

19 **Abstract**

20 Himawari-8 is a new generation geostationary meteorological satellite launched
21 by Japan Meteorological Agency. It carries the Advanced Himawari Imager (AHI)
22 onboard, which can continuously monitor high-impact weather events with high
23 frequency space and time. The assimilation of AHI radiance data was implemented
24 with the three-dimensional variational data assimilation system of Weather Research
25 and Forecasting model for the analysis and prediction of Typhoon Soudelor (2015) in
26 the Pacific Typhoon season. The effective assimilation of AHI radiance data in
27 improving the forecast of the tropical cyclone during its rapid intensification has been
28 realized. The results show that after assimilating the AHI radiance data under clear
29 sky conditions, the typhoon position in the background field of the model was
30 effectively corrected compared with the control experiment without AHI radiance data
31 assimilation. It is found that the assimilation of AHI radiance data is able to improve
32 the analyses of the water vapor and wind in typhoon inner-core region. The analyses
33 and forecasts of the minimum sea level pressure, the maximum surface wind, and the
34 track of the typhoon are further improved.

35 **Key words:** Weather Research and Forecasting model; Three-Dimensional
36 Variational Data Assimilation; AHI Radiance Data; Typhoon

37

38 **1. Introduction**

39 In recent years, although researchers have made great progress in the field of
40 numerical weather prediction (NWP), the huge challenges are encountered in the
41 accurate forecasts of tropical cyclones (TCs) with rapid intensifications (DeMaria et
42 al., 2014). The predictability of these TCs is limited because it entails complex
43 multi-scale dynamic interactions (Minamide and Zhang 2018). These interactions
44 include environmental airflows, TC vortex interactions, atmosphere-ocean
45 interactions, and the effects of mesoscale and micro-convective scale, together with
46 the microphysics and atmospheric radiation. In order to attain a better initial condition
47 and improve the accuracy of the forecast, data assimilation seeks to fully utilize the
48 observations. The life span of most TCs is over the ocean where conventional
49 observations are relatively insufficient compared to the land. Therefore, by analyzing
50 observed data from satellites and planes over the ocean, it is crucial to adopt effective
51 data assimilation (DA) methods to improve the analysis and forecast of TCs.

52 With the rapid development of atmospheric radiative transfer model, many
53 numerical weather prediction centers have adopted variational DA method to
54 assimilate a variety of radiance data from different satellite observation instruments
55 (Bauer et al., 2011; Buehner et al., 2016; Derber et al., 1998; Hilton et al., 2009;
56 Kazumori et al., 2014; McNally et al., 2006; Prunet et al., 2000). These data can take
57 up 90% of all data used in global DA system and can improve the accuracy of the
58 numerical model results strikingly (Bauer et al., 2010). Some researches demonstrated

59 that in global model, satellite radiance DA makes more contribution to improving the
60 accuracy of the numerical model results than conventional observation DA does
61 (Zapotocny et al., 2007, Yan et al., 2010; Geer et al., 2017).

62 Generally speaking, radiance data are derived from microwave and infrared
63 detecting instruments, which are from polar-orbit satellites and geostationary satellites,
64 respectively. Polar-orbit satellites cover the sphere of all the earth, thereby suitable for
65 global NWP models (Jung et al., 2008). Besides, they have finer resolutions compared
66 to geostationary satellites (Li et al., 2017; Shen et al., 2015; Xu et al., 2013). However,
67 it is highlighted that they are not able to generate continuous observations for a fixed
68 regional area and so may miss rapidly intensified TCs or storms. On the contrary,
69 because geostationary satellites rotate with the earth, although their resolutions are
70 lower than that of polar-orbit satellites, they can capture the formation and
71 development of mesoscale convective systems by continuous monitoring (Montmerle
72 et al., 2007; Stengel et al., 2009; Zou et al., 2011).

73 Geostationary satellites are able to continuously detect a region at a higher
74 frequency, thus observing TCs over the vast ocean effectively. As the first new
75 generational geostationary satellite, Himawari-8 plays a pioneering role for the
76 geosynchronous imagers to be launched in US, China, Korea and Europe. It has an
77 advanced imager called Advanced Himawari Imager (AHI) with 16 visible and
78 infrared bands, including 3 moisture channels, which can conduct a full-disk scan
79 every 10 minutes. Meanwhile, it can also acquire regional scanning images and that is

80 to say it can scan the Japan and the target areas every 2.5 minutes. Compared to the
81 early geosynchronous imagers, AHI has more spectrum bands and this can monitor
82 the state of atmosphere with a higher frequency.

