15 **Abstract**

16 This publication highlights theoretical work that could explain four different empirical observations
17 indicating a direct relationship between magnetic fields and earthquakes, which would allow the description
18 of a causal mechanism prior to and during the occurrence of earthquakes. These theoretical calculations
19 seek to elucidate the role of the magnetic field in different aspects of solid earth dynamics, with an interest
20 in the study and comprehension of the physics that could generate earthquakes accompanied by
21 simultaneous magnetic signals within the lithosphere. The Motion of Charged Edge Dislocations (MCD)
22 model and its correlation with the magnetic field have been used in order to include the generation of electric
23 currents. The electric currents resulting from stress variation in the lithosphere helps us to analyze the
24 lithosphere as a critical system, before and after the occurrence of earthquakes, by using the concept of
25 earthquake entropy. Where it is found that the non-existence of seismic and magnetic precursors could be
26 interpreted as a violation to the second law of thermodynamics. In addition, the Seismic Moment and the
27 Moment Magnitude of some great earthquakes are quite accurately calculated using the co-seismic magnetic
28 field. The distance-dependent co-seismic magnetic field has been theorized for some of the largest recorded
29 earthquakes. Finally, the frequency of oscillation of the Earth's magnetic field that could be associated with
30 earthquakes is calculated and being consistent to the ultra-low frequency (ULF) signals that some authors
31 propose in the so-called "LAIC Effect" (lithosphere-atmosphere-ionosphere coupling).

1 **Introduction**

A number of investigations attempting to relate the magnetic field to seismic events have emerged over the past few years, (e.g. Park, 1996; Surkov et al., 2003; Johnston et al., 2006; Balasis and Manda 2007; Sgrigna et al., 2007; Saradjian and Akhoondzadeh, 2011; Varotsos et al., 2011; De Santis 2014; Donner et al., 2015; Schekotov and Hayakawa, 2015; Daneshvar and Freund, 2017; De Santis et al., 2017; Cordaro et al., 2018, 2019; Marchetti and Akhoondzadeh, 2018; Pulinets et al., 2018; among others). However, there is still no unified causal mechanism that is widely accepted and that may account for the physics of all these observations prior to or during the occurrence of an earthquake (Hough, 2010), although the laboratory evidence shows the possibility of an increase in the conductivity of rocks when subjected to stress changes, either through microcracks or chemical imperfections (Freund, 2003; Anastasiadis et al., 2004; Cartwright-

1 Taylor et al., 2014). Therefore, this paper will attempt to explain the physics of magnetic observations
2 recorded by different researchers accurately, organizing them in four categories:

3

4 1.- Since the lithosphere can be considered a non-equilibrium system (De Santis et al., 2011), it is necessary
5 to study the any change in stress on rocks. The generation of current and magnetic field resulting from stress
6 changes in rocks and their relationship with earthquakes has been shown empirically and theoretically by
7 Vallianatos and Tzanis (2003), Anastasiadis et al. (2004), Scoville et al. (2015), among others. This
8 information is relevant, as any mechanism to be related to earthquakes should provide some connection with
9 stress changes in the lithosphere. Many explanations have been offered about the generation of currents
10 through stress changes in rocks, including the piezoelectric effect (Tuck et al., 1977), the presence of fluids
11 in rocks through the so-called electrokinetic effect (Morgan et al., 1989) or chemical processes in rocks
12 (Paudel et al., 2018). However, the generation of transient currents occurs in rocks either with or without
13 the presence of water or liquids (Yoshida et al., 1998), in non-piezoelectric materials (Freund and Borucki,
14 1999), and in materials under non-elastic conditions (Triantis et al., 2012). Thus, a simple model for the
15 study of current generation by stress changes is the so-called Motion of Charged Edge Dislocations (MCD),
16 which consists of the movement of charges due to the generation of microcracks within a brittle and semi-
17 brittle material similar to the crust that has undergone a stress change (Triantis et al., 2012). Once the
18 physical mechanism that generates magnetism by stress changes has been found, it is essential to study the
19 temporal evolution of the lithospheric system, which is referred to in group 2.

