11 **Abstract.** A Mw 6.5 earthquake struck the Jiuzhaigou region of Sichuan Province, China at 21:19 pm on Tuesday, 8 August
12 2017, and triggered a large number of landslides. For mitigating the damages of earthquake-triggered landslides to
13 individuals and infrastructures of the earthquake affected region, a comprehensive landslide susceptibility mapping was
14 attempted with an integrated weighted index model by combining the frequency ratio and the analytical hierarchy process
15 approaches under GIS-based environment in the earthquake heavily attacked Zhangzha town of the Jiuzhaigou region. For
16 this purpose, a total number of 842 earthquake-triggered landslides were visually interpreted and located from Sentinel-2A
17 images acquired before and after the earthquake at first, and then the recognized landslides were randomly split into two
18 groups to establish the earthquake-triggered landslide inventory, among which 80 % of the landslides was used for training
19 the integrated model and the remaining 20 % for validation. Nine landslide controlling factors were considered including
20 slope, aspect, elevation, lithology, distance from faults, distance from rivers, land-use/cover, normalized difference
21 vegetation index and peak ground acceleration. The frequency ratio was utilized to evaluate the contribution of each
22 landslide controlling factor on landslide occurrence, and the analytical hierarchy process was used to analysis the mutual
23 relationship between landslide controlling factors. Finally, the landslide susceptibility map was produced by using the
24 weighted overlay analysis. Furthermore, an area under the curve approach was adopted to comprehensively evaluate the
25 performance of the integrated weighted index model, including the degree of model fit and model predictive capability. The
26 results demonstrated the reliability and feasibility of the integrated weighted index model in earthquake-triggered landslide
27 susceptibility mapping at regional scale. The generated map can help engineers and decision makers assess and mitigate
28 hazards of the earthquake-triggered landslides to individuals and infrastructures of the earthquake affected region.

2 **1 Introduction**

3 Recent natural disasters and their associated death tolls and financial costs have put mitigation of natural hazards at the
4 forefront of societal needs. Landslides are the most common natural disasters (geological hazards) that cause heavy human
5 casualties and damage to property every year in many areas of the world (Saha et al., 2002; Su et al., 2015). Landslides can
6 be caused by several factors, such as strong earthquakes, intense or prolonged rainfall and multiple human actions (Guzzetti
7 et al., 2012; Sato et al., 2007).

8 On August 8, 2017, a catastrophic earthquake of magnitude 6.5 struck the Jiuzhaigou region of Sichuan Province, China.
9 The epicentre of this earthquake with a depth of 20 km was located latitude 33.20° N and longitude 103.82° E, close to the
10 Jiuzhaigou National Nature Reserve, about 39 km West to the city of Jiuzhaigou. According to China Earthquake
11 Administration, the epicentre of the Jiuzhaigou earthquake was located near the Minjiang, Tazang and Huya faults (as can be
12 seen in Fig. 1), and this earthquake was caused by tectonic movement of an NW-SE-oriented left-lateral strike-slip fault
13 (Wang et al., 2018a). Although intense rainfall was not observed after the earthquake, numerous landslides were triggered by
14 strong seismic vibration of ground (Zhao et al., 2018). Many scenic spots in the Jiuzhaigou National Nature Reserve were
15 destroyed, as presented in Fig. 2(b), the Sparkling Lake was damaged. Due to numerous landslides blocking the roads, many
16 tourists were trapped in the region, as can be seen in Fig. 2(d), the S301 highway was severely obstructed by a significant
17 number of small-scale landslides. Based on field investigation, most of these landslides were small-scale rock slides, rock
18 falls and debris slides (Fan et al., 2018; Zhao et al., 2018). As China Earthquake Administration reported, this earthquake
19 caused 25 deaths and 176,492 injured or affected (Lei et al., 2018; Wang et al., 2018b). Landslides seriously threaten the
20 anthropogenic activities, as well as tourist facilities of the region. Comprehensive earthquake-triggered landslide
21 susceptibility mapping in the earthquake affected area, therefore, is essential to assess landslide hazard and mitigate landslide
22 damages through proper prevention actions for the future.

