainfall, and concluded that El-Niño can enhance the annual precipitation by nearly 40%. They stated that due to the increase of rainfall, the river discharge will be affected directly. So far, many studies have focused on the impact of El-Niño over river flow. Alizadeh-Choobari and Najafi (2017) indicated that the ENSO cycle contributes to the interannual climate variability over Iran. According to their results, about 26% of the variance in annual precipitation over Iran is related to the El-Niño. Based on their achievements, In spite of the seasonality of the ENSO signal and its intervene variability, Iran is anomalously wet during the EP El-Niño and dry during La Niña and the impacts of La Niña and the EP El-Niño are generally stronger over the warm and arid regions of Iran.

Although, the effect of ENSO on the precipitation has been frequently studied in Iran, there are few studies about ENSO influence on the socioeconomic impacts of floods even around the world (Ward et al. 2014). The main reason for the limited research on the economic impacts of climate and hydrologic variability is said to be the lack of economic data on flood damages (Changnon 2003). Analyzing the National Flood Insurance Program daily claims and losses and Multivariate ENSO Index (MEI), Corringham and Cayan (2019) quantified insured flood losses across the western United States from 1978 to 2017. They showed that in coastal Southern California and across the Southwest of the United States, El-Niño has had a strong effect in producing more frequent and higher magnitudes of insured losses, while in the Pacific Northwest, the opposite pattern with weaker and less spatially coherent has been reported. Changnon (2003) revealed that the strong El-Niño events of 1982/83 and 1997/98 have caused significant flood damages over \$2.8 billion in Southern California. Null (2014) demonstrated that from 1949 until 1997 out of the six seasons that flood damages costs exceeded \$1 billion in California three cases had been El-Niño years; one very strong (1982), one moderate (1994) and one weak (1968). Ward et al. (2014) showed that ENSO exerts strong and widespread influences on both flood hazard and risk. They assessed ENSO's influence in terms of affected population, gross domestic product and economic damages on the flood risk at the global scale and showed that climate variability, especially from ENSO, should be incorporated into disaster-risk analyses and policies. They revealed that, if the frequency and/or magnitude of ENSO events were to change in the future due to climate change, change in flood-risk variations across almost half of the world's terrestrial regions is happened. Ward et al. (2016) provided a global modelling exercise to examine the relationships between flood duration and frequency and ENSO. They indicated that the duration of flooding compared to flood frequency is more sensitive to ENSO.

The above studies indicate the importance of teleconnection in the flood characteristics in many parts of the world, but to the best of the authors' knowledge few investigations have focused on the assessment of the expected damages under the El-Niño or La-Niña conditions. Obviously, damage assessment is an important part of flood risk analysis, which determines the need for flood management programs and their priorities. The question addressed in this research is that, given the increasing impact of rainfall due to El-Niño, how much damages are expected to be added in a given study area. To answer this question, the catchment of Kan River in north of Tehran metropolis was selected. Due to importance of the basin, numerous flood risk studies have been conducted in this area (WRI 2011a,b,c; Yazdi and Salehi Neyshabouri 2012; Yazdi et al. 2013). Hence, this paper focuses on the impact of El-Niño not only on the precipitation amount but also on the flood damages that are expected to be increased due to the El-Niño event.

2 Study area

Kan River basin is one of the most important flooding basins located in the north of Tehran city and a vulnerable area against flood (Yazdi and Salehi Neyshabouri 2012). It is reported that in the flood of July 15, 2015 a 20-minute storm caused 8 losses of life, several bridge and diversion dam failures, and more than 10 million dollars in damages to the residential, commercial and agricultural areas (ISNA 2015). In June 1968 a heavy rain as 6 times as the annual precipitation happened in

2 days had caused 31 losses of life in Tehran central area and huge damage to the properties. In general, during a period of 60-year (from 1954 to 2015) at least 8 flood events that resulted in loss of life (in total 2200 people) have been reported in Kan and central Tehran areas. Existence of many restaurants, demographic, recreational, tourist and pilgrimage centres adjacent to the sloping Kan River have exacerbated the potential for damages (WRI 2011a).