20

21

22 2.- According to De Santis et al. (2011) and De Santis et al. (2014), the measurement of the temporal
23 evolution of stress is achieved by measuring the "Earthquake Entropy", since the occurrence of an
24 earthquake is an irreversible process comparable to a "critical system", due to the irreversible change in the
25 state of such system, i.e. from a high-stress to a lower-stress lithosphere during an earthquake (De Santis et
26 al., 2017). However, in order to correctly apply the stress configuration in an area of the lithosphere, it is
27 necessary to know the "b-value" of Gutenberg-Richter's empirical law, since according to Schorlemmer et
28 al. (2005), this value can be interpreted as a type of inverse measure of stress and therefore the temporal
29 evolution of "b-value" could be related to the temporal evolution of stress and magnetic field through group
30 1.

31

32 3.- Once the evolution of the stress has been determined according to the magnetic field, the calculation of
33 the Seismic Moment and the Moment Magnitude of Earthquakes will be carried out by using the co-seismic
34 magnetic field since, as stated by Utada et al. (2011), a possible co-seismic magnetic variation of 0.8 nT
35 was recorded at about 100 km from the Tohoku 2011 Mw9.0 earthquake rupture area while Johnston et al.
36 (2006) also reported changes in the magnetic field close to earthquake fault during the Parkfield 2004 M6.0
37 earthquake and during the Loma Prieta 1989 Mw7.1 earthquakes also were reported possible co-seismic
38 changes in magnetic field (Karakeliana et al., 2002).

39

40 4.- The last group of measurements corresponds to the recording of ultra-low frequency (ULF) magnetic
41 signals, i.e. frequencies below 1 Hz, as many researchers have found such anomalous frequencies prior to
42 or during earthquake, mainly close to mHz and μ Hz (Fenoglio et al., 1995; Sorokin and Pokhotelov, 2010;
43 Schekotov and Hayakawa, 2015; De Santis et al., 2017; Cordaro et al., 2018, 2019; Marchetti and
44 Akhoondzadeh, 2018; among others), although according to Vallianatos and Tzanis (2003) the magnetic
45 field oscillation frequencies that could be related to earthquakes have a range of at least three orders of
46 magnitude, so that kHz variations measured by other groups could also be included (Rozhnoi et al., 2008;
47 Büyüksaraç et al., 2015; Potirakis et al., 2018a; among others).

48

49

1 After the general description of each of these four topics, each theoretical framework is developed in
2 sections 2, 3, 4, and 5 respectively, maintaining the same order set out in this introduction. Finally, Section
3 6 summarizes the calculations and results obtained, and where the conclusions reached are presented.

4 5 **2 Rock physics, stress change, current generation and magnetic field**

6
7 The Zener-Stroh mechanism explain the generation and propagation of microcracks within a solid as the
8 pile-up of edges dislocations at a certain location due critical external mechanical stress or load (e.g. Stroh,
9 1955). The movement of an edge dislocation stops when they encounter an obstacle or barrier within the
10 solid (a scheme is shown in Figure 1a). Other edges dislocations may also reach the obstacle and will begin
11 to pile up if they cannot overcome that obstacle (Figure 1b). This stacking will create a shear stress τ , which
12 will create a microcracks (blue triangle in Figure 1b) (e.g. Fan, 1994 and references therein). The
13 microcracks can continue the propagation through different paths within the material (e.g. Xie and
14 Sanderson, 1995) (blue lines in Figure 1c). This will generate avalanches of cracks due to the nucleation of
15 neighboring cracks, which will allow large-scale cracks (blue lines in Figure 1d)(e.g. Main et al., 1993;
16 Wang et al., 2015 and references therein).

