15 **ABSTRACT**

16 In several countries, the rising occurrence of sinkholes has led to severe social and economic damage. Based
17 on the mechanism of sinkhole development, researchers have investigated the correlation between rainfall
18 intensity and sinkholes caused by damaged sewer pipes. In this study, the effect of rainfall intensity on the
19 formation of eroded zones, as well as the occurrence of sinkholes caused by soil erosion due to groundwater
20 infiltration through pipe defects, has been analyzed through model tests. The ground materials in Seoul were
21 represented by weathered granite soil, which is generally used for backfill sewer pipes, and groundwater
22 levels corresponding to three different rainfall intensity conditions were considered. The ground level
23 changes and ground displacements were measured continuously, and the particle image velocimetry (PIV)
24 algorithm was applied to measure the displacement at each position of the model ground. The results indicate
25 that impeding the excessive rise of groundwater levels by securing sufficient sewage treatment facilities can
26 effectively prevent the development of sinkholes caused by pipe defects.

27 **1 Introduction**

28 In recent times, cases of sinkholes have been reported in several countries, such as the US, Japan, Italy, South
29 Africa, China, Spain and South Korea. Major social and economic issues have ensued owing to the resulting
30 structural problems, such as the collapse of buildings and road erosion (Galloway et al., 1999; Waltham et
31 al., 2005; Gutierrez et al., 2008; Kuwano et al., 2010a; Oosthuizen and Richardson, 2011; Beck et al., 2012;
32 Guarino and Nisio, 2012; Yokota et al., 2012; Gao et al., 2013; Intrieri et al., 2015; Bae et al., 2016; Parise,
33 2019). In general, sinkholes can be classified into two types: (1) natural sinkholes and (2) anthropogenic
34 sinkholes (Guarino and Nisio, 2012; Gutierrez et al., 2008, 2014; Beck, 2012; Parise, 2019). Natural
35 sinkholes occur when the underlying ground layer (e.g., karst landscape) is easily soluble in water, whereas
36 anthropogenic sinkholes may occur also in a non-karst environment (Parise, 2015), caused by human activity
37 such as sewage damage, inadvertent excavation, or groundwater lowering.

38 Both types of sinkholes have similar mechanisms, and the detailed process of occurrence is as follows
39 (Rogers, 1986; Brinkmann et al., 2008; Caramanna et al., 2008; Kuwano et al., 2010a; Oosthuizen and
40 Richardson, 2011; Martinotti et al., 2017): (1) A cavity is formed underground by external factors (the water-
41 soluble ground layer dissolves in groundwater to cause a natural sinkhole, or soil erosion occurs along with
42 the groundwater outflow due to sewage damage or excavation to cause an anthropogenic sinkhole). (2) The
43 groundwater level rises during rainfall and falls after the rainfall, causing the soil around the cavity to be lost
44 and the cavity to expand. (3) A sinkhole is finally generated because of the repeated increase and decrease of
45 the groundwater level.

46 Based on the mechanism for both types of sinkholes (natural and anthropogenic), a direct relationship can be
47 inferred between the rainfall intensity, which leads to the transition of the groundwater level (rise and fall),
48 and the occurrence of sinkhole. Notably, the change in climate due to global warming has resulted in higher
49 rainfall intensity with fewer rainy days (Alpert et al., 2002; Kristo et al., 2017; Rahardjo et al., 2019). In
50 South Korea, the maximum daily rainfall has increased over the decades in most regions and is expected to
51 increase significantly in the future (Nadarajah and Choi, 2007; Wi et al., 2016; Choi et al., 2017). For
52 landslides, many studies have established the influences of rainfall on those geological hazards (Peruccacci
53 et al., 2012; Rossi et al., 2012; Vessia et al., 2012). In this context, there is a growing need to study the
54 correlation between rainfall intensity and sinkhole occurrence.

55 Martinotti et al. (2017) and Parise et al. (2018) showed that a period of torrential rain and the rainfall intensity
56 triggered natural sinkholes in Italy. Gao et al. (2013) confirmed that the groundwater level rise due to
57 extremely heavy rainfall has a significant effect on sinkhole generation in a karst environment in China. Van
58 Den Eeckhaut et al. (2007) showed that the formation of numerous natural sinkholes in Belgium
59 corresponded with periods of high rainfall and high groundwater recharge, which commonly increased the
60 weight of the overburden and decreased its cohesion.