- 5 Kan Basin is located between the longitude of the 51° 10' and the 51° 23' and the latitude of 35° 45' to 35° 58'. The basin can be divided into 10 sub-basins (Figure 1). The highest point of the basin is 3823 m and the lowest point is 1328 m with the average of 2377 m above sea level. The area of the basin is 216 km². The average annual precipitation is 640 mm and the average annual discharge is 78.23 Mm³ at Sulaghan station. The hydrometric stations include Kiga (Gage1), Keshar (Gage2) and Sulaghan (Gage3) (Figure 1). As shown in Figure 1, three rain gage stations in the basin and four synoptic stations
10 around the basin record the precipitation.

3 Methodology and data

In this study southern oscillation index (SOI), MEI, AO, NAO, and MJO teleconnection indices were evaluated to select an index that has the highest correlation with the precipitation in the study area. In this paper, Fisher's exact test of independence was used to test the significance of correlation between the teleconnection indices and precipitation. In the
15 Fisher's exact test the null hypothesis is that "two variables are independent". In other words, the relative proportions of each teleconnection index are independent of the precipitation:

$$\begin{aligned} H_0 : \rho &= 0 \\ H_1 : \rho &\neq 0 \end{aligned} \tag{1}$$

- 20 Considering the Fisher's exact test, if p-value is less than 0.05 the null hypothesis is rejected; i.e. the p-value must be less than 0.05. According to the results (Table 1), there would be a statistically significant association between the SOI (MEI and NAO, as well) and Precipitation. However, SOI has the highest correlation with **the precipitation in Kan Basin**. Therefore, ENSO is the most important large-scale atmospheric signal that affects Iran's climate. It has been shown that rainfall intensity increases in the conditions of El-Niño and decreases in the conditions of La-Niña. Accordingly, the present study will assess the increase in flood damage due to El-Niño occurrence. For this purpose, the following steps have been taken.

- Step I:** Estimating the lag time (T_l) between the El-Niño event and the precipitation in the study area. As the effect of ENSO
25 takes time to be experienced in far geographic locations, the lag time between the ENSO occurrence and the related influences in Kan River Basin was firstly calculated. This lag time can be revealed by comparison the variations of SOI and local precipitation time series. The monthly rainfall at the nearby synoptic stations of Mehrabad (1951-2017), Shemiran (1988-2017), Tehran-Geophysics (1992-2017) and Chitgar (1997-2017) (See Figure 1) and monthly SOI values are used. A statistical method, average mutual information (AMI), is used to determine the time delay. This method is based on the
30 Shannon entropy theory and is a measure of "amount of information" obtained about one random variable, through the other

random variable. Guiasu (1977) defined the mutual information of two random variables as a measure of the mutual dependence between two variables. Not limited to real-valued random variables and linear dependence like the correlation coefficient, mutual information is more general and determines how different the joint distribution of the pair (X,Y) is to the product of the marginal distributions of X and Y (Guiasu 1977). Suppose A is monthly precipitation in the representative station of the basin and B is SOI. The AMI is defined between two measurements a_i and b_i belonging to the sets A and B, respectively as follows (Cover and Thomas 1991):

$$I_{AB} = \sum_{i=1}^K \sum_{j=1}^K P_{AB}(a_i, b_j) \log \left(\frac{P_{AB}(a_i, b_j)}{P_A(a_i)P_B(b_j)} \right) \quad (2)$$

where $P_{AB}(a_i, b_j)$ is the conjugate probability density for measurements A and B with values of a and b , respectively; $P_A(a_i)$ and $P_B(b_j)$ are the probability density function for measurements A and B. If a_i (the measurements of A) is independent of b_i (the measurements of B) then the value of I_{AB} will be zero. In this paper, probabilities P_A and P_B were calculated using empirical frequency analysis in which the relative frequency histograms for both time series, SOI and precipitation were determined. The values of AMI for different arbitrary lag-times (1 to 12 months) between SOI and precipitation were calculated. The higher AMI value, the more dependency between two time series. Therefore, that lag-time corresponding to the highest AMI value was selected as the lag-time between the time series. This method determines the time between two time series by using the nature of the data itself and without any predetermined format based on probabilistic concepts (Cover and Thomas 1991). In Eq. (2), K is the optimal number of statistical categories for fitting the statistical distribution on the measurements A and B. When dealing with large sets of numbers, Sturge's rule (Sturges 1926) can be used to choose the number of categories. Sturge's rule is widely used in the statistical packages like excel for making histograms. According to Sturge's rule the data range should be split into K equally spaced classes where:

$$K = 1 + 3.332 \log_{10}(n) \quad (3)$$

where n is the number of data in the corresponding interval (here $n = 480$); therefore, in the present study, $K = 10$. Noted that there is uncertainty in the optimal number of categories that may influence the lag time between the precipitation in the basin and SOI.