83 In recent years, some experts and scholars have carried out some studies on the
84 data assimilation of geostationary satellite observations. Firstly utilizing Gridpoint
85 Statistical Interpolation (GSI) from National Centers for Environmental Prediction
86 (NCEP), Zou, et al (2011) conducted direct assimilation on imagers' data from
87 GOES-11 and GOES-12 to estimate their potential influences on quantitative
88 precipitation forecasts (QPF) of coastal regions in the eastern part of American. They
89 found that assimilating radiance data from GOES's imager has a remarkable
90 improvement on 6 to 12 hour's QPF near northern Mexico Gulf coast. Their work was
91 continued by Qin, et al (2013), which put thinned radiance data into GSI system to
92 make a comprehensive investigation on the issue on combined assimilation of GOES
93 Imager data together with Advance Microwave Sounding Unit-A (AMSU-A),
94 Advance Microwave Sounding Unit-B (AMSU-B), Atmospheric Infrared Sounder
95 (AIRS), Microwave Humidity Sounder (MHS), High Resolution Infrared Radiation
96 Sounder (HIRS), GOES Sounder (GSN). The results showed the effect of single
97 assimilation of AHI radiance data are better than combined assimilation in term of
98 precipitation forecast. Zou, et al (2015) adopted the GSI system to assimilate radiance
99 data from four infrared channels on GOES-13/15 and set up two experiments for
100 comparison. A symmetric vortex was used for initialization in the first experiment and

101 an asymmetric counterpart for the other experiment. Results showed that direct
102 assimilation of GOES-13/15's radiance data could yield positive effects on the track
103 and intensity forecasts of hurricane "Debbie". As the new instrument of himawari-8,
104 there are few studies on the DA of himawari-8 data. Ma, et al (2017) used
105 four-dimensional ensemble variational (4DEnVar) DA in NCEP's GSI system to
106 assimilate radiance of three moisture channels of AHI radiance data under clear-sky
107 condition and then NCEP Global Forecast System (GFS) was utilized to estimate the
108 impacts of AHI radiance data assimilation on weather forecast. They found it had a
109 positive impact on the forecast of global vapor at high level of troposphere. Wang, et
110 al (2018) investigated the impact of assimilating three water vapor channels under
111 clear sky on the analysis and forecast of a rainstorm in Northern China with the
112 3DVAR method. It pointed out that the assimilation of AHI radiance data could
113 improve the wind and vapor fields and the accuracy of rainfall forecast in the first 6
114 hours lead time.

115 Although previous researches have made several achievements in satellite data
116 assimilation and application, it is still a challenge to make more effective use of the
117 new generational geostationary satellite imager data with high spatial and temporal
118 resolution. In most of the previous studies, researches usually use a 6 hour's or even
119 longer time interval with a coarse spatial resolution. Therefore, the rapid updating
120 assimilation techniques of the geostationary satellite radiance data have not been well
121 carried out at convective scale. This study intends to build a data assimilation system

122 aiming at AHI radiance data based on the new generational mesoscale Weather
123 Research and Forecasting (WRF) model. A case of Typhoon Soudelor is studied by
124 performing numerical simulation to address the impacts of convective DA on the
125 improvement of the initial conditions of TC and the enhancement of track and
126 intensity forecasts. Our study focuses mainly on assimilating the three water vapor
127 channels (6.2, 6.9, and 7.3 μ m) since they are very sensitive to the humidity in the
128 middle and upper troposphere and have a certain effect on the lower troposphere.
129 Thus, a large amount of effective atmospheric information can be provided for AHI
130 radiance data assimilation in the troposphere. The weighting functions for the three
131 channels are provided in Fig. 1.

132 Section 2 describes the observations and the data assimilation system. Introductions
133 to the typhoon case and the experimental setup are provided in section 3. The detailed
134 results in terms of the analyses and the forecasts are illustrated in section 4 before
135 conclusions are summarized in section 5.