23 Over the last decades, many approaches for landslide susceptibility mapping were proposed, among which the application of
24 remote sensing associated with GIS modelling techniques became the most popular and effective ones (Alexander, 2008;
25 Carrara et al., 1991; Dai and Lee, 2002; Guzzetti et al., 1999; Lee, 2005; Mantovani et al., 1996; Mansouri Daneshvar, 2014;
26 Xu et al., 2012a). The most commonly used methods for landslide susceptibility mapping include logistic regression
27 (Ayalew and Yamagishi, 2005; Bai et al., 2010; Manzo et al., 2013; Ozdemir and Altural, 2013), weights of evidence
28 (Althuwaynee et al., 2012; Regmi et al., 2010), analytical hierarchy process (AHP) (Kayastha et al., 2013; Komac, 2006;
29 Mansouri Daneshvar, 2014; Yalcin, 2008), frequency ratio (FR) (Guo et al., 2015; Lee and Pradhan, 2007; Li et al., 2017;
30 Mohammady et al., 2012), support vector machine (SVM) (Marjanović et al., 2011; Su et al., 2015), decision tree
31 (Nefeslioglu et al., 2010; Saito et al., 2009) and artificial neural network (ANN) (Caniani et al., 2008; Catani et al., 2005;
32 Conforti et al., 2014; Ermini et al., 2005; Pradhan and Lee, 2009). These methods have been proved capable of mapping the

1 locations that are prone to landslides, however, some shortcomings yet exist in these methods, which reduce the efficiency of
2 these susceptibility methods when applied individually (Tien Bui et al., 2012; Umar et al., 2014). For example, the AHP can
3 be used to identify the mutual relationship between landslide controlling factors and the landslide susceptibility, but the
4 process and results mostly depend on the expert's knowledge, which are somehow subjective in practice (Youssef et al., 2015;
5 Zhang et al., 2016). The FR is capable of representing the influence of the categories of each controlling factor due to
6 landslide occurrences (Lee and Talib, 2005), however, the mutual relationship between the factors is mostly neglected
7 (Zhang et al., 2016), and the same issue also exists in the modelled result. Logistic regression is good at analysing the
8 relationships among the landslide controlling factors but is not capable to evaluate the impact of the categories of each factor
9 individually on landslides (Umar et al., 2014). Fuzzy logic has also been employed in landslide susceptibility mapping, but
10 the modelled results largely rely on the expert's knowledge, which often leads to a high degree of uncertainty (Tilmant et al.,
11 2002). In addition, machine learning models (e.g. SVM, decision tree and ANN models) are very popular methods in
12 landslide analysis, nevertheless, heavy dependence of a very high-speed computer along with large amounts of training data
13 needed constrain their practical applications to some extent (Umar et al., 2014).

14 In addition, the combined approach has been gradually used for landslide susceptibility assessment (Ba et al., 2017; Boon et
15 al., 2015; Dehnavi et al., 2015; Kadavi et al., 2018; Pham et al., 2018; Shrestha et al., 2017; Umar et al., 2014; Youssef et al.,
16 2015). For instance, Umar et al. (2014) used an ensemble method of FR and logistic regression to assess the landslide
17 susceptibility in West Sumatera Province, Indonesia, and the similar integrated method was also applied by Youssef et al.
18 (2015). Dehnavi et al. (2015) combined the step-wise weight assessment ratio analysis method and adaptive neuro-fuzzy
19 inference system to produce a landslide susceptibility map of Iran. Ba et al. (2017) proposed an improved information value
20 model based on grey clustering for landslide susceptibility mapping in Chongqing. Kadavi et al. (2018) proposed a hybrid
21 machine learning approach of AdaBoost, LogitBoost, Multiclass Classifier, and Bagging models for spatial prediction of
22 landslides. Although those studies suggested effectiveness of the integrated method in some areas of the world, the
23 universality and efficiency of the integrated method were yet remained as an important issue to be confirmed in different
24 regions of the world (Reichenbach et al., 2018).