Step II: Estimating the amount of rainfall variation under the influence of El-Niño: Secondly, the influence of El-Niño on the precipitation amount in Kan River Basin is quantified. The influence is estimated using a statistical method by calculating the expected value of the changes of precipitation amount in the El-Niño episodes compared to those in the neutral periods. Doing so, SOI a standardized index based on the observed sea level pressure differences between Tahiti and Darwin is applied. In this study SOI values were obtained from National Oceanic and Atmospheric Administration (NOAA) website (<https://www.cpc.ncep.noaa.gov/data/indices/soi>). Prolonged periods of negative SOI values accompany the abnormally warm ocean waters across the eastern tropical Pacific. La-Niña and El-Niño are characterized respectively by $SOI > +1$ and $SOI < -1$ (WRCC, 2010). Then, precipitation change (PC) in the El-Niño condition is calculated as follow:

$$PC_t = (P_{El_t} - P_N) / P_N \quad \forall t = 1..T \quad (4)$$

where P_{El_t} is annual rainfall in every El-Niño episode; P_N average annual rainfall in the normal episodes; and T is number of El-Niño events in the time period (here $T=6$). Then, median of PC values (ΔP) will be used to construct synthesized rainfall storms. It is a limitation of this research that the annual change factor is applied in the extreme rainfalls of short time scales.

5 Certainly, it was better to consider the monthly or seasonal change factor or calculation of change factor on the basis of recorded storms the applying it in a continues hydrologic model to have a more accurate prediction of El-Niño effect then calculating annual damages, but because of data limitation this paper uses annual data.

Step III. Estimation of design rainfalls with different return periods: Thirdly, several design storms are generated to be applied in a rainfall-runoff model. The rainfall storms are synthesized based upon the average precipitation change during El-Niño events. The designed storms are used for assessing the flood damages in a certain return period. To do so, the intensity-duration-frequency (IDF) rainfall curve of Kan basin was obtained from WRI (2011b). Time of concentration (T_c) of the basin is 135.19 min (Using Kirpich equation). Therefore, the intensity of design rainfall (i_d) can be deduced for different return periods (here, three return periods of 5-yr, 10-yr and 50-yr are considered). These return periods are selected in accordance with the paper's objective to show the importance of small floods in flood management plans compared to the high return period floods. Then, the rainfall intensity in the El-Niño condition (i_E) can be calculated by multiplying i_d and ΔP .

Step IV: Hydrological modeling: Fourthly, the HEC-HMS hydrologic model is used to simulate the rainfall-runoff process. The hydrologic model is run for every return period; then the peak discharge is used in the next step to estimate the flooding depth. In the hydrologic model, the SCS method is used to calculate the effective rainfall (P_e):

$$20 \quad P_e = \frac{(P - 0.2S)^2}{P + 0.8S} \quad (5)$$

where P is rainfall; and S is storage potential. The constant value 0.2 is selected based on SCS recommendation to estimate initial losses as $I_a=0.2S$ (Ponce and Hawkins 1996), because we did not have any estimate for this losses in the study area.

Moreover, Clark instantaneous unit hydrograph method is applied to transform the effective rainfall into runoff (Q) and two-parameter Muskingum method is used for flood routing. The Muskingum method calculates the discharge within the river given the inflow hydrograph at the upstream end. For calibration of the HEC-HMS model, hourly historical storms which had been recorded in three rain gage stations in the basin and the related runoffs at the hydrometric stations (Figure 1) are used. Noted that for calculation of rainfall specified to every sub-basin, the gage weight method is used where the weights were determined from Thiessen method. The curve numbers (CN) and time of concentrations (T_c) are calibrated within 10 sub-basins. For calibration and verification of the hydrologic model four storm events were extracted from 15 years available data (2000-2014): 1) the storm of 15–18 April 2003 in which a flood of maximum 38.22 m³/s was recorded at Gage3; 2) the storm of 16–19 April 2002 where the peak discharge rate of 32.3 m³/s was recorded at 10 Gage3, 3) the storm of 15–17 April 2009 in which a flood of maximum 34 m³/s was recorded at Gage3 and 4) the storm of 11–13 March 2011 where the peak

discharge rate of 55.1 m³/s was recorded at Gage3. Then the calibrated model can be used for modelling the rainfall of given return periods to calculate the flood hydrographs at the outlet of the sub-basins.