17
18 For the other hands, the edges dislocations are electrically neutral in thermal equilibrium (Whitworth, 1975).
19 However, the generation of microcracks is a dynamic process that breaks the ionic bonds that hold the solid
20 together, so the microcracks will be accompanied by polarization and current density (e.g. Vallianatos and
21 Tzani, 1999). This phenomena is known as the Motion of Charged Edge Dislocations model (MCD model)
22 (A scheme of polarization by MCD model is shown in Figure 1b, d). Several authors have shown that it is
23 possible to detect electrification when a rock sample is compressed (Pressure Stimulating currents)
24 uniaxially as shown in Figure 2a (e.g. Stavrakas et al., 2004 and references therein). It is thought that the
25 electrification is due to the MDC model and it can scale with the rock fracture (Figure 1d) (e.g. Vallianatos
26 and Triantis, 2008). According to Tzani and Vallianatos (2002) the generation of a current density J within
27 rocks can be represented as the temporal change in plastic deformation that rocks undergo under
28 compressional stress changes with time ($d\sigma/dt$) by:

29
30

$$J = \frac{\sqrt{2} q_l}{\beta b} \left(\frac{1}{Y_{eff}} \frac{d\sigma}{dt} \right) \quad (1)$$

31
32 Where q_l is the linear charge density of edge dislocation, b is the Burgers vector module, β varies between
33 1 and 1.5 and corresponds to the ratio $(\Lambda^+ + \Lambda^-)/(\Lambda^+ - \Lambda^-)$. Λ^+ and Λ^- represent dislocations number
34 created by compression and uniaxial tension within a rock (Whitworth, 1975; Vailianatos and Tzani, 1998),
35 and Y_{eff} is the Young's effective module (Turcotte et al., 2003). Figure 2b is a schematic showing the
36 direction of main currents J when the stress σ changes with time. The currents would tend to be parallel
37 to the axes of fracture, however, the electrification of rocks can also propagate in other directions within the
38 rock samples (Saltas et al., 2018) (Figure 1d).

39
40 On the other hand, Vallianatos and Tzani (2003) model the magnetic field on the lithosphere surface as the
41 magnetic field measured at the interface (with r and θ coordinates) of a conductive half-space (since the
42 rocks could become (semi)conductive when they undergo stress changes (Freund, 2003; Anastasiadis et al.,
43 2004)). Then, the magnetic field could be created by a polarized sphere embedded in this conductive
44 medium (Griffiths, 1996; Vallianatos and Tzani, 2003). A scheme can be seen in Figure 3. According to
45 Vallianatos and Tzani, 2003, the magnetic field on the surface of the lithosphere is determined by:

$$\vec{B}(t) = \frac{3\mu_m V}{4\pi r^2} \sin \theta \frac{\partial P_2}{\partial t} \hat{z} \quad (2)$$

Where μ_m is the magnetic permeability of the medium (half-space), $J_2 = \frac{\partial P_2}{\partial t}$ is the horizontal current density, r the distance to the sphere and the volume of the polarized sphere. Equation 2 is valid for any source that generates polarization changes in the medium. According to Vallianatos and Tzanis (2003) if electric current is generated by microcracks then has a volume lower than V . This can be seen from the scheme of Figure 1d, where microcracks are represented by blue lines and do not cover the entire volume. The paths of these microcracks and their distribution are fractal in nature (e.g. Xie and Sanderson, 1995; Uritsky et al., 2004). According to Turcotte (1997), the fractal volume of all the microcracks within the medium can be represented by:

$$V \approx \frac{4\pi}{3} \frac{AD}{3-D} (l_{max})^{3-D} S_R \quad (3)$$

Where l_{max} is the radius of the largest microcracks, D is the rock fractal dimension, $S_R \approx 1$ and $A \approx (D - 2)(l_{min})^{D-2} S$, where l_{min} is the radius of the smallest microcracks and S is the largest fracture area. Therefore, the maximum magnetic field ($\sin \theta = \pi/2$) is reached by replacing Equation 3 in 2:

$$B \approx \frac{\mu_m AD}{(3-D)r^2} (l_{max})^{3-D} J_2 \quad (4)$$

If J_2 correspond to the total current density J present in the half-space, then Equation 1 may be replaced in 6:

$$B \approx \frac{\sqrt{2}q_l \mu_m AD}{(3-D)\beta br^2} (l_{max})^{3-D} \left(\frac{1}{Y_{eff}} \frac{d\sigma}{dt} \right) \quad (5)$$