25 The main purpose of this study is to map the susceptibility of earthquake-triggered landslides by applying an integrated
26 weighted index model by combining FR and AHP. The integrated model is capable of evaluating the contribution of each
27 landslide controlling factor to landslide occurrence using FR method, meanwhile taking mutual relationships among
28 controlling factors into account by the use of AHP. Such integration is capable to generate a complete model that largely
29 restrains the shortcomings of these two individual methods and reduces the uncertainty and subjectivity resulted by the
30 utilization of individual method. The experiment site was selected at the Zhangzha town of Jiuzhaigou, a region seriously
31 affected by the Jiuzhaigou earthquake. An earthquake-triggered landslide susceptibility map was produced by using the
32 integrated weighted index model along with the remotely sensed information, and a validation analysis by using an area
33 under the curve approach was conducted to the generated susceptibility map of the study area for evaluating the reliability
34 and feasibility of the integrated model. This manuscript is structured as follows: Section 2 introduces the study area. Section

1 3 describes the data utilized and data preparing procedures. Section 4 gives the detailed explanation about the integrated
2 weighted index model. Section 5 presents the results and discussions focusing on validations on the generated earthquake-
3 triggered landslide susceptibility map of the study area followed by the conclusions drawn in Section 6 at the end.

4 **2 Study area**

5 The study area with an area of 1345.19 km², as shown in Fig. 1, is located in the Zhangzha town of Jiuzhaigou County
6 between 33.03° N – 33.35° N Latitude and 103.63° E – 104.05° E Longitude in the Min Shan Mountains to the north of the
7 Sichuan basin, eastern margin of the Tibetan Plateau. As pointed out in Deng (2011), the geological conditions of this region
8 are complex, and the tectonic movement strongly uplifted the entire western region of Jiuzhaigou, while the eastern region
9 had different fault block movements along the early faults. Regional tectonic movements are intense (Wang et al., 2018b), as
10 summarized in Fan et al. (2018), more than 50 earthquake events with magnitude 5.0 or greater occurred in the Jiuzhaigou
11 area in the past century. Active regional tectonic uplift and tilting cause the elevation of the study area to vary from 1624 m
12 to 4855 m above mean sea level. The Jiuzhaigou County belongs to a cold sub-humid and cold semi-arid monsoon climate
13 with annual precipitation about 550 mm (Li et al., 2014). The topography of the region is characterized by alpine karst
14 terrain formed by glacial, hydrological and tectonic activity, and with karstification in travertine deposits, many travertine
15 dikes and shoals appeared in the study area. Soluble carbonate rocks are widely distributed along with tufa deposition of
16 karst developed. Due to abundant recharge supply of groundwater in this region, many lakes and streams develop over
17 extensive alpine karst region, which favours hill slope erosion processes, and results in frequent occurrence of rock slides,
18 debris flows, and rock falls (Florsheim et al., 2013).

19 **3 Data**

20 In order to map the landslide susceptibility of the study area, we designed and developed a spatial database with the help of
21 ArcGIS (version 10.2) software. This database contained two primary parts: (1) the landslide inventory dataset for
22 earthquake-triggered landslides; and (2) the datasets of background condition representing the landslide controlling factors.
23 The data layers used in the landslide susceptibility mapping were briefly described in Table 1.

24 **3.1 Landslide inventory**

25 Landslide inventory is essential for assessing landslide hazard or risk on a regional scale (Pellicani and Spilotro, 2015). The
26 Jiuzhaigou earthquake triggered numerous landslides in the study area. To derive landslide inventory containing detailed and
27 reliable information on landslide distribution, location, etc., Sentinel-2A images on July 29, August 13 and September 7,
28 2017 were used to recognize and locate the earthquake-triggered landslides. Sentinel-2A image has 13 spectral bands (from
29 blue to shortwave infrared) with the spatial resolution of 10 m, 20 m and 60 m, respectively. In this study, three visible bands

1 (red, green, blue) with the spatial resolution of 10 m were adopted to analysis the image characteristics of earthquake-
2 triggered landslides. With the aid of ArcGIS and ENVI tools, the landslide information of the study area was extracted using
3 on-screen visual interpretation on pre- and post-earthquake Sentinel-2A images. In order to ensure the quality of visual
4 interpretation, GF-1 images with spatial resolution of 2 m on January 15, 2017, were used to verify the results. Consequently,
5 a total number of 842 earthquake-triggered landslides were recognized and positioned. Smaller landslides with total pixels
6 less than 20 were not included as they were not clear enough in visual features. We assumed that the distribution of the
7 earthquake-triggered landslides was reasonably accurate and complete at regional scale in order to make the problem
8 tractable. For earthquake-triggered landslide susceptibility mapping, the landslide inventory dataset was randomly split into
9 two groups, among which 80 % (673 landslides) of the recognized landslides was used for training the integrated weighted
10 index model and the remaining 20 % (169 landslides) for validation.

