#### General comment

The manuscript deals with a potentially interesting case study of a landslide driven by the temporary build up of pressure in a gravel layer interbedded between the bedrock and an overlying clay layer with much smaller hydraulic conductivity. The manuscript is correctly structured, the English language is poor, and should be revised with the help of a native speaker, but the manuscript is anyway understandable. In spite of the interesting case study, which could be of interest for part of the readership of NHES, the manuscript suffers from many issues, related to: the description of the study case; the mathematical modeling; the interpretation of the results. All these issues make the

C1

drawn conclusions too weak, and so I regret to recommend rejection of the manuscript in its present form.

Detailed comments (more can be found in the attached annotated manuscript)

The description of the scientific context which this study belongs to is incomplete. The literature review is poor, and some of the cited papers seem not relevant to the studied type of landslide.

The description of the case study lacks much information: the slope is poorly described; the installed monitoring sensors are not described at all; the description of the supposed failure mechanism is confused and unclear.

The interpretation of the monitoring results is trivial: arguing that an increase of pore water pressure under the destabilized layer strongly contributes to the failure is obvious. What is less obvious, and should be the focus of the study, is why water easily infiltrates into the coarse layer, but it is not drained out with the same easiness. The reason for this cannot be searched in the characteristics of the rainfall (intensity and duration), nor in the hydraulic conductivity of the gravel (in fact, it controls both infiltration and drainage), but rather on some feature of the hydraulic boundary condition at the toe of the slope, which can be related to the geometry and/or to some factor external to the gravel layer. Here the authors completely miss the chance of making this study really novel and interesting, as they completely neglect the drainage mechanism, both in the interpretation of the results and in the (following) mathematical modelling exercise.

The mathematical model is not clearly described: the hydraulic boundary conditions are only partially specified, and in the end it is not clear how water gets in and out of the modelling domain. Although somewhere in the paper it seems that the authors would link the release of the pressure (also to the deformations of the soil, the model seems to be developed in the hypothesis of rigid soil (although also this information is not explicitly given).

C2

The results of the model simulations are quite far from the observed evolution of the landslide: the maximum predicted pressure is half the observed, although the simulations have been carried out with rainfall events much more intense than the observed, and with a conductivity of the gravel much smaller than what is declared. Given the lacking information about the model, it is difficult to understand the reason for these large discrepancies. I guess that something about the boundary conditions, controlling the rate of infiltration and drainage from the system is completely missing in the model.

Finally, the drawn conclusions are quite obvious, and indeed it could not be different, given the neglect of the most interesting features of the studied phenomenon. The authors come out with some ideas for stabilization measures, also quite obvious, as they suggest to avoid too much water entering the gravel layer, and to extract water to facilitate the drainage of water already entered.