Step V: Hydraulic modeling: Fifthly, the HEC-RAS model is used for hydraulic modeling and determination of flood depth at the target points (Residential areas shown in Figure 1). Based on the obtained flood depth, the flooding area is determined for designed storms in the El-Niño and neutral episodes. HEC-RAS is a one-dimensional model based on the numerical solution of the Saint-Venant equations. The model is calibrated by adjusting the Manning roughness coefficients at different river sections. The calibrated model then is used under steady state condition to model the obtained peak discharges from HEC-HMS in order to calculate flood depths at the target points.

Step VI. Estimating expected damage cost: Finally, flood damage is assessed for all 6 runs of the model. These damages can be compared to each other in order to determine the role of El-Nino on the flood damages. Damage caused by flooding can be divided into two groups: tangible and intangible damages. Intangible damages are those caused by illnesses and mental problems due to loss of life or properties. Tangible damage can be categorized into two direct and indirect damages. Direct damage is that caused from flooding of the buildings and properties such as home equipment, crops, livestock and poultry. Indirect damages are those caused due to disruption of trade and business, threatening life and needs to emergency services, and so on. Noted that, this paper focuses on the direct tangible damages only.

Damage caused by flood is a function of its characteristics, including flow depth and inundation amount, duration of inundation, and flow velocity. One of the commonly used methods for estimating flood damages is damage-elevation curve method which gives the relationship between damage percentile and flood depth (Corry et al. 1980, KGS_Group 2000, Messner et al. 2007; Olesen et al. 2017; Wobus et al. 2017; Jamali et l. 2018). Damage-Elevation curves that are prepared for different land uses of Kan River Basin are presented in Figure 2. This method has been developed by the Federal Emergency Management Administration (Berkman and Brown 2015). The main land uses of the Kan River floodplain are residential buildings, restaurants, and fruit gardens (WRI 2011c). The damage cost then is calculated having entire monetary value of the inundated land uses. A comprehensive analysis of physical damages due to flooding requires many information including accurate updated land use map, area and age of buildings, type of the structure, number of floors, exact areas of different agricultural crop in the flood-prone area, crop number per unit area, value of crops, value of buildings (residential and non-residential) and their contents, number of residential, administrative, and commercial buildings in flood prone areas, the area and elevation of buildings, their locations, and spatial distribution of flood depth values in the inundated areas for different return periods. In this paper a simplistic approach is used for this regard. For the building damage analysis, separating residential and commercial ones, the total area of inundated buildings, average inundation depth, and the average economic value of the buildings and their contents for every building type are used. For agricultural damage analysis, considering the dominant crops of cherry and apple, the area of inundation, average inundation depth, crop density, and average price of one single crop, the flood damage cost is evaluated.

4 Results and discussion

Monthly analyses of the precipitation in the synoptic stations and SOI using AMI method showed that there is no lag time between rainfall and SOI time series (the lag time is less than one month).

5 Evaluation of the monthly SOI over the period from 1951 to 2017 shows that 161 months with El-Niño and 128 months with La-Niña have been occurred. The average monthly rainfall at Mehrabad station in the months of El-Niño is 21.4 mm and in the months of La-Niña 16.2mm, while in the normal months, the average rainfall is 19 mm. In Figure 3, the annual rainfall of stations is plotted against the SOI index. It is obvious that with decreasing SOI index, annual rainfall increases in the study area and vice versa. In the period of 1951 to 2017, a total of 6 El-Niño (SOI<-1) and 5 La-Niña (SOI>+1) events have been occurred. Out of 6 El-Niño years, 5 periods have experienced increase in the precipitation (2%-45%) and 1 period with
10 decrease in the precipitation (-34%). The largest event for El-Niño dates back to 1983 and 1987 with respectively 334 mm and 252 mm recorded rainfall in Mehrabad station. Furthermore, based on the trendlines, in average one unit decrease in SOI, will enhance 22.5 mm annual rainfall in Mehrabad station (Figure 3a). For further analyses, Mehrabad station was chosen because it has more data than the other stations.