The only amounts that are explicitly time-dependent are B y $\frac{d\sigma}{dt}$ so that at the end, the temporal evolution of stress is proportional to the temporal integral of the magnetic field:

$$\sigma(t) = k(Y_{eff}) \int B(t) dt \quad (6)$$

With $k(Y_{eff}) = \left(\frac{\sqrt{2}q_l \mu_m AD}{(3-D)\beta br^2} \frac{(l_{max})^{3-D}}{Y_{eff}} \right)^{-1}$, k in units of A/m/s, or magnetization per seconds. The Equation 6 shows that it is possible to use the magnetic field to measure the evolution of stress in laboratory rocks. While k represents the geometric and mechanical properties of the source of electrification in laboratory rocks. If these experiments are correct, it would be expected that the magnetic field could reveal changes of stress on a geodynamic scale.

3 b-value, earthquake entropy, magnetic field and critical system

The seismicity of an area is statistically determined by Gutenberg-Richter's law on a geodynamic scale (Gutenberg and Richter, 1944). This law shows the number of earthquakes N with magnitude equal to or greater than M under the logarithmic relation: $\log N = a - bM$ and where parameters a and b depend on each study area. Each earthquake is generated by a sudden release of energy that is not recovered, so the Gutenberg-Richter's law describes the occurrence of a set of irreversible events (e.g. Stein and Wyssession,

2003). Since parameters a and b give information about the stress conditions in which these irreversible events occur, De Santis et al. (2011) developed the concept of earthquake entropy H based on Shannon entropy. Shannon's entropy measures the information of a system and its changes, however, the information of this system corresponds to the stress states of the lithosphere. In this way, the concept of earthquake entropy can be understood as the measure of the transition between different states of stress in the lithosphere. Using this, De Santis et al. (2011) found that the temporal variation of b-value of Gutenberg-Richter's law is related to earthquake entropy $H(t)$ through:

$$b(t) = b_{max} 10^{-H(t)} \quad (7)$$

Where $b_{max} = e \log_{10} e$, which is constant. As $H(t)$ can be understood as the measure of lithospheric stress (De Santis et al., 2011), the earthquake entropy can be directly related to stress through: $H(t) \equiv k_0 \sigma(t)$, where k_0 is in units of inverse stress. If the result shown by Equation 6 is self-similar and is also applicable at geodynamic scale, it implies that the b-value of Gutenberg-Richter's law (Equation 7) can be temporarily related to the magnetic field (Equation 6) by means of:

$$b(t) = b_{max} 10^{-k_0 k(Y_{eff}) \int B(t) dt} \quad (8)$$

On the other hand, De Santis et al. (2017), Marchetti and Akhoondzadeh (2018) and Cordaro et al. (2019b) found that the daily accumulation of magnetic field anomalies before and after the Nepal 2015 Mw7.8, Mexico 2018 Mw8.2, Maule 2010 Mw8.8, Iquique 2014 Mw8.2 and Illapel 2015 Mw8.3 earthquakes had a behavior similar to that of a critical system so the shape of the magnetic field can be approximated to a sigmoid function: $B \sim (1 + e^{-(t-t_0)})^{-1}$ (Figure 4 upper panel). The integral of the sigmoid is shaped: $\ln(1 + e^{t-t_0})$, so by choosing $k(Y_{eff}) = 1$ and $t_0 = 10$ in Equation 8, it may show the b-value temporal evolution (Figure 4 lower panel). In it, the b-value decreases before an earthquake, suggesting that there must be a change in the lithospheric regime (to an imminent collapse) because of increased seismicity prior to the occurrence of an earthquake, i.e., the existence of seismic or foreshock swarms (Schorlemmer et al., 2005; Ruiz and Madariaga, 2018). This is consistent with other research that suggests that a b-value decrease may serve as an earthquake predictor since a decreasing b-value means that earthquakes of higher magnitudes are required in order to satisfy the Gutenberg-Richter's law (Imoto, 1991; Kulhanek et al., 2018).