11 **3.2 Landslide controlling factors**

12 The occurrence of landslides is a consequence of geological, meteorological, anthropogenic and triggering factors,
13 commonly referred to as landslide controlling factors (Bai et al., 2010). Standard guidelines for choosing the optimal
14 landslide controlling factors are unavailable, but the scale of analysis, the nature of the study area, the data availability and
15 the quasi-empirical and statistical criterions in literatures can be referenced (Romer and Ferentinou, 2016; Zhou et al., 2016).
16 In this study, slope, aspect, elevation, lithology, distance from faults, distance from rivers, land-use/cover (LULC),
17 normalized difference vegetation index (NDVI) and peak ground acceleration (PGA) were selected as the landslide
18 controlling factors, as shown in Fig. 3.

19 Among all landslide controlling factors, slope, aspect and elevation have been recognized as the most important topographic
20 factors closely related to landslides (Ayalew and Yamagishi, 2005; Chalkias et al., 2016). Slope directly affects the velocity
21 of both surface and subsurface flows (Su et al., 2015). Landslides become more possible once the slope gradient is higher
22 than 15° (Lee and Min, 2001). In the study area, the slopes were generally steep, with an average slope angle of about 30°.
23 Aspect, referred to the direction of slope faces, is related to soil moisture, surface runoff and vegetation, which indirectly
24 affects landslide development (Zhang et al., 2016). The elevation, as the measure of the land surface height, is a key factor
25 determining gravitational potential energy of terrain and is often considered in relevant studies (Conforti et al., 2014; Peng et
26 al., 2014). Topographic factors can be calculated with DEM. The DEM from SRTM database was used to extract slope (0°–
27 78°), aspect and elevation (1624–4855 m) in the study area.

28 Lithology is directly related to the slope stability, which plays an important role as one of landslide controlling factors (Guo
29 et al., 2015, Saha et al., 2002). Ten geological formation units including Quaternary (Q, Qh), Triassic (T1, T2, T3), Permian
30 (P, P2), Carboniferous (C), and Devonian (D) outcrop in the study area (Wang et al., 2018a). During the Jiuzhaigou
31 earthquake, most landslides in the study area occurred in the carboniferous formations which is mainly composed of
32 metamorphic quartzite sandstones, limestone and slate (Fan et al., 2018). In addition, the Permian limestone and Triassic
33 sandstone also exhibited a large number of landslides. In this study, the lithological data was obtained from the geological

1 map at 1: 500,000 scale and was digitized in ArcGIS for further analysis. The distances of a slope from faults as well as from
2 the river channels are also important factors in terms of slope stability (Kanungo et al., 2006). In addition, earthquake-
3 triggered landslides are usually found in the vicinity of active faults. Hence, the distances of a slope from geological tectonic
4 zone were often taken into account in slope stability analysis. Fan et al. (2018) had revealed that this earthquake occurred
5 along a previously unknown blind fault probably belonging to a south branch of the Tazang fault or north part of the Huya
6 fault. However, due to its great uncertainty, this blind fault was not taken into account in the study area. In this study, the
7 faults were digitized from the geological map at 1: 500,000 scale, and the river channels were interpreted from remote
8 sensing images. And the LULC map is one of controlling factors that pose direct impact on the occurrence of landslides
9 (Song et al., 2012; Mansouri Daneshvar, 2014). In this study, the LULC map was downloaded from the Geographical
10 Information Monitoring Cloud Platform.