61 The majority of sinkholes in non-karst environments are known to occur because of damaged sewer pipes.
62 In Seoul, South Korea, an average of 677 sinkholes and subsidence occurred annually from 2010 to 2015, of

63 which 81.4 % were due to damage to old sewer pipes (Bae et al., 2016). In Japan, local governments in
64 sewage projects were surveyed to identify cases of subsidence due to damage to sewer pipes. As a result, a
65 total of 17,000 data were reported from 2006 to 2009 (Yokota et al., 2012).

66 Considering these factors, several researchers have conducted statistical analysis and model experiments to
67 investigate the correlation between rainfall intensity and sinkholes caused by damaged sewer pipes. Kwak et
68 al. (2016) showed that the number of anthropogenic sinkhole cases increased with the increase in total
69 monthly precipitation. In addition, it was confirmed that anthropogenic sinkholes are prone to occur after
70 exceptionally heavy rains. By quantifying Pearson's correlation coefficient between two relevant
71 observations, Choi et al. (2017) showed that the monthly accumulated precipitation and the quantity of
72 subsidence are related to a certain extent. Guo et al. (2013) and Tang et al. (2017) used model experiments
73 and evaluated the effect of the defect size, groundwater level, and particle size on soil erosion due to
74 groundwater infiltration through pipe defects. However, they only used non-cohesive soils and covered
75 extreme cases with groundwater levels significantly exceeding the ground level.

76 In this study, the urban area in Seoul has been simulated, and model tests have been conducted to analyze the
77 effect of rainfall intensity on the formation of eroded zones, as well as the occurrence of sinkholes caused by
78 soil erosion due to groundwater infiltration through pipe defects. The model ground was constructed using
79 weathered granite soil (which is generally cohesive), mainly used to backfill the sewer pipes in Seoul. Three
80 rainfall intensity conditions (heavy rainfall, very heavy rainfall, and extremely heavy rainfall) were set for
81 the groundwater level, based on summer rainfall patterns in Korea, to be applied in the model tests. The
82 groundwater level change, discharged soil volume, and ground displacement were measured continuously
83 throughout the tests. In particular, the particle image velocimetry (PIV) method, which can continuously
84 measure and analyze the displacements in the ground, was applied to quantify the ground deformation with
85 the occurrence and expansion of underground cavities.

86 The remainder of this paper is organized as follows. Section 2 describes the model test device, model grounds,
87 and test conditions. Section 3 discusses the model test results. Finally, Section 4 presents the conclusions.

88 **2 Experimental program**

89 **2.1 Experiment apparatus**

90 In this study, experiments were performed using the model tester developed by Kwak et al. (2019) to simulate
91 ground subsidence (Figure 1). The distance between each pipe in the sewer pipe network in Seoul was
92 examined and found to be around 1.2 m. In order to exclude the effects of unnecessary boundary conditions,
93 the width of the model soil was set to 1.4 m, with respective left and right margins of 0.1 m. Considering that
94 the average landfill depth of a sewage pipe in Seoul is 0.9 m (Kim et al., 2018), the soil chamber was built to
95 a height of 1.0 m, including a 0.1 m clearance to facilitate sample composition. The depth of the soil chamber

96 was set to 0.1 m to simulate the plane strain condition, and the front plate of the chamber was made of acrylic
97 plate to allow the inside of the ground to be photographed during the test.
98 A slit was installed at the bottom of the soil chamber to simulate the damage of the sewer pipe allowing the
99 inflow and outflow of sewage and the outflow of soil during the model test. The width of the slit(B) was set
100 to 2 cm, based on the study by Mukunoki et al. (2012), such that B/D_{max} was 4.2 (maximum particle diameter
101 of weathered soil $D_{max} = 4.76$ mm). A supply valve and a drain valve were installed under the slit to control
102 the inflow and outflow of groundwater as well as the outflow of eroded soil. The external water tank
103 connected to the inlet valve was designed to maintain a constant level even when water is continuously
104 supplied to the model ground. Through experimental assessment (Table 1), the National Disaster Management
105 Institute of Korea (2014) suggested a relationship between the rainfall intensity and the hydraulic head in the
106 sewage network conditions near Gangnam station (sewer pipe with 1000 mm of diameter was simulated). It
107 should be noted that the hydraulic head increases linearly with the rainfall strength until the rainfall strength
108 is 40 mm/h, but thereafter increases sharply. In the present study, the height of the external tank was made
109 adjustable to simulate the various rainfall intensity (related to hydraulic head).

