Abstract

Recently, it has been shown theoretically how the lithospheric stress changes could be linked with magnetic anomalies, frequencies, spatial distribution and the magnetic-moment magnitude relation using the electrification of microfractures in the semi brittle-plastic rock regime [Venegas-Aravena *et al.* Nat. Hazards Earth Syst. Sci. **19**, 1639 – 1651 (2019)]. However, this Seismo-electromagnetic Theory has not been connected with the fault's properties in order to be linked with the onset of the seismic rupture process itself. In this work we provide a simple theoretical approach to one of the key parameters for seismic ruptures as the friction coefficient and the stress drop. We use sigmoidal functions to model the stress changes in the non-elastic regime within lithosphere. We determine the temporal changes in frictional properties of faults. We also use a long-term friction coefficient approximation that depends on the fault dip angle, and four additional parameters that weigh the first and second stress derivative, the spatial distribution of the non-constant stress changes and the stress drop. We found that the friction coefficient is not constant in time and evolves prior and after the earthquake occurrence regardless of the (non-zero) weight used. When we use a dip angle close to 30 degrees and the contribution of the second derivative is more significant than the first derivative, the friction coefficient increases prior to the earthquake. During the earthquake event the friction drops. Finally, the friction coefficient increases and decreases again after the earthquake occurrence. Important to mention that when there is no contribution of stress changes in the semi brittle-plastic regime, no changes are expected in the friction coefficient.

Keywords: Seismo-electromagnetic Theory, Friction coefficient, Magnetism, Earthquakes, LAIC effect.

1.- Introduction

The electromagnetic phenomena that could be linked with earthquake occurrences are usually considered within the lithosphere-atmosphere-ionosphere-coupling effect (or LAIC effect) (e.g. De Santis *et al.*, 2019a). Some of these electromagnetic phenomena have been recorded both prior and after the earthquakes using different methodologies, data, earthquakes and instrumentation. For example, some researchers have shown co-seismic magnetic variations during some earthquakes (e.g. Utada *et al.* (2011) during Tohoku 2011 earthquake). While others researches have been focusing on the oscillation frequency ($\mu\text{Hz} - \text{kHz}$ range) of magnetic field prior to the occurrence of some earthquakes (Schekotov and Hayakawa, 2015; Cordaro *et al.*, 2018; Potirakis *et al.*, 2018a, b, among other). One of the most recent methodology corresponds to the measurement of magnetic anomalies, which detects the number of

1 magnetic peaks (or events) that exceed a given threshold that represents the normal conditions of the
 2 magnetic field during long periods of time (De Santis et al., 2017). There is some research that shows that
 3 the increases in the number of anomalies could be linked with the impending earthquakes. For instance,
 4 De Santis et al. (2019b) have recently found an increase in the amount of daily magnetic anomalies prior
 5 to 12 major earthquakes between 2014 and 2016. These magnetic anomalies were confirmed by other
 6 researchers (e.g. Marchetti and Akhoondzadeh (2018)).

7
 8 It is well known from laboratory experiments that rock samples undergoing fast changes in the semi
 9 brittle-plastic rock regime generate microfractures, displacement of dislocations and electrification (e.g.
 10 Anastasiadis et al., 2004). This physical mechanism of rock electrification is described mathematically by
 11 The Motion of Charged Edge Dislocations (MCD) model (e.g. see Vallianatos and Tzanis (1998) or
 12 Vallianatos and Tzanis (2003) for a comprehensive derivation of the MCD model). This model is a
 13 plausible electromechanical mechanism that could explain the magnetic measurements. Starting from the
 14 experimental evidences Venegas-Aravena et al. (2019) developed a Seismo-electromagnetic Theory based
 15 on microcracks and stress changes. This theory showed how the fractal nature of the cracks explains the
 16 observed magnetic frequency range, the co-seismic magnetic field and the conditions for generating
 17 magnetic anomalies. However, this theory (neither the others, e.g. Freund, 2003, De Santis et al., 2019a)
 18 does not explain any change on the parameters that control the generation of seismic ruptures using
 19 magnetic measurements. This prevents to link the seismo-electromagnetism and the classical seismology.
 20 In this work, we address this link using one of the key points that control seismic rupture and slip on the
 21 fault: friction force and stress drop. Our model uses the tectonic geometry and stress drop of Maule 2010
 22 Mw8.8 earthquake in order to provide real data and validate our analysis. The paper is divided as follows,
 23 in section 2 we consider the friction coefficient adding the brittle-plastic stress changes contribution to the
 24 usual elastic stress. In section 3 we discuss the temporal variations of the brittle-plastic friction and their
 25 connections with the spatial distribution on the fault and the lithosphere. In section 4 we provide the
 26 relation between the stress drop and the co-seismic magnetic field. The spatial-temporal friction
 27 coefficient along the fault is calculated by adding the elastic stress drop. In section 5, the Gutenberg-
 28 Richter's law is written in terms of the semi brittle-plastic shear stress. The rupture time is discussed in
 29 section 6. Finally, the discussion and conclusions are drawn in section 7.