11 Vegetation coverage poses effect on soil water erosion, which indirectly affects the occurrence of landslides. NDVI, as the
12 measure of vegetation coverage, is usually adopted in landslide susceptibility analysis (Siqueira et al., 2015). The NDVI is
13 calculated from these individual measurements as follows:

$$14 \quad NDVI = \frac{DN_{NIR} - DN_R}{DN_{NIR} + DN_R}, \quad (1)$$

15 Where, DN_{NIR} stands for the spectral reflectance derived from the measured radiances in the near-infrared regions (NIR), and
16 DN_R stands for the spectral reflectance derived from the measured radiances in the visible (Red) regions.

17 In this study, the NDVI map was generated from the Landsat-8 image acquired on April 8, 2017 over the study area.

18 Earthquake as an important dynamic factor, often triggers slope failures (Xu et al., 2012a). Usually, the impact of earthquake
19 on landslides is measured and quantified by recording the absolute maximum amplitude of ground acceleration (PGA)
20 (Chalkias et al., 2016). In this study, the PGA map of the study area was downloaded from the USGS website
21 (<https://www.usgs.gov>).

22 To ensure the consistency and easy process of these data, all factor layers were converted into raster data format (GeoTIFF)
23 with an identical spatial projection (WGS84 datum) and resampled to a resolution of 30 m by ENVI 5.3 and ArcGIS 10.2.

24 **4 Methodology**

25 In this study, an integrated weighted index model was developed as a complete landslide susceptibility model by combining
26 AHP and FR approaches. As shown in Fig. 4, the integrated weighted index model was run through three general steps: (1)
27 determining the relative importance of landslide controlling factors using AHP method, (2) characterizing the relationships
28 between controlling factors and landslide locations using FR and GIS techniques, and (3) predicting landslide susceptibility
29 using Weighted Overlay Analysis tool of ArcGIS.

1 **4.1 Analytical hierarchy process (AHP)**

2 The AHP method, developed by Saaty (Saaty, 1977), is an important multiple criteria decision-making method (Vaidya and
3 Kumar, 2006), which has been applied for landslide susceptibility assessment for many years (Akgun, 2012; Barredo et al.,
4 2000; Kayastha et al., 2013; Komac, 2006; Pourghasemi et al., 2012; Yalcin, 2008).

5 In the AHP, a complex non-structural problem is first broken down into several component factors. Then, based on the
6 expert's prior experience and knowledge, a pair-wise comparison matrix can be constructed through comparing the relative
7 importance of each factor (Vargas, 1990). An underlying 9-point recording scale is used to rate the relative importance of
8 factors (Mansouri Daneshvar, 2014). Specifically, when a factor is more important than another, the score varies between 1
9 and 9. Conversely, the score varies between $1/2$ and $1/9$. The higher the score, the greater the importance of the factor. With
10 the help of a pair-wise comparison matrix, the contribution of factors can be converted into numerical values. Note that a
11 consistency check of comparison matrix needs to be carried out, and the Consistency Ratio (CR) of less than 0.1 is generally
12 accepted.

13 In this study, the relative importance of landslide controlling factors was determined from the prior experience and
14 knowledge of experts. Since the knowledge source varies from person to person, the best judgment always comes from an
15 individual who has good expertise (Ayalew et al., 2004). To find the appropriate correlation between controlling factors, we
16 investigated some related literatures (Shahabi and Hashim, 2015; Xu et al., 2012b; Zhang et al., 2016) and consulted with
17 some professional experts. Finally, the pair-wise comparison matrix was determined by means of discussion (Table 2) and a
18 general consensus achieved by experts. Weights of factors were determined in the process of a pair-wise comparison matrix
19 using Python software, as shown in Table 2. The Consistency Ratio (CR) for this study was 0.017, which showed that the
20 pair-wise comparison matrix satisfied the consistency requirement.