110 **2.2 Model ground**

111 The vast majority of prior studies that have experimentally assessed the ground subsidence and sinkhole due
112 to sewer pipe damage have been conducted on poorly-graded non-cohesive soils (Kuwano et al., 2010a,
113 2010b; Guo et al., 2013; Sato and Kuwano, 2015; Indiketiya et al., 2017; Tang et al., 2017). However, in
114 several countries, the sewage reclamation specifications allow the landfill soil to contain 15–25 % of fine
115 contents. There are no restrictions on particle size distribution apart from the maximum particle size (Japan
116 Road Association, 1990; Ministry of Environment of Korea, 2010). In the present study, to simulate the
117 ground in Seoul in which weathered granite soil, which is a well-graded cohesive soil, is widely distributed,
118 the model ground was created by collecting Gwanak weathered soil and adjusting the fine content to 7.5% to
119 meet the fine content standard. The degree of compaction was also set to 93 % of the standard maximum unit
120 dry weight $\gamma_{d,max}$ to satisfy the sewer pipe landfill standards, and the model ground was constructed with the
121 optimum moisture content. Figure 2 shows the particle size distributions of the adjusted and natural Gwanak
122 soil in comparison with the sewer pipe landfill standards in South Korea and Japan. Table 2 lists the basic
123 physical properties, strength parameters and saturated permeability coefficient of the adjusted Gwanak soil
124 used in the model test.

125 **2.3 Digital image analysis**

126 In geotechnical engineering, digital imaging techniques are primarily used to measure the deformation of
127 target samples (Alshibli and Sture, 1999; White et al., 2003; Indiketiya et al., 2017; Kim et al., 2017; Kwak
128 et al., 2019). In the present study, the displacement at each position of the model ground was measured by
129 applying the PIV algorithm (Adrian, 1991), which is the most widely used technique in the field of

130 geotechnical engineering. The PIV cross-correlation on the pixel sets of the pre-deformation and post-
131 deformation images were calculated to obtain the point with the highest correlation. The position of the
132 sample set with the highest correlation is used to estimate the relative displacement at each position of the
133 sample (Kim et al., 2011; White et al., 2003). In this study, the internal displacement of the sample was
134 evaluated using GeoPIV (White and Take, 2002), a commercial program that is widely used to apply the PIV
135 technique in geotechnical engineering. With the displacement, the volume and shear strain are estimated
136 together for the analysis.

137 In general, when applying the PIV technique, high accuracy analysis results can be obtained when the
138 uniqueness of the pixel set increases with the size of the pixel set. However, in order to calculate
139 displacements at various positions, it is necessary to set an appropriate size for the set of pixels. Accuracy
140 and precision verification of the GeoPIV program was performed for various-sized pixel subsets (40x40,
141 60x60, 80x80, 100x100, and 120x120) by comparing two digital images: the original image of the model
142 ground and the image artificially shifted by ten pixels at the four edges of the model ground. The optimum
143 size of the pixel set was chosen as 100 by 100 pixels, which shows a 0.0069 pixel maximum error in accuracy
144 and precision. As shown in Figure 3, the PIV technique was applied to the positions of a total of 2600 pixel
145 subsets (65 by 40). To minimize the boundary effect between the interface of the sample and the soil chamber,
146 the vicinity of the wall was excluded from the analysis. In addition, any excessive relative displacement due
147 to soil erosion (no highly correlated pixel sets found in the post-deformation image) was excluded from the
148 analysis.

149 **2.4 Test procedures**

150 Once the model ground was created, the model tests which consisted of a water supply stage and a water
151 drainage stage were conducted. The water supply stage represents the infiltration of sewer water from the
152 pipes to the ground through damaged sections during heavy rainfall periods. This phenomenon was simulated
153 in the model test by introducing water from the external water tank into the soil chamber through the supply
154 valve and slit to reach the target groundwater level (i.e. hydraulic head). After heavy rainfall, the hydraulic
155 pressure of a sewer pipe becomes lower (as the sewer pipe becomes vacant), thus, it is the most likely that
156 the groundwater will flow back through the damaged section. The water drainage stage simulates the drainage
157 of groundwater into the sewer pipes through the damaged sections after heavy rainfall periods by closing the
158 supply valve and opening the drainage valve. The soil also discharged through the lower slit along with the
159 water drainage. Table 3 shows the conditions of the three model tests conducted in this study, simulating
160 cases with rainfall intensities of 40 mm/h (represent the rainfall intensity of heavy rain watch in South Korea)
161 and 50 mm/h (represent the rainfall intensity of heavy rain warning in South Korea) presented in Table 1, as
162 well as that with the groundwater level rising to the ground surface.