136 **2. Observational data and DA system**

137 *2.1 An introduction to Himawari-8 AHI radiance data*

138 Himawari-8 satellite was launched by JMA to a geosynchronous orbit on 17
139 October 2014 and has begun its operational use since 7 July 2015 (Bessho et al.,
140 2016). It is located between the equator and 140.7°E, thus the earth is observed
141 between 60°N and 60°S meridionally and between 80°E and 160°W zonally.
142 Compared to its previous generation Himawari-7, its detective ability can get

143 significantly improved since the instrument AHI on Himawari-8. Besides, its device is
144 comparable to imagers on American GOES-R satellite (Goodman et al., 2012; Schmit
145 et al., 2005; Schmit et al., 2008; Schmit et al., 2017). AHI is able to provide a full-disk
146 image every 10 minutes and complete a scan over Japan every 2.5 minutes. AHI
147 conducts continuous scan and detection on a moving targeted typhoon. It has 16
148 channels covering visible, near-infrared, and infrared spectral bands with a resolution
149 of 0.5 km or 1 km, and 2 km respectively. Channel 8 to 10 (6.2, 6.9, and 7.3 μm) are
150 water vapor bands that are sensitive to the humidity in the middle and upper
151 troposphere (Di et al., 2016). Other channels (channel 11, 12, 16: 8.6 μm , 9.6 μm , and
152 13.3 μm) are either monitoring other fields such as the thin ice clouds, volcanic SO₂
153 gas, the ozone or CO₂, or the atmospheric window channels (13-15: 10.4, 11.2, and
154 12.4 μm) function as monitors for ice crystal/water, low water vapor, volcanic ash, sea
155 surface temperature and other phenomena (Bessho et al., 2016).

156 *2.2 WRFDA system and AHI radiance data*

157 WRFDA system is designed by National Center for Atmospheric Research
158 (NCAR) and it contains 3DVAR, 4DVAR, Hybrid parts. This research is based on the
159 3DVAR method. An interface that is suitable for AHI DA is built in WRFDA system.
160 Currently, WRFDA is able to assimilate many conventional and unconventional
161 observations. In terms of satellite radiance data, this system is compatible with the
162 Radiative Transfer model of the Television and Infrared Observational Satellite
163 Operational Vertical sounder (RTTOV) and Community Radiative Transfer Model

164 (CRTM, Liu and Weng, 2006) as observation operators. In this study, CRTM is
165 utilized as the observation operator to simulate and compute AHI radiance data.
166 Estimating the systematic bias and random error of the observations caused by the
167 errors of numerical models and instruments are the key factors to directly assimilate
168 the satellite radiance data. Apart from eliminating cloud pixels, other procedures are
169 implemented inside the data assimilation framework for the quality control are as
170 follows. (1) when reading the data, remove the observed outliers with values below 50
171 K or above 550 K; (2) only the marine observations are applied by removing the
172 observations on the land and the observations over complex surfaces; (3) remove
173 observations when the observation minus the background is larger than 3 times of the
174 observation error; (4) the pixels are removed when the cloud liquid water path
175 calculated by the background field of the numerical model is greater than or equal to
176 0.2 kg/m²; (5) eliminate the data when the observation minus background is greater
177 than 5 K. These two parameters are used for these radiances on different sensors of
178 various satellites such as AMSU-A, MHS, and the Advanced Microwave Scanning
179 Radiometer 2 (AMS2) (Wang et al., 2018, Yang et al., 2016).

180 By using 3DVAR algorithm, the assumption is that there is no bias between
181 observation and background (Dee et al., 2009; Liu et al., 2012; Zhu et al., 2014). A
182 bias correction scheme for observation is essential before DA. Usually, radiance bias
183 can be obtained by a linear combination of a set of forward operators.

184
$$\tilde{H}(x, \beta) = H(x) + \beta_0 + \sum_{i=1}^{N_p} \beta_i P_i \quad (1)$$

185 Here, $H(x)$ represents the initial observation operator (before the bias
 186 correction) and x represents the mode state vector. N_p is the number of the
 187 predictions. β_0 represents a constant component of the total bias (constant part),
 188 while P_i and β_i represent the i -th predictor and its coefficient respectively. In this
 189 study, four potentially state-dependent predictors (1000–300 hPa and 200–50 hPa
 190 layer thicknesses, surface skin temperature, and total column water vapor) are applied.
 191 The variational bias correction (VarBC) scheme is utilized to update the bias
 192 correction coefficient variationally with the new observation operator considered in
 193 the cost function of 3DVAR.