21 **4.2 Frequency ratio (FR)**

22 The FR method is one of the most widely used approaches to assess the landslide susceptibility at regional scale (Guo et al.,
23 2015; Li et al., 2017; Mohammady et al., 2012), which is based on the observed spatial relationship between landslide
24 locations and controlling factors (Lee and Pradhan, 2007; Poudyal et al., 2010). The assumption behind the FR is that future
25 landslides will occur under similar environmental conditions as historical landslides (Guzzetti et al., 1999; Pourghasemi and
26 Rahmati, 2018), and the susceptibility can be evaluated from the relationship between the controlling factors and the
27 landslide occurrence locations (Zhu et al., 2014). The definition of FR is the ratio of the probability of occurrence to non-
28 occurrence for given properties (Lee and Talib, 2005). The spatial relationship between landslides and controlling factors can
29 be investigated by using the FR method. Therefore, the FR values of each controlling factor category were calculated from
30 their relationship with landslide occurrence locations as illustrated in Table 3. The average value of FR is 1 so that a value
31 larger than one represents a higher correlation and those less than it, a lower correlation (Romer and Ferentinou, 2016).

32 The FR value can be calculated as follows (Ghobadi et al., 2017):

1
$$FR_i = \frac{Ncell(S_i)/Ncell(N_i)}{\sum Ncell(S_i)/\sum Ncell(N_i)}, \quad (2)$$

2 Where, $Ncell(S_i)$ represents number of grid cells recognized as landslides in class i , and $Ncell(N_i)$ represents total number
3 of grid cells belonging to class i in the whole area; while $\sum Ncell(S_i)$ stands for the total number of grid cells recognized as
4 landslides in the whole area, and $\sum Ncell(N_i)$ represents total number of grid cells in the whole area.

5 **4.3 Integrated weighted index**

6 The integrated weighted index is considered to measure the probability of slope failures. By combining FR and AHP
7 methods, the integrated weighted model can assess the correlation between the controlling factors and also the influence of
8 each landslide controlling factor on landslide occurrence.

9 The integrated weighted index can be calculated as follows:

10
$$I = \sum_i^m (W_i \times FR_i), \quad (3)$$

11 Where, m stands for number of controlling factors, W_i is the weight of each controlling factor calculated by the AHP method,
12 FR_i is the FR value of the controlling factor calculated by the FR method.

13 In this study, the values of W_i and FR_i were used to obtain the integrated weighted index of each grid cell in the study area,
14 and the final landslide susceptibility map was generated by using Weighted Overlay Analysis tool of ArcGIS.

15 **5 Results and discussions**

16 **5.1 Landslide susceptibility mapping**

17 The AHP method was used to assign the weights for each controlling factor. The higher the weight was, the more impacts on
18 landslide occurrence could be expected. As shown in Table 2, the weight of slope was highest, implying the most significant
19 influence of slope on the landslide occurrence, and the weights of aspect and NDVI were the lowest, which indicated that
20 these two factors played the least role in the landslide occurrence.

21 The FR values of each controlling factor category were calculated by using the Eq. (2) (as shown in Table 3). Table 3 clearly
22 shows the relationship between each controlling factor and the landslide occurrence. In the term of the relationship between
23 landslide occurrence and slope, landslides mostly occurred in the slope ranging from 40° to 60°. For the elevation, landslides
24 mostly occurred below the elevation of 3400 m, which implied that the probability of landslide occurrence was higher in
25 moderate steep mountainous region. In terms of the aspect, the FR value was very high for the class of E, N, SE and NE, and
26 it was lowest for the class of Flat. For the lithology, the highest FR value was achieved for Permian System which influenced
27 the landslide occurrence. For the factor of distance from faults, the highest FR value belonged to the area higher than 2000 m.
28 The distance from rivers with the highest FR value for frequent landslide occurrence was found usually between 0 and 600 m,
29 and landslides mostly occurred in the region with low vegetation cover of less NDVI value. In the case of PGA, the value of

1 0.26 g had the highest FR value, which indicated the significant influence of the earthquake on the landslide occurrence. In
2 general, our results were basically consistent with the previous study (Fan et al., 2018), which found that most of the
3 landslides mainly occurred in proximity of rivers and the epicentre, with an elevation of 2600 m to 3200 m and a slope of 35°
4 to 55°.

5 Finally, the landslide susceptibility map of study area was generated by using Weighted Overlay Analysis tool of ArcGIS,
6 and the study area was classified into seven categories of landslide susceptibility levels as presented in Fig. 5: very high,
7 high, relatively high, moderate, relatively low, low and very low by using Natural Breaks (Jenks) method with ArcGIS,
8 respectively.