31 **2. - Friction coefficient in the brittle-plastic regime**

32
 33 The standard friction force can be understood as the complex dissipation of mechanical energy in the form
 34 of plastic or elastic deformation of asperities (mechanical interaction), thermal dissipation (heat) and the
 35 adhesion (interatomic interaction) of two sliding surfaces (e.g. Sun and Mosleh, 1994). When we consider
 36 a particular contact area between two dry surfaces, the static friction coefficient μ that describes this
 37 interaction can be written approximately as the ratio of the shear τ and the normal N stress (load) as shown
 38 by Equation (1) (e.g. Byerlee, 1978, Chen, 2014, and references therein).

$$39 \quad \mu = \frac{\tau}{N}. \quad (1)$$

40 The static friction coefficient μ gives some information about the contact behavior. For instance, μ tends
 41 to be large when the contact area is increased due to the surface's plastic deformation (e.g. Chen, 2014). If
 42 we also consider the pure plastic regime, we can add a small plastic shear stress ($\delta\tau_{plastic}$) and a small
 43 plastic normal stress ($\delta N_{plastic}$) contribution in Equation (1) leading to the following expressions:

$$44 \quad \tau = \tau_{elastic} + \delta\tau_{plastic}. \quad (2)$$

$$N = N_{elastic} + \delta N_{plastic}. \quad (3)$$

If we do not consider the pure plastic effects, the plastic contribution vanishes and the ratio of $\tau_{elastic}$ and $N_{elastic}$ describes the usual (non-linear) friction behaviors that occur during the complete frictional cycle: Pre-Sliding (increase of friction coefficient when there is no-apparent or residual displacement), Gross-Sliding (observable displacement and decrease of friction coefficient) and Healing (friction coefficient recovery) (e.g., Parlitz et al., 2004, Marone and Saffer, 2015, Papangelo et al., 2015, and references therein).

Venegas-Aravena et al. (2019) state that the electrification within rocks is mainly due to a non-constant stress change during the semi brittle-plastic transition. This means that the temporal changes of the semi brittle-plastic stress ($\delta\sigma_{sbp}$) rules the total plastic stress ($\delta\sigma_{plastic}$). Thus, it implies that the plastic shear and normal stress can be written in terms of a linear combination of the temporal changes of $\delta\sigma_{sbp}$ as shown in Equations (4) and (5).

$$\delta\tau_{plastic} = k_1\delta\tau_{sbp} + k_2\delta^2\tau_{sbp} + o(\delta^2\tau) = k_1\dot{\tau}_{sbp}\delta t + k_2\ddot{\tau}_{sbp}(\delta t)^2 + o((\delta t)^2), \quad (4)$$

$$\delta N_{plastic} = k_3\delta N_{sbp} + k_4\delta^2 N_{sbp} + o(\delta^2 N) = k_3\dot{N}_{sbp}\delta t + k_4\ddot{N}_{sbp}(\delta t)^2 + o((\delta t)^2), \quad (5)$$

where k_1 , k_2 , k_3 and k_4 are dimensionless constants to be determined later, δt and $(\delta t)^2$ are the temporal variations from the first and second order time contribution, respectively. The temporal variations of the shear and normal semi brittle-plastic stress contributions are $\dot{\tau}_{sbp}$, $\ddot{\tau}_{sbp}$, \dot{N}_{sbp} and \ddot{N}_{sbp} respectively. The series expansions in Equations (4) and (5) are convenient and allow to write the plastic contribution as a sum of stresses that depend on time. This is relevant because the seismic-electromagnetic theory seeks to relate the temporal variable of the earthquake and the stress within the lithosphere. From now on, we refer to the semi brittle-plastic stress as the uniaxial stress σ .

It is possible to relate this shear, and the normal stresses from Equations (4) – (5) with the uniaxial stress using the geometry shown in Figure 1. In this Figure, we have a simple schematic representation of the lithosphere under uniaxial stress change $d\sigma/dt$ in the presence of a fault with static friction coefficient μ and a dip angle of 30 degrees. We can write this uniaxial stress change in terms of the dip angle θ , normal and tangential direction (in red on Figure 1) of the fault, as shown in the following expression

$$\frac{d\sigma}{dt} = \frac{d\sigma}{dt} (-\sin\theta \hat{N} + \cos\theta \hat{t}), \quad (6)$$

where $d\sigma/dt$ corresponds to the magnitude of uniaxial temporal stress change. Using this expression, we write the brittle-plastic stress contributions in term of uniaxial stress change as:

$$\dot{N} = -\frac{d\sigma}{dt} \sin\theta. \quad (7)$$

$$\dot{\tau} = \frac{d\sigma}{dt} \cos\theta. \quad (8)$$

Replacing the Equations (2) – (8) in Equation (1), and considering a second-order linear combination, we obtain the static friction coefficient as a function of time, the fault angle and the semi brittle-plastics changes within lithosphere given by:

$$\mu(t) \approx \frac{\tau_0 + (k_1 \dot{\sigma} + k_2 \ddot{\sigma} \delta t) \cos\theta \delta t}{N_0 - (k_3 \dot{\sigma} + k_4 \ddot{\sigma} \delta t) \sin\theta \delta t}, \quad (9)$$

1 where the dots above σ are the notation for the first and second temporal derivative of the uniaxial stress.
 2 According to Venegas-Aravena et al. (2019), the temporal stress change $\dot{\sigma}$ has approximately a sigmoidal
 3 shape, which can be written as $\dot{\sigma}(t) = a/(b + e^{(t_0-t)*w})$, where a, b, w and t_0 are constants. In Figure 2
 4 we represent $\dot{\sigma}$ and $\ddot{\sigma}$ as a function of time where we have used $a = b = w = 1$ and $t_0 = 10$ a.u..
 5 According to De Santis et al. (2019b), most of the earthquakes recorded occurred close to the center of the
 6 Figure 2, which is when $t_{EQ} = t_0$. For instance, Marchetti and Akhoondzadeh (2018) have shown that the
 7 Mexico earthquake Mw8.2 occurred after this time ($t_{EQ} > t_0$). They also use daily values of magnetic
 8 anomalies ($B \propto \frac{d\sigma}{dt}$, which comes directly from the experimental equation: $I = \alpha_0 \frac{d\sigma}{dt}$, where I is the
 9 electric current and α_0 is a constant of proportionality (see Vallianatos, F. and Triantis and references
 10 therein)), thus $\delta t = 1 \text{ day} = 86400 \text{ s}$.