4 Seismic Moment, Moment Magnitude and Co-Seismic Magnetic Field

The area S of Equation 4 is considered to calculate the co-seismic magnetic relation B_{cs} with earthquakes, since it may correspond to the rupture area (Turcotte, 1997):

$$S \approx \frac{B_{cs} r^2 (3 - D)}{\mu_m J_2 D(D - 2)} (l_{min}^{2-D}) (l_{max}^{D-3}) \quad (9)$$

By replacing Equation 9 in the Scalar Seismic Moment equation M_0 ($M_0 = \mu A d \approx \mu S d$, where μ is the shear modulus and d the average slip) there is (Aki, 1966):

$$M_0 \approx \mu \frac{B_{cs} r^2 (3 - D)}{\mu_m J_2 D(D - 2)} (l_{min}^{2-D}) (l_{max}^{D-3}) d \quad (10)$$

1 With the Scalar Seismic Moment it is possible to calculate the Moment Magnitude Scale M_w ($M_w =$
 2 $\frac{2}{3} \log_{10}[M_0 \times 10^7] - 10.7$, for M_0 in Nm units, and where 10^7 has $(Nm)^{-1}$ units, Hanks and Kanamori,
 3 1979). Then, according to the co-seismic magnetic field the Moment Magnitude is:

$$4 \quad M_w \approx \frac{2}{3} \log_{10} \left[\left(\mu \frac{B_{cs} r^2 (3-D)}{\mu_m J_2 D(D-2)} (l_{min}^{2-D}) (l_{max}^{D-3}) d \right) \times 10^7 \right] - 10.7 \quad (11a)$$

6 If we consider the fractal dimension of granite ($D = 2.6$) (Turcotte, 1997) we have a more compact version
 7 of Equation 11a:

$$8 \quad M_w \approx \frac{2}{3} \log_{10} \left[\left(\frac{1}{3.9} \frac{\mu B_{cs}}{\mu_m J_2} \frac{dr^2}{(l_{min}^{0.6})(l_{max}^{0.4})} \right) \times 10^7 \right] - 10.7 \quad (11b)$$

11 Utada et al., (2011) reported a variation of $B_{cs} = 0.8$ nT at a distance r of the order of 100km from the
 12 fault plane during the Tohoku Earthquake 2011 Mw9.0 (Table 1). If we consider a minimum fracture of
 13 $l_{min} \approx 10^{-3}$ m (Shah, 2011), for granite $\mu_m = 13.5 \times 10^{-7}$ N/A² (Scott, 1983), $J_2 = 5 \times 10^{-6}$ A/m²
 14 (Tzanis and Vallianatos, 2002). In addition to the data provided by the USGS $A = 625 \times 260$ km², $d = 5.27$
 15 m, $\mu = 57$ GPa, where $l_{max} = \sqrt{A/\pi}$, the Moment Magnitude calculated with the magnetic field must be:

$$16 \quad M_w \approx \frac{2}{3} \log_{10} [(4.1463 \times 10^{22}) \times 10^7] - 10.7 = 9.0451 \quad (12a)$$

17 On the other hand, Johnston et al. (2006) reported changes in the magnetic field at several stations fairly
 18 close to Parkfield 2004 M6.0 earthquake (Table 1). For instance, the station GDM (Latitude: 35.8420;
 19 Longitude: -120.3380) measured a variation of $B_{cs} = 0.3$ nT at a distance $r \approx 2.5$ km from the fault. Using
 20 the general values μ_m, J_2 and l_{min} and the earthquake information: $\mu = 30$ GPa (Barbot et al., 2009), $A \approx$
 21 20×10 km² (Kim and Dreger, 2008) and $d = M_0/(\mu A) = 0.22$ m, with $M_0 = 1.3 \times 10^{18}$ Nm (Kim and
 22 Dreger, 2008). Moment Magnitude calculated with the magnetic field is:

$$23 \quad M_w \approx \frac{2}{3} \log_{10} [(8.1545 \times 10^{17}) \times 10^7] - 10.7 = 5.9076 \quad (12b)$$