9 According to the landslide susceptibility map, the location close to the epicentre and rivers was classified as the most
10 susceptible areas for landslides, and the high and very high landslide susceptible areas mostly located in the middle central
11 mountainous region. The low and very low susceptibility areas far from the epicentre and less affected by the earthquake,
12 mainly distributed in the North and South-West parts of the study area. Table 4 presented the distribution of seven landslide
13 susceptibility levels. As indicated in Table 4, the very low susceptible area covered 9.72 % of the whole area, whereas low,
14 relatively low, moderate, relatively high, high and very high susceptible areas covered 25.34 %, 22.92 %, 17.76 %, 13.27 %,
15 7.97 % and 3.02% of the whole area, respectively. A total of 61.76 % of the landslides were observed in the high and very
16 high susceptibility areas, and only 3.08 % of the landslides were observed in the low and very low susceptibility areas. For
17 the landslide density, the values for very low, low, relatively low, moderate, relatively high, high and very high were 0.03,
18 0.06, 0.11, 0.37, 0.96, 3.03 and 4.79, respectively. The landslide density for the very high susceptible area was significantly
19 larger than for the other susceptible areas.

20 **5.2 Validations**

21 For landslide susceptibility mapping, validation of the modelled results is essential. A simple procedure of validation can
22 make a comprehensive and reasonable interpretation of the future landslide hazard (Chung and Fabbri, 2003).

23 In this study, operating characteristics curve (ROC) approach (Brenning, 2005; Bui et al., 2016) was adopted to evaluate the
24 performance of the integrated weighted index model, including the degree of model fit and model predictive capability. The
25 ROC curve was obtained by calculating the area under the curve (AUC) and the AUC value varied from 0.5 to 1.0 (Umar et
26 al., 2014). The AUC value of 1.0 implied a perfect performance of the model, whereas a value close to 0.5 indicated that the
27 model performed not so well. To assess the fitting performance of the integrated weighted index model, five sub-datasets
28 containing 20 %, 40 %, 60 %, 80 % and 100 % of training dataset (i.e., 673 landslides) respectively, were used to obtain the
29 fitting curves. Figure 6(a) shows a quantitative measure of the ability of integrated weighted index model to describe the
30 known distribution of landslides. The AUC values of five sub-datasets were 82.57 %, 84.52 %, 84.99 %, 86.08 % and
31 85.65 %, respectively, which suggested the effective fitting capability of the integrated weighted index model developed in
32 this study.

1 To investigate the prediction performance of the integrated weighted index model, we also adopted five sub-datasets
2 containing 20 %, 40 %, 60 %, 80 % and 100 % of validation dataset (i.e., 169 landslides) respectively, to estimate the
3 prediction rates. Note that the validation dataset (i.e., 20 % of the landslide inventory dataset) was not used in the training
4 process. The AUC values of five sub-datasets, as presented in Fig. 6(b), were 78.71 %, 81.66 %, 84.27 %, 86.09 % and
5 87.16 %, respectively. With the increase of input data, the performance of the integrated weighted index model was
6 significantly improved, which indicated a reliable predicting capability of the integrated weighted index model adopted in
7 this study.

8 In addition, the landslide density distribution of each susceptibility level was computed by associating landslides with the
9 classified landslide susceptibility map (as shown in Table 4). There was a clear trend that the increase in the level of
10 landslide susceptibility was highly correlated with the density of landslides. The high and very high susceptibility levels had
11 the significant high landslide density values, while the low susceptibility categories were just the opposite, which also
12 implied the effectiveness of the generated landslide susceptibility map of the study area.

13 **5.3 Discussions**

14 Landslide susceptibility is defined as the likelihood of landslides occurring in an area under local environmental conditions
15 (Fell et al., 2008; Reichenbach et al., 2018). There are numerous methods that have been proposed to evaluate the
16 susceptibility. The main purpose of this study is to assess the spatial probability of landslide occurrences by using an
17 integrated weighted index model in association with the utilization of FR and AHP approaches. The FR is a data-driven
18 statistical approach which can derive spatial relationship between landslide locations and controlling factors. However, the
19 FR method does not consider the mutual relationships between controlling factors. The AHP method is an important multiple
20 criteria decision-making method, which can overcome this shortcoming. To some extent, the integrated method preserves the
21 advantages of FR and AHP methods and restrains their weak points. Some similar studies have also pointed it out
22 (Reichenbach et al., 2018; Youssef et al., 2015; Zhou et al., 2016).