11 Let us now estimate the values of the constants of Equation (9). First, the dip or subduction angle θ ,
 12 according to Maksymowicz (2015), this angle is close to 20 degrees at the depth ($\sim 30 \text{ km}$) and location
 13 ($35^\circ 54' 32''\text{S}$, $72^\circ 43' 59''\text{W}$) of the Maule 2010 earthquake. Maksymowicz (2015) claimed that the static
 14 friction coefficient in the Chilean convergent margin is close $\mu_{ch} \approx 0.5$. Lamb (2006) calculated that the
 15 initial value of τ_0 is 15.4 MPa (constant) in southern Chile. Using μ_{ch} , it is expected that N_0 should be
 16 approximately equal to 30.8 MPa (constant).

17 In addition, rock experiments show that the values of $\dot{\sigma}$ are close to 1 MPa/s (e. g. Saltas et al., (2018)).
 18 This implies that $|k_1|$ and $|k_3|$ must be close to $\sim 10^{-4}$, in order to balance the δt factor. The values
 19 of k_2 and k_4 must be equal or lesser than $\sim 10^{-9}$, otherwise the values of the friction coefficient would be
 20 greater than 1. If we consider an initial increase of the normal stress, the sign of the constants should
 21 be negative for k_3, k_4 and positive for k_1, k_2 . In Figure 3 we can see how the friction coefficient changes
 22 in time, when using values of k_1 and k_3 described above, and different values of k_2 and k_4 (second order
 23 contribution). When we use values of k_2 and k_4 of the order of $\sim 10^{-9}$, it is possible to observe how the
 24 friction decreases after the earthquake. Furthermore, it is important to note that the earthquake does not
 25 occur when the friction has its maximum value, but occurs close to the maximum. When we use values of
 26 k_2 and k_4 similar or lesser than $\sim 10^{-10}$ the contribution of $\ddot{\sigma}$ in Equation (9) vanishes.

27 Another critical point is related to the differential time. For instance, when we consider $\delta t \leq 1 \text{ s}$, the semi
 28 brittle-plastic stress term vanishes and the usual friction is recovered. This fact is especially relevant
 29 because the semi brittle-plastic contribution to the friction coefficient seems to be relevant only during
 30 large time scales. To summarize, the friction coefficient of Equation (9) could be seen as a generalization
 31 of the standard friction coefficient when large time scales are considered.

32

33

34 **3. - Spatial distribution of stress changes and friction**

35

36 In the previous section we have linked the friction coefficient to the semi brittle-plastic regime that
 37 generates microcracks and electrification within the rocks. An important caveat is that this phenomenon
 38 does not occur everywhere. For instance, Dobrovolsky et al. (1979) described a specific "preparation
 39 zone" required close to the future hypocenter in order to accumulate sufficient stress to trigger the
 40 earthquake. This criterion has been widely used by researchers to establish a threshold for determining
 41 where the magnetic measurements can be associated to earthquakes (e.g. De Santis et al., 2019a, De Santis
 42 et al., 2019b). In other words, the phenomenon is local. However, if this is applied, a variation of the
 43 friction coefficient related to the rock electrification phenomenon close to the fault would be expected,
 44 while a friction variation outside the zones of semi brittle-plastic influence would not.

1 In order to consider the local variations, we add to our model a separable spatial function to the uniaxial
 2 stress as given by $\bar{\sigma}(x, t) = \gamma(x)\sigma(t)$ (for simplicity we choose a uniaxial dependence).
 3 Where $\sigma(t)$ correspond to the same time function as considered in section 2 and $\gamma(x)$ is the dimensionless
 4 spatial distribution parallel to the fault (see the coordinate system in Figure 4). Let us mention that the
 5 values of $\gamma(x)$ are different when constant and non-constant stress changes are considered. With this in
 6 mind, we can re-write Equation (9) as:

$$7 \quad \bar{\mu}(x, t) \approx \frac{\tau_0 + \gamma(k_1 \dot{\sigma} + k_2 \ddot{\sigma} \delta t) \cos \theta \delta t}{N_0 - \gamma(k_3 \dot{\sigma} + k_4 \ddot{\sigma} \delta t) \sin \theta \delta t}. \quad (10)$$

8 After straightforward derivations, we get that the gradient of the friction coefficient along the fault using
 9 Equation (10) is given by:

$$10 \quad \nabla \bar{\mu}(x, t) = \gamma' \frac{AN_0 + B\tau_0}{(N_0 - \gamma B)^2} = \gamma' \frac{\alpha \dot{\sigma} \delta t + \beta \ddot{\sigma} \delta t^2}{(N_0 - \gamma B)^2}, \quad (11)$$