24 The last example corresponds to the Loma Prieta 1989 M7.1 earthquake (Table 1). During the earthquake,
 25 at a distance of $r \approx 7$ km (Corralitos station) a peak of 0.9 nT that exceeded the intense (non-seismic)
 26 magnetic noise was measured (Fenoglio et al., 1995; Karakeliana et al., 2002; Thomas et al., 2009). Using
 27 the same values of this section μ_m, J_2 and l_{min} and for this earthquake: $B_{cs} = 0.9$ nT, $r \approx 7$ km (Karakeliana
 28 et al., 2002), $\mu = 30$ GPa and $A \approx 40 \times 10$ km² (Wallace and Wallace, 1993), $d = 1.2$ (Berkeley Seismology
 29 Lab), the Moment Magnitude calculated is:

$$30 \quad M_w \approx \frac{2}{3} \log_{10} [(9.1073 \times 10^{19}) \times 10^7] - 10.7 = 7.2729 \quad (12c)$$

31 The result of Equation 12a, b and c are similar to the real one, therefore Equation 11 is valid for the following
 32 analyses. The expected co-seismic magnetic field can be obtained from Equation 11b in accordance with
 33 distance:

$$34 \quad B_{cs} \approx 3.9 \frac{\mu_m J_2 (l_{min}^{0.6})(l_{max}^{0.4})}{\mu d r^2} 10^{\frac{3}{2}(M_w+6)} \quad (13)$$

35 The factor $10^{\frac{3}{2}(M_w+6)}$ here holds Nm units. Keeping the same values of μ_m, J_2 y l_{min} used so far, plus the
 36 data for the Tohoku 2011, Maule 2010, Sumatra 2004, Illapel 2015, Parkfield and Loma Prieta earthquakes
 37 (Table 1) the expected co-seismic magnetic variation for these events can be observed in Figure 5, which
 38 also shows that co-seismic magnetic variations can reach hundreds of kilometers of radial distance from the
 39
 40
 41

1 rupture area. Even these variations can reach the ionosphere (48 km high
2 https://www.nasa.gov/mission_pages/sunearth/science/science/atmosphere-layers2.html), which could
3 disturb the electron density within the ionosphere (Astafyeva et al., 2013; Kelley, 2017; Marchetti and
4 Akhoondzadeh, 2018; Potirakis et al., 2018b).

5
6

7 **5 Ultra Low Frequency Magnetic Signals**

8

9 After establishing the magnitude of the expected co-seismic magnetic field, it is necessary to determine the
10 order of magnitude of the oscillations present in the magnetic field. With this purpose, we consider that the
11 current density is oscillating and can be expressed as a function of the polarization density as: $J = \dot{P} = \omega P_0$,
12 so replacing the above in Equation 13 the following result is obtained:

13
14

$$15 \quad \omega \approx \frac{1}{3.9} \frac{\mu}{\mu_m} \frac{dr^2 B_{cs}}{(l_{min}^{0.6})(l_{max}^{0.4})P_0} 10^{-\frac{3}{2}(Mw+6)} \quad (14)$$

16
17

18 Where $P_0 = \delta\Lambda q_l dx / \sqrt{2}$ (Vallianatos and Tzanis, 1998), where the displacement of the fracture dx is
19 normally comparable to the Burgers vector and has a typical value of 5×10^{-10} m (Slifkin, 1993), a
20 minimum excess dislocation $\delta\Lambda = 1 \times 10^8$ m⁻² in semiconductor materials (JAMS-CS, 1999) and the
21 electrical charge line $q_l \sim 10^{-11}$ C/m (Slifkin, 1993). Considering $l_{min} \approx 10^{-3}$ m (Shah, 2011), $\mu_m =$
22 13.5×10^{-7} N/A² (Scott, 1983), $J_2 = 5 \times 10^{-6}$ A/m² (Tzanis and Vallianatos, 2002). Also the data for the
23 2010 Tohoku earthquake from Table 1 and $B_{cs} = 0.8$ nT and $r = 100$ km (Utada et al., 2011), the frequency
24 of the magnetic field oscillation associated with the 2011 Tohoku earthquake is of the order of 10⁶Hz;
25 however, the co-seismic displacement dx is not comparable to the Burgers vector but to the average
26 displacement d , i.e., $dx \approx d = 5.27$ m, so the magnetic field oscillation frequency is:

27
28

$$29 \quad \omega \sim 1.7 \text{ mHz} \quad (15)$$

30

31 Oscillations of the order of mHz have been detected by De Santis et al., (2017), which is consistent with
32 Equation 15, although frequencies of the order of μ Hz have been detected by Cordaro et al. (2018).
33 However, according to Vallianatos and Tzanis (2003), the frequency of magnetic field oscillation associated
34 with earthquakes is manifested in a range of at least three orders of magnitude, and this coincides with the
35 measurements of Cordaro et al. (2018) (μ Hz) and De Santis et al., (2017) (mHz). The above information
36 implies that in order to generate oscillation frequencies of the magnetic field in the pre-seismic stage similar
37 to the co-seismic frequencies, polarizations P_0 and current densities J within lithosphere should be similar
38 to those found in the co-seismic stage ($P_0 \sim 3.7 \times 10^{-3}$ C/m² and $J \sim 5 \times 10^{-6}$ A/m²) and even these
39 electrical conditions should be in some places of the lithosphere away from the fracture zone (main fault)
40 (Scoville, et al., 2015). On the other hand, if the polarization is similar and the current density is lower,
41 frequencies lower than those presented in Equation 15 are obtained. For example, if the lithosphere
42 polarization is maintained in the pre-earthquake stage and the current density decreases by two orders of
43 magnitude (i.e. $J \sim 10^{-8}$ A/m²) it is possible to obtain frequencies of the order of the μ Hz ($\omega = J/P_0 \sim$
44 10^{-6} Hz), which means that according to Equation 1, to create lower magnetic frequencies there must be a
45 lower stress change.

6 Summary and conclusions

This work studied the role of the magnetic field in the lithospheric dynamics; specifically, the physics that could be associated with various measurements that relate magnetic fields and earthquakes in a complete cycle, i.e. from a stress disturbance to the magnetic frequencies correlated with the occurrence of an earthquake. The results of each section are below:

Since a change in stress could trigger an earthquake, section two discussed the way a change in stress causes fractures within the rocks, the flow of electrical currents and the generation of magnetic fields. Therefore, the goal of this section was to achieve a relationship (equation 6) between the temporal evolution of stress with the integral over time of the magnetic field through a constant k . It was also possible to store all the electrical and mechanical information of the rocks in the constant k , which represent the magnetization per second of the rocks.

The goal of section three is of great relevance since it established a relationship between the behavior of the magnetic field (critical system) and a b-value decrease of the Gutenberg-Richter Law before and after the occurrence of earthquakes through earthquake entropy concept (Equation 8 and Figure 4). This was possible by assuming that the behavior of laboratory samples would exhibit the same physics as lithospheric rocks. Another goal of this section was to obtain a more physical interpretation about the entropy of earthquakes, its relation with magnetism and the impending earthquakes: As entropy can be considered as the energy diffusion of a system, the accumulation of stress (energy) in the lithosphere (open system) must be diffused. This means that the increment in the number of magnetic anomalies and their relationship with an increase in seismicity (earthquake swarms and/or seismic precursors) prior to the occurrence of large earthquakes are part of the energy diffusion mechanisms. However, this may also be interpreted inversely: The non-existence of seismic and magnetic precursors could violate the second law of thermodynamics. However, more studies are needed to corroborate whether the emission of magnetic signals really has any relationship with the entropy of earthquakes.