In the risk analysis, it is required to evaluate the annual damage costs. To evaluate the annual damage costs, under the effect
15 of El-Niño, at first the years with El-Niño condition were recognized. There are 6 years with El-Niño and 55 normal years among the total of 66 years (1951-2017). Using Eq. (4), for 6 years with El-Niño condition, PC value ranges from -34% to 45% while the latter is related to the year 1983 in which 334 mm rainfall was recorded. Then, the median can be calculated as $\Delta P=12.2\%$. It should be noted that, the threshold of SOI=-1 is an assumption that affects the results significantly.

The Kan River basin has 135.19 min time of concentration. Therefore, considering the duration of the design rainfall as
20 $D=150$ min, i_d can be estimated from IDF curves. For return periods of 5, 10, and 50-yr, i_d values are 7.8, 9.5, and 13 mm/hr, respectively. Thus, i_e values can be calculated as 8.76, 10.66, and 14.59 mm/hr respectively for return periods of 5, 10, and 50-yr.

4.1 Hydrologic and hydraulic modeling

HEC-HMS is calibrated using an actual rainfall and runoff event recorded in April 2003. The calibration parameters include
25 curve number and concentration time (T_c) of the sub-basins. In the process of automatic calibration, the parameters are determined such a way that the model could simulate the hydrologic behaviour of the basin accurately. The main objective is to predict the exact peak discharge and time to peak of the hydrograph in the hydrometric stations by minimizing the mean squared error (MSE) between predicts and observations. Comparison the observed and simulated hydrographs in Gage3 is illustrated in Figure 4a. Moreover, Figure 4b shows the results for the upstream gages (Gage2 and Gage3). In Table 2, the
30 calibration result of the hydrologic model is presented. Then the hydrologic model is verified with the storm event in April 2002, April 2009 and March 2011 resulted in floods with respectively peak discharges of 31.5 m³/s, 34.4 m³/s and 54.1 m³/s. Comparison between the simulated and observed flood hydrographs are shown in Figure 4c. It is noted that, for the flood of

11-13 March 2011, the peak of 54.1 m³/s has been estimated by Regional Water Company of Tehran. It is noted that, for these flood events, the discharges are not available in the upstream stations. As a result, the model can be used for modelling the design storms in the three scenarios to calculate the flood hydrographs at the sub-basins.

Then HEC-RAS software is used to simulate the flood travelling and to determine the flood depths of different return periods in the target points. For starting the hydraulic modelling, HEC-RAS requires cross sections of the river in different points. In this study the cross sections were extracted from Digital Elevation Model. Flood hydrographs of the sub-basins with different return periods were simulated by the calibrated rainfall-runoff model (HEC-HMS) and the peak values were used as the boundary conditions for the HEC-RAS model. For the model's calibration, the peak discharges produced in the hydrologic model's calibration step (flood 15–18 April 2003) are input into the hydraulic model as the boundary conditions at the upstream reaches and the flood depth and discharge at Sulaghan station is compared with the observed one. The calibration parameters are Manning roughness coefficients that are calibrated manually. For the model verification, flood in 16–19 April 2002 and the upstream peak discharges generated in the hydrologic model are used.

Therefore, the hydraulic model can be used for calculating the flow depth at the target points. **The hydrologic and hydraulic models are applied for modelling the design storms of different 5, 10, and 50 return periods to be compared to those under El Nino effect. It means that totally 6 different runs of the sequent models are required.** Using the obtained inundated depths, the flood mapping can be done in ArcMAP. **Figure 5** illustrates the inundation areas at two target points (Sulaghan and Sangan villages) for the 50-yr flood in the first scenario.