11 where $A = (k_1 \dot{\sigma} + k_2 \ddot{\sigma} \delta t) \cos \theta \delta t$, $B = (k_3 \dot{\sigma} + k_4 \ddot{\sigma} \delta t) \sin \theta \delta t$, $\alpha = N_0 k_1 \cos \theta + \tau_0 k_3 \sin \theta$ and
 12 $\beta = N_0 k_2 \cos \theta + \tau_0 k_4 \sin \theta$. Equation (10) and (11) imply that if we distribute the constant and non-
 13 constant temporal stress change in a non-uniform manner along the fault, then, it could be said that this
 14 phenomenon is local. This can be understood using the example of Figure 4: The Figure 4a shows a blue
 15 area of length L where we have a non-constant temporal stress change. There one observes a change in the
 16 friction coefficient inside the projected gray area (Figure 4b). Conversely, outside the area of length L
 17 (Figure 4c), we assume a constant stress change then there is no change in the friction coefficient (Figure
 18 4d). Let us remind that the entire fault suffered from stress accumulation during the entire process.
 19 However, only the grey area is directly affected by the friction change. This shows that the temporal
 20 friction changes are restricted only to a specific area (grey area) on the fault. Hence, one observes non-
 21 zero friction coefficient gradient on the fault and we have a local phenomenon ($\nabla \bar{\mu} \neq 0 \Leftrightarrow Local$).

22
 23 The process described in Figure 4 reveals why the magnetic measurements are not global. It also validates
 24 the locality criteria in terms of fault properties. Furthermore, the spatial distribution of magnetic field
 25 measurements is expected to have a length scale comparable to the friction coefficient change due to the
 26 dependency of $\gamma(x)$ in Equation (10). That is, the larger the detection area of magnetic anomalies, the
 27 larger the area where fault friction is changing. In addition, Venegas-Aravena et al. (2019) described how
 28 the uniaxial stress change implies a change in the b-value of the Gutenberg-Richter Law. It also implies
 29 that a significant earthquake is needed in order to satisfy this change in the Gutenberg-Richter Law.
 30 Therefore, a greater expected magnitude could be related to changes in the coefficient of friction within an
 31 area within the fault. However, changes in the friction coefficient do not directly imply the earthquakes
 32 generation itself.

34 **4. - Stress drop and total friction coefficient: Spatial-temporal behavior**

35
 36 Up to this point, no changes in the elastic stresses have been considered in Equation (10). This section
 37 focuses on one of the elastic parameter that is involved in the seismic rupture process: the stress drop $\Delta\tau$.
 38 This parameter is one of the most relevant because it shows the shear stress differences prior and after the
 39 onset of the earthquake within the fault rupture area (e.g. Aki, 1966). Furthermore, this parameter is also
 40 related to the seismic waves radiated (through the corner frequency of waves) and the seismic moment
 41 M_0 (e.g. Eshelby, 1957, Brune, 1970, Baltay et al., 2011, and references therein). If we consider a circular

1 rupture area with radius d_{crack} , the stress drop $\Delta\tau$ is linked with the seismic moment M_0 through the
 2 following equation (Eshelby, 1957).

$$3 \quad \Delta\tau = \frac{7}{16} \frac{M_0}{d_{crack}^3}. \quad (12)$$

4 On the other hand, the seismic moment M_0 and the moment magnitude Mw in terms of the co-seismic
 5 magnetic field are also related. Hence, the seismic moment is given by:

$$6 \quad M_0 \approx \mu_{sm} \frac{B_{cs} r^2 (3-D)}{\mu_m J D(D-2)} (l_{min}^{2-D})(l_{max}^{D-3})d, \quad (13)$$

7 where μ_{sm} is the shear modulus, d the average slip, D fractal dimension of rock, B_{cs} the co-seismic
 8 magnetic field, J corresponds to the total electric current density, μ_m is the magnetic permeability of the
 9 medium, r the distance to the fault, l_{max} and l_{min} are the radius of the circular rupture area and the
 10 smallest microcrack length, respectively. The circular rupture is calculated using $l_{max} = \sqrt{S/\pi}$,
 11 where S corresponds to the total rupture area.

12 In this case, the rupture geometry is circular in both formulations, thus, $d_{crack} = l_{max}$. Replacing this
 13 into Equation (13) and Equation (12) we obtain:

$$14 \quad \Delta\tau \approx \frac{7}{16} \mu_{sm} \frac{B_{cs} r^2 (3-D)}{\mu_m J D(D-2)} (l_{min}^{2-D})(l_{max}^{D-6})d. \quad (14)$$

15 Equation (14) relates the stress drop with the co-seismic magnetic field, seismic rupture, and the electrical
 16 and mechanical properties of rocks (lithosphere). We can use the data from the Maule earthquake in order
 17 to compare the result of Equation (14) with those found by other researchers. If we use the fault
 18 values: $\mu_{sm} = 3.3 \times 10^{10} Pa$, $d = 4 m$ and $S = 450 \times 120 km^2$ (Vigny et al., 2011; Yue et al., 2014),
 19 the granite rock and brittle properties: $\mu_m = 13.5 \times 10^{-7} NA^{-2}$ (Scott, 1983), $J = 5 \times$
 20 $10^{-6} Am^{-2}$ (Tzanis and Vallianatos, 2002), $l_{min} = 10^{-3} m$ (Shah, 2011) and $D = 2.6$ (Turcotte, 1997).
 21 The magnetic data $B_{cs} \approx 0.1 nT$ at $r \approx 250 km$ (Figure 5 in Venegas-Aravena et al. (2019)), we obtain a
 22 stress drop $\Delta\tau \approx 3.4 MPa$. This result is in close agreement with the result of Luttrell et al. (2011) (4
 23 MPa). Using this value, we can calculate the elastic shear stress as:

$$24 \quad \tau_{elastic} = \tau_0 - \gamma_2 \Delta\tau H(t - t_0), \quad (15)$$