23 The implementation of the integrated weighted index model revealed that landslide susceptibility levels were basically
24 consistent with the distribution of earthquake-triggered landslides. The high susceptibility areas were concentrated in the
25 central mountainous region close to the epicentre of the earthquake of the study area, which indicated the significant
26 influence of the Jiuzhaigou earthquake on the landslide occurrence. From the landslide susceptibility map (as shown in Fig. 5
27 and Table 4), the “very high” and “high” susceptibility areas covered 10.99 % of the whole area and most of the Jiuzhaigou
28 National Nature Reserve was classified as the most landslide susceptible areas.

29 Even though, some limitations yet existed in the proposed method. Firstly, the accuracy of FR method is highly depended on
30 the quality of dataset, especially the landslide inventory (Zhou et al., 2016). Nevertheless, the landslide inventory is
31 generally incomplete (Fell et al., 2008), and is affected by many factors, such as the quality and scale of remote sensing
32 images, the tectonic setting complexity of study area, and the expertise of the interpreter involved (Malamud et al., 2004). In
33 this study, we mainly focused on the interpretation of earthquake-triggered landslides, and interpretation results were

1 basically consistent with the previous studies (Fan et al., 2018; Wang et al., 2018a; Wang et al., 2018b). We didn't
2 accurately identify the landslides before the Jiuzhaigou earthquake due to the limitations of historical images, and smaller
3 landslides were also not completely identified. Future work should focus on the preparation of more detailed landslide
4 inventories. Secondly, in this study, as the proposed method was applied to medium-scale datasets, the results may not be
5 suitable for specific analysis of large or detailed scale. At large or detailed scales, more detailed landslide inventory dataset
6 and controlling factor layers are required. Additionally, the assumption behind much of the landslide susceptibility mapping
7 is that future landslides will occur under similar environmental conditions as historical landslides (Guzzetti et al., 1999;
8 Pourghasemi and Rahmati, 2018). However, results obtained in the past environmental conditions are not a guarantee for the
9 future (Guzzetti et al., 2005). In this study, we used a weighted index model by integrating the AHP and FR approaches to
10 map the earthquake-triggered landslides susceptibility and the generated susceptibility map of the study area was made for
11 the present situation. The susceptibility results need to be adapted as soon as environmental conditions or their causal
12 relationships obviously change in the future. Despite its limitations, the integrated method can generate a reliable landslide
13 susceptibility map at regional scale which can provide rapid assessment for reconstruction of tourism facilities, regional
14 disaster management etc.

15 **6 Conclusions**

16 Earthquake is one of the dynamic causes in landslide occurrence. Earthquake-triggered landslides can cause extensive and
17 significant damages to both lives and properties. In this study, given the main motivation to adopt an integrated weighted
18 index model based on FR and AHP methods for earthquake-triggered landslide susceptibility mapping at the Zhangzha town
19 of the Jiuzhaigou County where a Mw 6.5 earthquake struck on Tuesday, 8 August 2017, nine factors such as slope, aspect,
20 elevation, lithology, distance from faults, distance from rivers, LULC, NDVI and PGA as landslide controlling factors were
21 adopted in the integrated weighted index model for generating the landslide susceptibility map of the study area with
22 reclassification of seven levels of landslide susceptibility areas within a GIS environment. The ROC approach was used to
23 comprehensively evaluate the performance of the integrated weighted index model, including the degree of model fit and
24 model predictive capability. The results demonstrated the reliability and feasibility of the integrated weighted index model in
25 landslide susceptibility mapping at regional scale.

26 Even some limitations do exist, the integrated weighted index model can generate a reliable landslide susceptibility map at
27 regional scale that is useful for engineers and decision makers to understand the probability of landslides and mitigate
28 hazards. Furthermore, the integration of some machine learning techniques should be taken into account in the integrated
29 weighted index model for advancement in future studies.