4.2 Damage analysis

In this section, with the help of GIS tool and the land use maps (generated from maps of 1/25000 scale) which were obtained from the local municipality, a simple analysis of damages to the buildings, their contents, and agricultural areas is carried out. In this step just five Sub-basins of Imamzadeh Davood, Rendan, Sangan, Sulaghan and Keshar are considered; because of lack of land use maps, low population, and low development in the other sub-basins. As noted previously, here a simplistic approach with several limitations is used. The main reason for this is the lack of precise land use information and accurate spatial value of each property in the basin. At the basin level, for example, there is a lot of gardens along the river, some with less than one-year-old trees and some with more than 20 years old trees that have different economic values and various vulnerability to the flood. In this article, all such gardens are seen in the same way. Moreover, it is supposed that all the agricultural land is used for apple and cherry because other fruit gardens include of very low area in the basin. Furthermore, in the basin there are buildings of one to three floors with different areas, some of them are new and some are old; therefore, they are not of equal value and same vulnerability to flood. While in this article all buildings are considered similar and the damage cost to them was estimated by total area of buildings in the inundation area.

For this regard, applying the inundation map on the land use maps, the average depth of inundation and area of inundation for every land use are calculated. Then from the damage-elevation curves percentile of damage to the land uses can be

5 estimated. Finally the damage cost to each of land uses is calculated by the average economic value of one unit of that land use. It should be noted that for agricultural physical damages analysis in every sub-basin, two dominant products of cherry and apple were identified and based on the percentage of each of them, average crop number per unit area and value of each crop, the damage analysis was performed. Percentages of crops, number of them per unit area and their economic value as well as value of different assets in the flooding area is obtained by a field survey and interviews with the local authorities and local inhabitants, and engineering judgment. Table 3 provides details of the physical damage costs to the present land uses for different return periods. Similarly, the increased rainfall due to El-Niño is simulated and the damages are estimated in the same procedure (Table 4). Results revealed that, firstly, the expected flood damages cost during El-Niño event increases much more than that of rainfall increase, and secondly, in the smaller return periods, the increases of flood damages is much more than that in the bigger return periods. In the return period of 5-year, in average El-Niño increases the damages to 1671%. The main reason for this high amount is that the average depth of 5-yr flood is very small (<0.04m) and with an increase of 12.2% in the rainfall intensity, the flood depth increases considerably (about 0.5m). During the 10-yr and 50-yr floods, due to El-Niño, damages increases by average of 176% and 52%, respectively.

10 It should be noted that, the high %-increase for 5-yr return period may relate to the fact that the initial losses and infiltration amounts are considerable compared to the 5-year rainfall. In such condition, effective rainfall is so reduced that it produces not too much runoff. For higher return periods while the rainfall amount rises but the event duration does not change, infiltration and initial losses increase slightly and, in total, the runoff increases significantly. It is clear that if the increase in precipitation is significant enough, then the runoff increase will also be significant. Therefore, in the cases of large return periods in which the rainfall amounts are large, the infiltration and initial losses are not significant, and so the increase in rainfall intensity will be mainly seen in the increase in the effective precipitation and direct runoff.

5 Conclusions

In the present paper, the effect of El-Niño on the flood damages was investigated. The methodology was based on the calculation of increasing rainfall amount during El-Niño event compared to the normal conditions. Considering SOI=-1.0 as the threshold of El-Niño, the annual %-increased rainfall is 12.2%. Noticed, the annual change factor cannot necessarily be transferred to extreme values. While, considering monthly rainfalls the effect of El Niño might be negative in some periods when extreme rainfall occurs. The annual change factor was then applied for generating design storms of different return periods of 5, 10 and 50 years. Using HEC-HMS and HEC-RAS models flood zoning was performed for both episodes of neutral and El-Niño. Therefore, a total of 6 models were developed and flood zoning results turned into physical damage. To estimate the flood damage cost the damage-elevation curve method was used. The results showed that the occurrence of El-Niño in less return periods, which is more frequent, increases the relative damages very much and for the higher return periods the increase percentile are not considerable. More specifically in a flood with a return period of 5 years, an increase of 1671% in damages may be occurred. The average increase in the expected damages cost is 1176% for 10-yr return period,

while it is 52% for 50-yr return period. It implies that flood managers should pay more attentions to small floods during El-Niño years. In other words, flood management in small flood cases requires much less financial budget and may result in much more effective approaches. These results is a warning to decision makers to take in to account the probable effect of El-Niño on the programs of flood risk management. These results provide decision makers with essential information on flood risk and highlight the importance to take in to account the probable effect of El-Niño in flood risk management.