25 where $H(t - t_0)$ correspond to the step function centered at t_0 (the moment of the earthquake occurrence)
 26 and γ_2 is a dimensionless second step function that represents the fault area where the stress drop exists.
 27 This means that $\gamma_2 = 0$ outside the rupture area, and $\gamma_2 = 1$ if the point is within the rupture area.
 28 Combining this result into Equation (10), we calculate the total friction coefficient $\bar{\mu}_T$ of the fault as:

$$29 \quad \bar{\mu}_T(x, t) \approx \frac{\tau_0 - \gamma_2 \Delta\tau H(t - t_0) + \gamma(k_1 \dot{\sigma} + k_2 \ddot{\sigma} \delta t) \cos \theta \delta t}{N_0 - \gamma(k_3 \dot{\sigma} + k_4 \ddot{\sigma} \delta t) \sin \theta \delta t}. \quad (16)$$

30 This total friction coefficient $\bar{\mu}_T$ is especially relevant because of the dependence of the co-seismic
 31 magnetic field B_{cs} (through the stress drop $\Delta\tau$) and the magnetic anomalies (through the relation $B \propto \dot{\sigma}$).
 32 Furthermore, Equation (16) explains the spatial distribution of friction along the fault in addition to their
 33 time variations. In Equation (16), the spatial changes of friction (represented by γ) are not necessarily
 34 related to the seismic rupture area (represented by γ_2). However, in the case when they are related, one
 35 expects that γ_2 is a function of γ . That is $\gamma_2 = \gamma_2(\gamma(x))$. In the general case the total friction coefficient
 36 gradient can be written as:

$$37 \quad \nabla \bar{\mu}_T = \nabla \bar{\mu} + \Delta\tau H(t - t_0) \Gamma(\gamma, \gamma_2), \quad (17)$$

1 where $\Gamma(\gamma, \gamma_2) = \frac{1}{(N_0 - \gamma B)^2} [\gamma_2'(\gamma B - N_0) - \gamma' \gamma_2 B]$, $\nabla \bar{\mu}$ is the friction gradient already defined in
 2 Equation (11), and the same definition for A and B are used. The second term of Equation (17) implies
 3 that a more complex spatial friction distribution on the fault is expected after the earthquake. When no
 4 brittle-plastic contribution is considered ($\gamma = 0$), the friction is only proportional to the gradient of fault
 5 rupture distribution ($\nabla \bar{\mu}_T = -\Delta \tau H(t - t_0) \gamma_2' / N_0$). When $\gamma_2 \approx \gamma$, the two terms of the Total Friction
 6 Coefficient will be proportional to the spatial distribution gradient ($\nabla \bar{\mu}_T \propto \gamma'$). If the earthquake does not
 7 occur, the second term vanishes and Equation (11) is recovered.

8 As an illustration, if we consider one point affected by the rupture area, and the same values as in Figure
 9 3, we can calculate the shape of the total friction coefficient as shown in Figure 5. The three cases show an
 10 increase of the friction coefficient prior to the earthquake, and in the three cases the friction reaches its
 11 maximum values before the earthquake (at $t=10$ a.u.). The subsequent decrease is due to the stress drop
 12 influence calculated using the co-seismic magnetic field B_{CS} . After the earthquake, in none of the cases,
 13 the friction is completely recovered to its values before the earthquake.

14 As a second illustration, it is also possible to compare the temporal behavior of the friction coefficient at
 15 different points within the fault. For instance, in Figure 6 (top) we show the different friction behaviors
 16 expected if we consider the Total friction coefficient. The red area indicates the area where the friction
 17 drop occurs. A friction drop is not expected to occur outside the red zone. However, it is possible to
 18 observe differences in the coefficient of friction close to the rupture zone where $\gamma_2 \neq \gamma$ (yellow area).
 19 Both in the rupture zone and its surroundings (marked as red and yellow areas respectively in Fig.6) show
 20 changes in the coefficient of friction prior to the rupture. In stark contrast, the standard friction drop is
 21 expected only in the rupture zone (red area) and a non-measurable change in friction is expected prior to
 22 the earthquake (Figure 6 bottom).

23 We can summarize our analysis by using two different distributions of γ and γ_2 . For instance, in Figure 7
 24 we show the double-sigmoidal distribution for γ and γ_2 (black and red curves respectively) along the fault
 25 x-direction (of total length $2x_{half}$). The dimensionless distribution is defined as a combination of
 26 sigmoidal function used in the section 2 as:

$$27 \quad \gamma(x), \gamma_2(x) = \begin{cases} \frac{a}{b - e^{(x_0 - x) * w}}, & x < x_{half} \\ 1 - \frac{a}{b - e^{(x_0 + L - x) * w}}, & x \geq x_{half} \end{cases}. \quad (18)$$