The great goal of section 4 was to find and corroborate an analytical relationship between co-seismic magnetic measurements and the magnitude of earthquakes (Equations 11a, b). It was possible to obtain Equations 11a, b by considering the area of rupture of the earthquake as a crack of the MCD model. Another goal of this section was to find an analytical relationship that would allow to determine the magnitude of co-seismic magnetic signals as a function of the epicentral distance (Equation 13). Figure 5 shows the intensity of the expected co-seismic magnetic variation for several earthquakes as a function of the distance to the area of rupture. It is observed that magnetic variations can easily reach the ionosphere for earthquakes of magnitudes greater than Mw8.3 (dashed blue line). Many magnetometers have the resolution of 0.1 nT (dashed red line) so magnetic variations produced by large earthquakes (~Mw9) could be detectable by magnetometers several hundred kilometers from the area of rupture. However, it is not expected that the magnetometers can detect magnetic variations related to small earthquakes, i.e. magnitudes much lower than Mw8.0 and tens of km from the source. For instance, during the L'Aquila 2009 M6.1 earthquake (central Italy), large magnetic variations were reported associated with displacements of the instruments due seismic waves (0.8 nT) at 6.7 km away from the source of the earthquake (Nenovski, 2015; Masci and Thomas, 2016). However, using $r \approx 6.7$ km (Nenovski, 2015), $Mw = 6.1$, $\mu = 32 \times 10^9$ Pa, $d = 0.4$ m and $A = 19 \times 13$ km² (Walters et al., 2019) and the same values of μ_m , J_2 y l_{min} used in section 5 into Equation 13 the expected co-seismic magnetic field is $B_{cs} \approx 0.04$ nT, which is quite close to the instrumental noise of the L'Aquila station (0.02 nT) (Villante et al., 2010), making these magnetic co-seismic variations almost undetectable.

1 The goal of section 5 was to theoretically find the oscillation frequencies of the magnetic field that may be
2 related to the occurrence of earthquakes. They were found to have frequencies of the order of mHz. The
3 existence of frequencies of different orders of magnitude prior to earthquakes were also analyzed. It is
4 concluded that for there to be magnetic variations in the lithosphere prior to earthquakes it is necessary that
5 the conditions of polarization and density of currents are similar to those that can be found in the co-seismic
6 stage. All these magnetic variations are part of the ULF reported by several authors.

7
8 Finally, it can be concluded that the controversial magnetic phenomena registered by different research
9 groups, behavior of cumulative daily number of magnetic anomalies, co-seismic magnetic field and
10 oscillation frequencies of the magnetic field, can all have the same and unique physical origin: the cracking
11 of brittles and semi brittles materials of the crust due to stress changes. However, there is still no clarity
12 about how these stress changes can generate the nucleation of earthquakes. Therefore, future studies should
13 focus on interpreting magnetic records as a tool to measure stress changes in the lithosphere. Especially
14 when there are no appreciable deformations of the lithosphere. This could provide new information to
15 seismic source studies.

 8 **Captions Figure**

9
 10 Figure 1: Schematic description of the generation of microcracks and currents due to mechanical stresses
 11 on rocks. a) A moving edge dislocation meets a barrier or obstacle. b) A set of edges dislocations are piled
 12 up generating a microcracks (blue triangle). The microcracks generate the breaking of ionic bonds, which
 13 allows polarization of the microcracks. c) Microcracks can propagate through different paths (blue lines).
 14 d) An avalanche of microcracks can cause larger scale cracks.

15
 16 Figure 2: Outline of the experiments carried out with rocks during compressive modes. a) The change of
 17 effort σ generates one failure of the rock at an angle 2θ . The black arrows indicate the relative slip within
 18 the rock. b) Electrification of the rock in microcracks zones close to the fault. The yellow arrows indicate
 19 the direction of the generated currents.

20
 21 Figure 3: Schematic magnetic field measured in an interface due to a polarized sphere of volume V
 22 embedded in a medium with magnetic permeability μ_m .

23
 24 Figure 4: Upper: Temporal evolution of the magnetic field in the form of a critical system (De Santis et
 25 al., 2017, Marchetti and Akhondzadeh, 2018). Lower: Temporal evolution of b-value prior to an
 26 earthquake. The vertical line indicates when an earthquake occurs according to De Santis et al. (2017).
 27

28 Figure 5: Expected co-seismic magnetic field as a function of distance for the Tohoku 2011, Maule 2010,
 29 Sumatra 2004, Illapel 2015 earthquakes and Parkfield 2004 (see Table 1 for earthquakes information).