194 **3. Introduction to the typhoon and experimental design**

195 *3.1 Typhoon Soudelor*

196 From the record of the China Meteorological Administration (CMA), Typhoon
 197 Soudelor was the 13th typhoon in 2015 as the second strongest tropical cyclone in that
 198 year. At 1200 UTC 30 July 2015, it formed at northwest Pacific Ocean as a tropical
 199 storm at 13.6° N, 159.2° E, then moved north-westwards. It upgraded to a strong
 200 tropical storm at 2100 UTC 1 August 2015. Afterwards, it went through a process of
 201 rapid intensification. It became a typhoon at 0900 UTC 2 August 2015, a strong
 202 typhoon at 2100 UTC 2 August 2015, a super typhoon at 0900 UTC 3 August 2015.
 203 Then it weakened to a strong typhoon in the morning on 5 August 2015. However, it

204 intensified to a super typhoon again at 1200 UTC 7 August 2015 with a maximum
205 surface wind of 52 m s^{-1} , moving west by north, and its intensity raised to its second
206 peak. It was reduced to a strong typhoon again at 1800 UTC 7 August 2015. It
207 decreased to a typhoon, entering to Taiwan Strait. It landed again as a typhoon at 1410
208 UTC on the coast of Fujian Province, China. Owing to continuous orographic friction,
209 it decreased to a tropical depression. Fig. 2 shows the track of Soudelor and different
210 color lines represent typhoon's maximum surface wind. It is displayed that after the
211 formation of typhoon, its track is relatively stable. After July 30, the tropical
212 depression moved west by north at a speed of about 20 km/h. Its moving tendency
213 changed slightly within 10 days of its generation. However, its intensity went through
214 a rapid intensification, a weakening, a second intensification, following by a
215 continuous weakening after landing on the China. Fig. 3 demonstrates the variation of
216 typhoon's intensity from 31 July 2015 to 5 August 2015. It is shown that typhoon's
217 maximum surface wind increased fast, while its minimum sea level pressure
218 decreased sharply. This was the stage of typhoon's rapid intensification. The period
219 from 1 August 2015 to 3 August 2015 during its rapid intensification is selected.

220 *3.2 Experimental design*

221 Two experiments are designed to investigate the effects of AHI radiance data
222 direct assimilation on the analysis and forecast of Typhoon Soudelor starting from
223 1800 UTC 1 August 2015 to 0000 UTC 3 August 2015. WRF 3.9.1 is employed as the
224 forecast model in this experiment. Arakawa C grid is used in the horizon with a 5 km

225 grid distance. As is known, Arakawa A grid is "unstaggered" by evaluating all
226 quantities at the same point on each grid cell. The "staggered" Arakawa B-grid
227 separates the evaluation of the velocities at the grid center and masses at grid corners.
228 Arakawa C grid further separates evaluation of vector quantities compared to the
229 Arakawa B-grid. Vertically, it has 41 eta levels using 10 hPa as its top with coarser
230 vertical spacing for the higher levels. The center of the model domain is located at
231 (17.5 °N, 140 °E) (Fig. 4). The initial condition and lateral boundary are provided by
232 0.5°×0.5° Global Forecasting System (GFS) reanalysis data. The following
233 parameterization schemes are used: The following parameterization schemes are used:
234 WDM6 microphysics scheme (Lim et al., 2010), Grell Devenyi cumulus
235 parameterization scheme (Grell et al., 2002), Rapid Radiative Transfer Model (RRTM)
236 longwave radiation scheme (Mlawer et al., 1997), shortwave radiation scheme
237 (Dudhia et al., 1989), and YSU boundary layer scheme (Hong et al., 2006) .