28 If we consider $a = b = 1$ and $x_{half} = 10$ a.u. in both distributions, and $x_0 = 5$ a.u. , $L = 10$ a.u. and $w =$
 29 1 a.u. for γ and $x_0 = 8$ a.u. , $L = 4$ a.u. and $w = 10$ a.u. for γ_2 , we get the two distributions of Figure 7.
 30 These values indicate the same situation as discussed in Figure 6. That is a rupture length ($L = 4$ a.u. in γ_2
 31 represents the x-direction of the red area in Figure 6) lesser than the friction coefficient influenced by semi
 32 brittle-plastic stress (here $L = 10$ a.u. in γ represent the x-direction of the yellow area in Figure 6). Using
 33 both sets of values, those used in the stress drop (Equation (14)) and also the same k -parameters used in
 34 Equation (9), we calculate the total friction coefficient (Equation (16)) as shown in Figure 8 (case $k_2 =$
 35 $k_4 = 10^{-9}$). At time $t = 0$ a.u., no friction changes occur ($\bar{\mu}_T = 0.5$). However, the friction increases at
 36 $t=5$ a.u., where the spatial distribution γ is initially defined as non-zero ($x \in [5, 15]$ a.u.). The friction
 37 increases up to $t=10$, a.u. the time corresponding to the earthquake occurrence. The earthquake rupture
 38 length is shown as a sudden friction decrease ($x \in [8, 12]$ a.u.) from 0.76 to 0.67. In the zone immediately
 39 close to the rupture, the friction increases even more up to the maximum values (0.77), while the rupture
 40 section decreases the friction. After this time ($t \sim 12$ a.u.), the rupture and the surrounding section
 41 experience a friction decrease.

1 The case of $k_2 = k_4 = 10^{-10}$ is shown in Figure 9. The rupture is shown as a blue area at $t=10$ a.u. in
 2 section $x \in [8, 12]$ a.u.. At this time and location, we observe that the friction decreases to similar initial
 3 values (~ 0.5). The friction of this rupture section increases after the earthquake up to ~ 0.6 . On the other
 4 hand, the rupture's surrounding section increases up to the maximum values (~ 0.7). Despite those facts,
 5 the initial ($t=0$ a.u.) and final ($t=20$ a.u.) friction values are almost identical for both cases. For instance,
 6 the rupture area has values close to 0.6 in Figures 8 and 9. The surrounding rupture section has values
 7 close to 0.69 in both cases and the section away from the rupture (close to $x=0$ a.u. and $x=20$ a.u.) always
 8 has the same initial value (0.5) in both cases. However, both cases exhibit a complex time behavior after
 9 the earthquake occurrence, as Equation (17) indicates.

10 Finally when the semi brittle-plastic contribution is not considered, we get that $\gamma = 0$. The result is shown
 11 in Figure 10 and is only observed when the sudden friction decrease at $t=10$ a.u. (and $x \in [8, 12]$ a.u.). In
 12 this later case none of the other complex friction behavior is observed.

14 5. - The semi brittle-plastic Gutenberg-Richter law

16 A general expression for friction has been obtained in Equation (16). Following this we can adapt the
 17 Gutenberg-Richter's law in this semi brittle-plastic context. Let us remind that this law establishes a
 18 relation between the number of earthquakes in a region and the magnitude of them (Gutenberg and
 19 Richter, 1944). Mathematically, this link is written as: $\log N = a - b \times m$. Where N is the number of
 20 earthquakes with magnitude equal to or greater than m , and a and b are constants. However, the b -value
 21 of this law might evolve in time. Indeed, De Santis et al. (2011) determined an equation that relates the
 22 temporal evolution of the parameter b ($b = b(t)$) and the measure of the entropy (stress) $H(t)$ of that
 23 region as $b(t) = b_{max} 10^{-H(t)}$, where $b_{max} = e \log_{10} e$. The entropy $H(t)$ is assumed to be proportional
 24 to the real stress in the lithosphere (Venegas-Aravena et al., 2019). If we consider the total shear
 25 stress τ_T in the fault described by Equation (16), we can write:

$$26 \quad b(t) = b_{max} 10^{-k_0 \tau_T}, \quad (19)$$

27 where $\tau_T = \tau_0 - \gamma_2 \Delta \tau H(t - t_0) + \gamma(k_1 \dot{\sigma} + k_2 \ddot{\sigma} \delta t) \cos \theta \delta t$ and k_0 is a constant with dimension of an
 28 inverse stress. If we use the same values as in Figure 5 ($k_2 = k_4 = 10^{-9}$), we get the temporal evolution
 29 of the b -value (Figure 11a). Figure 11a shows a decrease in the b -value until the earthquake occurs (at
 30 $t=10$ a.u.). Figure 11b shows the Gutenberg-Richter's law at three instants of time (and $k_0 = 0.01$, $a=1$):
 31 initial ($t=0$ a.u.), prior to the earthquake ($t=9$ a.u.) and final ($t=20$ a.u.). This Figure shows how large
 32 earthquakes ($M_w \sim 6$) are not expected at the initial moment (blue line). However, just before the
 33 earthquake, an M8-class earthquake should be expected (green line). After the earthquake one would only
 34 expect earthquakes no greater than $M_w \sim 7$ to exist (red line). Figure 12a and 12b show the same previous
 35 case but now considering $k_2 = k_4 = 10^{-10}$. In this case there is no difference between time, immediately
 36 before the earthquake ($t=9$ a.u.) and at the final time ($t=20$ a.u.). In addition, using these parameters ($k_2 =$
 37 $k_4 = 10^{-10}$), smaller magnitudes are reached than using $k_2 = k_4 = 10^{-9}$ ($M_w \sim 7$ and $M_w \sim 8$
 38 respectively). This is why it is more likely to find earthquakes of greater magnitude when considering the
 39 contribution of the $\ddot{\sigma}$ term in the analysis.

41 6. - Rupture time t_0

42 In section 5 we determine that $k_2 = k_4 = 10^{-9}$ were the most adequate values. Despite this fact, the
 43 Gutenberg-Richter law does not provide an approximate time t_0 for the earthquake occurrences. If we

1 look at Equation (16), the term \mathbf{t}_0 appears explicitly (in the step function). However, \mathbf{t}_0 appears only
 2 after the earthquake, so it is not possible to find \mathbf{t}_0 analytically before the rupture (using the rupture
 3 itself). This means that we must find an estimate using the other parameters. One way to do it is to
 4 consider the differential total friction coefficient $d\bar{\mu}_T$ to find an approximate rupture time t_0 . Figure 13
 5 shows $d\bar{\mu}_T$ considering $\gamma_2 = \gamma = 1$, $k_2 = k_4 = 10^{-9}$ and $k_2 = k_4 = 10^{-10}$. When major earthquakes
 6 ($k_2 = k_4 = 10^{-9}$) are considered, the rupture occurs after the maximum value $((d\bar{\mu}_T)_{MAX})$, when $d\bar{\mu}_T \approx$
 7 $\frac{1}{2} (d\bar{\mu}_T)_{MAX}$ (Figure 13 up). When $k_2, k_4 = 10^{-10}$, the rupture also occurs after the maximum value, in
 8 this case $d\bar{\mu}_T \approx 0.9 (d\bar{\mu}_T)_{MAX}$ (Figure 13 down). Considering these two limiting cases in this framework
 9 we conclude that earthquakes occur after $(d\bar{\mu}_T)_{MAX}$ when the differential total friction coefficient
 10 decrease to $d\bar{\mu}_T \approx C (d\bar{\mu}_T)_{MAX}$, where $C \in [0.5, 0.9]$.

11 The time between $d\bar{\mu}_T \approx (d\bar{\mu}_T)_{MAX}$ and $d\bar{\mu}_T \approx C (d\bar{\mu}_T)_{MAX}$ can be denoted by δ . This δ parameter
 12 increases when C decreases and viceversa, so δ is inversely proportional to C ($\delta \propto C^{-1}$). Then, we arrive
 13 at an expression for the general rupture time t_0 as follows:

$$14 \quad t_0 \approx t_{C(d\bar{\mu}_T)_{MAX}} = t_{(d\bar{\mu}_T)_{MAX}} + \delta, \quad t > t_{(d\bar{\mu}_T)_{MAX}}, \quad (20)$$

15 where $t_{(d\bar{\mu}_T)_{MAX}}$ is the time when $d\bar{\mu}_T \approx (d\bar{\mu}_T)_{MAX}$. Note that the Equation (20) is only valid after the
 16 maximum value $(d\bar{\mu}_T)_{MAX}$ is reached. Equation (20) is general, however, considering the Gutenberg-
 17 Richter law, we expect that C values close to 0.5 are necessary to represent earthquakes of greater
 18 magnitude in this theoretical framework.

19

20 **7. - Discussion and conclusions**

21

22 In this work we have linked key parameters associated with the geological fault with magnetic
 23 measurements. Both stress drops and the semi brittle-plastic stress were linked to friction coefficient (on
 24 the fault) equation in terms of magnetic measurements (Equation (16)). One of the main points of
 25 Equation (16) corresponds to the fact that the Total Friction Coefficient $\bar{\mu}_T(x, t)$ is entirely determined by
 26 the spatial distribution of the non-constant stress changes within the lithosphere. If the Seismo-
 27 electromagnetic theory is applied, it means that the rupture process is controlled by the non-constant stress
 28 changes that surround the fault and not by the fault itself. In this scenario, the earthquakes might occur at
 29 places on the fault that are being affected by a continuous friction increase prior to rupture (this friction
 30 increase occur regardless of the values of k_2 and k_4 used in the analysis). In our work we have shown that
 31 the Total Friction Coefficient depends on two different spatial distributions. The first one is associated
 32 with the uniaxial stress changes $\gamma(x)$ and the second one to the rupture area $\gamma_2(x)$. These two distributions
 33 are not necessarily correlated. In the case where they are comparable (that is: $|\gamma(x) - \gamma_2(x)| \approx 0$), it
 34 means that the lithosphere area affected by non-constant uniaxial stress changes is a determining factor for
 35 predicting the earthquake magnitude and location before it occurs. This is $\gamma(x) \approx \gamma_2(x) \approx 0$ if x belong
 36 to sections where $\dot{\sigma} = cte$ and $\gamma(x), \gamma_2(x) \neq 0$ if $x \in L$, where L is the rupture length (at places
 37 where $\dot{\sigma} \neq cte$). The seismic moment M_0 is proportional to this length L (Aki, 1966), and the seismic
 38 moment magnitude M_w depends on the seismic moment (Hanks and Kanamori, 1979), implying that the
 39 seismic moment magnitude depends on the spatial distribution of the total friction coefficient variations.
 40 As the non-constant uniaxial stress changes also could create magnetic signals due the microcracks of
 41 rocks (Venegas-Aravena et al., 2019, and references therein), it is reasonable to affirm that larger area of
 42 magnetic anomalies could imply a larger earthquake. This is the locality (or Dobrovolsky) criteria used by
 43 some researchers when they relate some electromagnetic measurements to earthquakes (e.g., De Santis et
 44 al., 2019a, and references therein). If in this case we also consider the initial time of friction increase
 45 (impending rupture time), the approximate magnitude, the approximate location and the approximate
 46 imminent time could be theoretically determined through Equation xxxx.