238 The experimental procedures are illustrated by Fig. 5. Firstly, a 6-hour's spin-up
239 conducted initialized from 1800 UTC 1 August 2015 to prepare the background field
240 for the data assimilation at 0000 UTC 2 August 2015. The 6-hour spin-up period is
241 commonly applied to initialize the typhoon or hurricane system the data assimilation
242 experiments, although longer spin-up period is also acceptable to introduce more
243 model errors in the background such as 12-hour or 24-hour. The first experiment is
244 assimilating GTS (Global Telecommunications System) conventional data (including
245 aircraft report, ship report, sounding report, satellite cloud wind data, ground station

246 data) only, which is called control experiment (CTNL). Another experiment is
247 configured with AHI radiance data assimilation (AHI_DA). AHI radiance data is
248 assimilated hourly further from 0000 UTC to 0600 UTC on 2 August 2015.
249 Afterwards, a 48 hours forecast is launched as the deterministic forecast. The
250 climatological background error (BE) statistics are estimated using the National
251 Meteorological Center (NMC) method. There are 5 control variables applied in this
252 study including U component, V component, full temperature, full surface pressure,
253 and pseudo-relative humidity. The observation error for each channel is estimated
254 based on the observed brightness temperature minus background brightness
255 temperature (OMB) from 0000 UTC on 1 August 2015 to 0000 UTC on 3 August
256 2015 every 6 hours.

257 Fig. 4 also shows the distribution of GTS observation data at the simulated
258 domain at 0000 UTC 2 August 2015. It is proved that raw radiance observations
259 thinned to a grid with 2–6 times of the model grid resolution are able to remove the
260 potential error correlations between adjacent observations (Schwartz et
261 al., 2012; Xu et al., 2015; Choi et al., 2017). Hence, 20 km is chosen to make
262 thinning of AHI radiance data. Also, sensitivity experiments with 25 km, and 30 km
263 thinning mesh are also conducted with similar results (Wang et al., 2018). The length
264 scale and the variance scale are set to be 0.5 and 1 respectively after several
265 sensitivity experiments conducted on tuning the background error. Similar
266 conclusions are also found in Shen and Min (2015) with the scale factors related to

267 the static background error covariance.

268 **4. Results**

269 *4.1 Minimization iterations*

270 In this study, minimization stops when the norm of the gradient for the cost
271 function is reduced by a factor of 0.01, which is commonly used in data assimilation
272 procedures. Inner minimization stops either when the criterion of the cost function
273 gradient is met or when inner iterations reach 200. Fig. 6 shows the cost function and
274 gradient with the iteration times. It is found that, for this case, the criterion of the cost
275 function gradient decrease is met. There is an obvious exponential decrease curve in
276 Fig. 6a, while Fig. 6b shows gradient decreases with the increase of iteration times. It
277 is seen from Fig. 6a that cost function decreases remarkably in the first 10 iterations.
278 However, after 30 times of iteration, the cost function curve becomes smooth
279 gradually. The differences between background field and observation were largest.
280 With continuous iterations, background field goes through continued adjustments.
281 Finally, the cost function tended to reach a stable minimum that represents the point
282 when cost function has its optimal solution. Besides, the gradient in Fig. 6b decreases
283 generally with increasing iterations. The exponential decrease of the cost function and
284 the change trend of its gradient indicate that the effectiveness of AHI radiance DA.
285 The final iterated analytical field was close to the observation. The wall clock times
286 used by CTNL and AHI_DA for the data assimilation procedures are rather
287 comparable with roughly 30 minutes and 40 minutes on a Linux workstation with 36

288 processors. It should be pointed out that computational cost of the deterministic
289 forecast and the pre-process for gridded GFS data are same in these two experiments.

290 *4.2 Analytical results of the brightness temperature*

291 Figs. 7a, c, and, e show the distribution of OMB, while the observed brightness
292 temperature minus the simulated brightness temperature from the analyses (OMA)
293 after the bias correction of AHI radiance data are presented in Figs. 7b, d, and f from
294 channels 8, 9, and 10 at 0000 UTC 2 August 2015. It should be pointed that even only
295 parts of the AHI radiance data (roughly 20000 clear sky pixels of total 50000 pixels
296 for each DA cycle) are applied after quality control in the data assimilation, the
297 radiative transfer model is able to simulate the brightness temperature for all the
298 model grid point with the background and the analysis respectively for the verification
299 purpose. The similar verification method is also applied in Yang et al., (2016). In the
300 Fig. 7a, part of typhoon's spiral cloud belt was clearly visible. The brightness
301 temperature in typhoon's inner-core area was low, while the brightness temperature in
302 other areas was high. The mean of observed OMB was -4.65 K, indicating that the
303 background brightness temperature was higher than the observation. It is found in Fig.
304 7b that the OMA values of most pixels were below 0.02 K, indicating that the
305 analytical field fitting the observation after analyzing. It can be inferred from Figs. 7a,
306 c, and e that the magnitude in OMB of channel 10 was generally larger than that of
307 channel 9, while that of the OMB in channel 8 was the smallest. This is because the
308 detection height of channel 10 was lower than that of channel 8 and 9 seen from the

309 weighting function (Fig. 1), indicating channel 10 is largely affected by the clouds.
310 Conversely, the weighting peak of the channel 8 was the highest, being least affected
311 by the clouds. In general, the simulated brightness temperature from the analyses
312 matched well with the observed brightness temperature of all the three water vapor
313 channels after the assimilation of AHI radiance data.

314 To validate the effect of the bias correction for AHI radiance data at 0000 UTC 2
315 August 2015, the scatter plots of the observed brightness temperature and the
316 brightness temperature from the background before the bias correction are shown in
317 Figs. 8a, d, and g. Similarly, the results after the bias correction are provided in Figs.
318 8b, e, and h. From Fig. 8a, before the bias correction, the values from the observation
319 and the background were comparable, but most of the scatter points were below the
320 diagonal line. This suggests that the observed brightness temperature was higher than
321 the background simulated brightness temperature. From Fig. 8b, after the bias
322 correction, the observed warm bias was corrected to some extent with the root mean
323 square error (RMSE) of OMB decreasing from 1.864 K to 1.627 K and the average
324 decreasing from 0.956 K to 0.358 K. The scatter plots of the observed brightness
325 temperature and the brightness temperature from the analyses after the bias correction
326 are shown in Figs. 8 c, f, and j. Compared to the result of Fig. 8b, the scatters in Fig.
327 8c were more symmetrical, fitting closely to the diagonal line. The mean and RMSE
328 were also significantly reduced, suggesting that the analytical fields match better with
329 the observation than background field. Among them the RMSEs of channel 10 are
330 smallest compared to those from channels 8 and 9 for the OMB and OMA samples,
331 which is likely related to strict cloud detection scheme for channel 10 with rather
332 lower detecting peak (Wang et al., 2018).

333 Fig. 9 shows the observation numbers, the mean, and the standard deviation of
334 OMB and OMA of channels 8, 9, and 10 before and after the bias correction. It can be

335 seen that after the quality control, 24057, 24181, 21785 observations are adopted in
336 the DA system for channels 8, 9, and 10, respectively. From the mean value of OMB
337 before the bias correction, the value of the three channels was relatively small,
338 indicating that the simulated brightness temperature of the three channels was close to
339 the observed brightness temperature. The lowest mean of 0.3 K was found in channel
340 10, indicating that the simulated brightness temperature of channel 10 was closest to
341 the observed brightness temperature. Bias correction effectively corrected the
342 systematic bias and reduces the mean value of observation residuals. After the bias
343 correction, the OMB mean value of the three channels significantly decreases to
344 nearly 0 K. With the bias correction, the simulated brightness temperature was almost
345 the same as the observed brightness temperature. The standard deviations (stdv) of
346 OMB were comparable before and after the bias correction, since they are calculated
347 by subtracting the mean of the bias. It is found that the bias was corrected effectively
348 with an overall same magnitude of bias for each pixel, leading the stdv almost same
349 before and after the bias correction. The standard deviation of OMA decreased by
350 about 80% compared to OMB, indicating that the analyses fit better with the
351 observations after the data assimilation. Differences between the standard deviations
352 of the OMB and OMA were statistically significant at the 95% level using zero
353 difference for the null hypothesis.

354 The RMSEs of the simulated brightness temperature by the NWP model before
355 and after the assimilation are also calculated against the AHI radiance observations.