1 For the limiting case when $|\gamma(x) - \gamma_2(x)| \gg 0$ we have seen that the locality criteria do not hold
2 anymore. Hence, the earthquakes occurrences cannot be related to the non-constant stress changes and the
3 magnetic field. This limiting case forbids the possibility of a real earthquake prediction using this simple
4 theoretical base. This later case may also imply that the cumulative stress on the fault is not enough to
5 generate a seismic rupture at any point on the fault (this is $\gamma_2(x) = 0$). This means that the accumulated
6 elastic energy that is injected into the fault is not sufficient to spread the rupture (the last energy is called
7 Fracture Energy G_C , see Ohnaka, 2013 and Nielsen et al., 2016). This scenario could indicates that the
8 stress changes in the semi brittle-plastic regime is not a sufficient condition to the earthquake generation,
9 however, it could be a necessary condition.

10 With respect to the size of earthquakes in the present model, the section 5 has shown that earthquakes
11 have greater magnitudes when $k_2 = k_4 \approx 10^{-9}$. If we consider those values in Figure 5, we see that the
12 total friction coefficient is also higher. This is ~ 0.75 when $k_2 = k_4 \approx 10^{-9}$ and sensibly larger than ~ 0.6
13 when $k_2 = k_4 \approx 10^{-10}$. This indicates that there is a correlation between the size of the earthquake and
14 the total friction coefficient. Hence, the earthquake has a greater magnitude when there is a higher total
15 friction coefficient (or shear stress τ). This means that $\gamma_2 = \gamma_2(\bar{\mu}_T)$, therefore, the rupture length L of
16 Equation (18) is proportional to $\bar{\mu}_T$ (that is: $L = \alpha \bar{\mu}_T(t_0)$). Note that this is independent of the value
17 of $|\gamma(x) - \gamma_2(x)|$, since it comes directly from the Gutenberg-Richter's law. However, in this case $\bar{\mu}_T$ is
18 homogeneous, so more studies will be needed in order to determine L .

19 Finally, this theoretical work has provided a possible mechanism that explains several magnetic
20 measurements performed recently. This work provides equally some necessary conditions of the fault in
21 order to trigger earthquakes in terms of their magnetic properties. We think that future researches of the
22 LAIC effect community should focus on the lithospheric-fault dynamics as one of the promising topics.
23 When the lithosphere part of this effect would be better understood, the other effects will have a stronger
24 theoretical basis that will help in order to perform measurements and/or accurate predictions.

Figure 1: Schematic description of the non-constant uniaxial stresses in presence of a fault with friction coefficient μ and dip angle θ .

Figure 2: Dimensionless representation of normalized first and second temporal change of the uniaxial stress used by Venegas-Aravena et al. (2019). According to De Santis et al. (2019a) the earthquakes occur close to the center of figures. Here it is when $t = t_0 = 10$ a.u..

Figure 3: Temporal behavior of the semi brittle-plastic friction coefficient using different parameters. In all the cases it's possible to observe an increase in the friction before earthquake ($t = 10$ a.u.). However, the friction decreases after the earthquake only if k_2 and k_4 has values of $\sim 10^{-9}$.

Figure 4: Schematic description of friction gradient on the fault. When a constant and non-constant temporal stress change is applied at different paces within the lithosphere, a non-zero friction coefficient gradient is expected.

Figure 5: Total friction coefficient from the Seismo-electromagnetic Theory derivation. If we consider one point within the rupture area, the highest values of friction are found before the earthquake ($t = 10$ a.u.). The friction decreases at $t=10$ a.u. was calculated using the stress drop in function of the co-seismic magnetic field. The maximum value is not completely recovery after the earthquake occur.

Figure 6: Schematic comparison among different friction behaviors related with seismic rupture area. Above the result of friction in the context of The Seismo-electromagnetic Theory is presented. At the bottom the classical view of the friction. When the rupture occurs, de friction drop is observed in the two theories. However, exist a friction increase in the case studied in this work.

Figure 7: Spatial distribution of γ and γ_2 . These functions represent the different sections (or behavior) of friction on the fault along x-direction. The distribution γ_2 represent the stress drop section and distribution γ represent the semi brittle-plastic influence region.

Figure 8: Spatial-temporal Total Friction Coefficient $\bar{\mu}_T(x, t)$ along fault x-direction using $k_2 = k_4 = 10^{-9}$, and the right color bar indicate the friction coefficient values at a certain time and position. The earthquake occurs when $t = 10$ a.u.. At this time, the stress drop (defined by the distribution γ_2) $\Delta\tau \in [8,12]$ a.u..

Figure 9: Same spatial-temporal Total Friction Coefficient, however, using $k_2, k_4 = 10^{-10}$.

Figure 10: Total Friction Coefficient using no semi brittle-plastic contribution. That is $\gamma(x) = 0, \forall x \in [0, 2x_{half}]$. The friction variation exists only when the earthquake occurs ($t = 10$ a.u.) and at the earthquake rupture place ($\Delta\tau \in [8,12]$ a.u. in this case).

Figure 11: Above: The b-value using $\sigma = \alpha \tau$; $k_2 = k_4 = 10^{-9}$ and $\alpha = 0.01$. Bottom: The Gutenberg-Richter Law for instants time $t = 0$ a.u., $t = 9$ a.u. and $t = 20$ a.u.. The b-value decreases before the earthquake implying stronger seismic events.

Figure 12: The b-value and Gutenberg-Richter Law using $k_2 = k_4 = 10^{-10}$. The green and red curves are the same.

Figure 13: Different rupture's time viewed from the differential total friction coefficient $d\bar{\mu}_T$ and using different values of k_2 and k_4 . The rupture occurs after the maximum differential total friction coefficient $(d\bar{\mu}_T)_{MAX}$, when $d\bar{\mu}_T$ have values close to 0.5-0.9 times $(d\bar{\mu}_T)_{MAX}$.