356 Fig. 10 shows the RMSEs during the DA cycles for channels 8, 9, and 10. As can be
357 seen from Fig. 10, RMSE decreased after each analysis in AHI_DA. The most
358 significant improvement was from the first analysis cycle of channel 8, where RMSE
359 of the brightness temperature after assimilation significantly decreases from 1.64 K to
360 0.46 K, possibly due to the largest adjustment on the background for the first analysis
361 time. The background before the assimilation was the short-term forecast from the
362 previous analysis. The increase of the RMSE in the fluctuation arised from the model
363 error in the 1 hour short-term forecast. Overall, the effect of the analysis from the
364 channel 10 was most significant.

365 *4.3 Analysis of the typhoon structure*

366 Fig. 11 shows the wind field at sea level and the distribution of water vapor at
367 850 hPa at 0000 UTC 2 August 2015. The obvious cyclonic eddy circulation
368 structures in the core area of the typhoon are found in both fields, while the
369 anti-cyclonic circulation existed in the northwest quadrant of the typhoon. The mixing
370 ratio of water vapor in the region where the typhoon located was very high and the
371 wind field is cyclonic, indicating that the typhoon has a continuous water vapor
372 advection. This contributed to the enhancement of typhoon (Kamineni, et al., 2003).
373 From the flow field of the control experiment in Fig. 11a, the water vapor
374 convergence in the center of the typhoon region was weak with the low intensity and
375 smaller coverage. As can be seen from Fig. 11b, after the assimilation of AHI radiance
376 data, the streamlines in the typhoon region become denser, indicating that the cyclonic

377 circulation was strengthened. Conversely, the intensity and distribution of the water
378 vapor after the assimilation of AHI radiance data tend to contribute to the developing
379 typhoon. This suggests that the field outside of the typhoon center was also adjusted
380 as the assimilation of AHI radiance data was able to improve the large-scale
381 environmental field in the simulation region of Typhoon Soudelor. It should be
382 pointed out that the model status in the cloudy area was modified due to the spatial
383 correlation in the background error covariance. The similar findings for small-scale
384 information in the cloudy area can also be referred in Wang et al., (2018).

385 *4.4 Track forecast*

386 In order to further evaluate the effect of AHI radiance data assimilation, a 48-hour
387 deterministic forecast was launched with the analyses initialized from 0000 UTC 2
388 August 2015 and 0600 UTC 2 August 2015 respectively. The best track data are
389 provided by the CMA (Yu et al., 2007; Song et al., 2010). The improvement is most
390 obvious at the start and end point. As can be seen in Fig. 12a, at the beginning of the
391 forecast, the initial location of the typhoon from the CTNL experiment has large south
392 bias and east bias at 0000 UTC and 0600 UTC respectively. Conversely, the location
393 of the typhoon in AHI_DA is relatively closer to the observation at the beginning..
394 During the following few hours of forecasts, the typhoon track predicted by the CTNL
395 continues to show a south-west bias with the environmental wind, while the track
396 predicted by AHI_DA match better with the best track. Fig. 12c shows the averaged
397 typhoon track error over the two forecasts predicted by the two experiments. At the

398 initial time of the forecast, the track errors of CTNL and AHI_DA were significantly
399 different, with the magnitude of 55.6 km and 13.4 km, respectively. During the
400 subsequent 48-hour forecast, the track error of the CTNL gradually increases with the
401 forecast time reaching 167.1 km at the end of the forecast. In contrast, the track error
402 of AHI_DA is consistently less than 122.5 km during the 48-hour forecast period. In
403 general, the average track error of the CTNL is 168.57 km, and the average track error
404 of AHI_DA experiment is only 67.0 km, indicating a significant improvement in the
405 track prediction.

406 Fig. 13 provides the time series of the typhoon intensity from the two
407 experiments in terms of the averaged maximum surface wind and minimum sea level
408 pressure error over the two forecasts initialized from 0000 UTC 2 August 2015 and
409 0600 UTC 2 August 2015 respectively. It can be seen that the maximum surface wind
410 error predicted by the AHI_DA was much lower than that by the CTNL for the first 30
411 hours, due to the overall under estimation for the intensity of Typhoon Soudelor
412 simulated in the background field. The maximum surface wind errors of AHI_DA are
413 generally smaller than those of CTNL. It should be pointed out that the difference
414 between the maximum surface wind errors of the two experiments reaches up to 7.5 m
415 s-1 after 24-hour forecast. In Fig. 13b, the results of the minimum sea level pressure
416 are consistent with Fig. 13a, while the improvement for the minimum sea level
417 pressure lasts for 40 hours.

418 **5. Conclusion**

419 An interface for AHI radiance data assimilation on the WRFDA system based on
420 the 3DVAR assimilation method was built. Based on the Typhoon Soudelor in 2015,
421 two experiments for comparison was designed to examine the impact of AHI water
422 vapor channel radiance data assimilation on the analysis and prediction of the rapid
423 development stage of Typhoon Soudelor under clear sky condition. Following
424 conclusions are obtained:

425 (1) The AHI radiance data on the new generation of geostationary meteorological
426 satellite is able to reflect the structure of Typhoon Soudelor very clearly. After a series
427 of pre-procedures such as the quality control, the bias correction, cloudy pixels are
428 able to effectively be eliminated, ensuring the validity and rationality of the Ahi
429 radiance data. The biases are also eliminated from the VarBC statistical method,
430 which is able to provide a positive impact on the data assimilation procedure for the
431 typhoon numerical simulation.

432 (2) Compared with the control experiment with only GTS data, the 3DVAR
433 assimilation including AHI radiance data is able to improve the structure of typhoon's
434 core and outer rain band. Also, the position and intensity of typhoon in the
435 background field are able to be corrected.

436 (3) Generally, the track and minimum sea level pressure from the AHI radiance data
437 assimilation experiment match better with the best track than the control experiment
438 does for the subsequent 48-hour forecast. The maximum surface wind forecast error is

439 reduced only for the first 30-hour.

440 In this study, the AHI water radiance data assimilation is conducted under the
441 clear sky condition. The results of the experiments indicate that AHI radiance data
442 assimilation has a positive effect on the analysis and prediction of rapidly intensifying
443 TC. Although, the whole developing stages of Typhoon Soudelor include a rapid
444 intensification, a weakening, a second intensification, only the first intensification
445 during 1 August to 4 August considered as the numerical period. It is worth
446 investigating the impact of AHI data assimilation on the whole period including the
447 first intensification, a weakening, and the second intensification of Typhoon Soudelor
448 to fully prove the advantages of AHI radiance data assimilation. Considering the
449 complex influence of underlying surface, only the rapid development stage of typhoon
450 at sea were studied, while the whole generation, development and disappearance stage
451 of typhoon can also be studied in the future. In addition, based on the AHI radiance
452 data of the water vapor channels under the condition of clear sky, only 3DVAR
453 method was adopted. Further improvements under the condition of all sky and hybrid
454 DA can be obtained in the future.

744 Code/Data availability. The WRF Model code used in this research is available at
745 https://www2.mmm.ucar.edu/wrf/users/download/get_source.html. The Himawari-8
746 AHI radiance data can be downloaded from <https://www.eorc.jaxa.jp/tree/index.html>.
747 Code/Data used in this research is available on request from the author.

748 Author contribution. Conceptualization, FFS, AQS and HL; methodology, FFS, AQS
749 and DMX; validation, FFS, AQS and DMX; supervision, HL and JZM; project
750 administration, HL and JZM. All authors discussed the results and contributed to the
751 final version of the paper.

752 Competing interests. The authors declare that they have no conflict of interest.

753 Acknowledgements. This research was primarily supported by the Chinese National
754 Natural Science Foundation of China (G41805016), the Chinese National Key R&D
755 Program of China (2018YFC1506404), the Chinese National Natural Science
756 Foundation of China (G41805070), the Chinese National Key R&D Program of China
757 (2018YFC1506603), the research project of Heavy Rain and Drought-Flood Disasters
758 in Plateau and Basin Key Laboratory of Sichuan Province in China (SZKT201901,
759 SZKT201904), the research project of the Institute of Atmospheric Environment,
760 China Meteorological Administration, Shenyang in China (2020SYIAE07,
761 2020SYIAE02). The numerical calculations in this paper have been done on the
762 supercomputing system in the Supercomputing Center of Nanjing University of
763 Information Science & Technology.