163 Linear variable displacement transducers (LVDTs) were installed at three locations on the surface of the
164 ground, at 0, 30, and 60 cm from the center of the soil chamber, to measure the surface displacement during

165 the tests (Figure 1). During the model tests, digital images of the ground were continuously captured, and the
166 PIV technique was applied to analyze the displacement and deformation (Adrian, 1991; Alshibli and Akbas,
167 2007; Kim et al., 2017; Kwak et al., 2019). In addition, the amount of soil discharged through the slit was
168 measured after the water supply and water drainage stages of each test.

169 **3 Experimental results and discussion**

170 **3.1 Test 1: Heavy rainfall intensity (47 cm hydraulic head)**

171 **3.1.1 Water supply stage**

172 Test 1 was conducted by introducing groundwater to a 47 cm initial hydraulic head (the height difference
173 between the slit and weir in the water tank) to simulate a heavy rainfall intensity of 40 mm/h. In the water
174 supply stage of Test 1, no soil deformation occurred on the ground surface (measured by the LVDTs) and in
175 the ground (measured by the PIV technique) as the groundwater level approached 47 cm. Immediately after
176 opening the slit, the water pressure acting on the ground directly above the slit was 4.5 kPa, and the vertical
177 earth pressure generated by the upper soil was about 16.7 kPa. Therefore, under this condition, the soil always
178 had a positive effective stress, and the piping phenomenon did not occur. In this study, since the model ground
179 was densely constructed ($D_R = 78\%$) with a sufficient degree of compaction ($R_C = 93\%$) according to
180 domestic specification, no water compaction (Kwak et al., 2019), which occurs mainly when sewage flows
181 into a loose sandy soil, was observed. From these results, it was confirmed in this experimental case that the
182 resistance factor (due to the soil strength parameter) was greater than the sum of the drag force (upward force
183 by infiltration pressure during water supply) and the gravity (downward force).

184 **3.1.2 Water drainage stage**

185 In the water drainage stage of Test 1, no soil deformation was observed on the ground surface as in the water
186 supply stage. The deformation in the ground was evaluated by applying PIV to the images captured during
187 the test. Figures 4, 5, 6 are the PIV analysis results showing the estimated displacement vector, volume, and
188 shear strain increments in six phases: (a) 0–30 s, (b) 30–60 s, (c) 60–90 s, (d) 90–120 s, (e) 120–150 s, and
189 (f) 150–180 s. For the volumetric strain, the red grid (the area with positive values) indicates that the area has
190 expanded, and the blue grid (the area with negative values) indicates that the area has been compressed.

191 In the water drainage stage, the water pressure applied through the slit disappeared, and the groundwater in
192 the soil chamber was discharged quickly through the slit. Unlike in the water supply stage, the ground below
193 the groundwater level became saturated and lost its apparent cohesion. The rapid outflow of groundwater
194 resulted in a downward infiltration into the ground, and the soil was discharged from the area immediately
195 above the slit, where there was no active restraining pressure (and thus, no shear strength), along with the
196 groundwater.

197 During the initial phase of the water drainage stage (0–60 s), the soil was discharged through the slit, causing
198 a downward displacement in the periphery of the cavity, and a triangular cavity was formed just above the
199 slit (Figure 4a and b). In addition, volume and shear strain increments occurred intensively around the cavity
200 (Figure 5a, b, Figure 6a and b). In the 60–90 s interval of the water drainage stage, as shown in Figure 4c,
201 the soils on both sides of the cavity collapsed, and the cavity expanded laterally. The volume and shear strain
202 increments were concentrated in small areas near the cavity, similar to the initial stage (Figure 5c and Figure
203 6c).

204 As shown in Figure 4d, during the 90–120 s interval of the groundwater drainage stage, the lateral expansion
205 of the cavity inside the ground was completed, and no downward displacement was observed in the upper
206 part of the cavity and the soils on the sides. The volume and shear strain increments were also not observed
207 in the outer region of the cavity (Figure 5d and Figure 6d). In this phase, the cavity collapsed; the soil
208 accumulated near the slit gradually shifted to escape into the slit, and the deformation was concentrated near
209 the slit. After 120 s, the soil regained its apparent adhesion due to surface tension, and its outflow stabilized
210 as the drainage completed. Finally, a mushroom-shaped cavity was formed (Figure 4e and f).

211 **3.2 Test 2: Very heavy rainfall intensity (70 cm hydraulic head)**

212 **3.2.1 Water supply stage**

213 Test 2 was conducted by setting the maximum groundwater level to 70 cm to simulate a high rainfall intensity
214 of 50 mm/h. During the water supply stage of Test 2, no soil deformation was observed on the ground surface
215 and in the ground by both LVDT and PIV analyses. As a result, owing to the soil strength parameter, the
216 resistance factor was found to remain greater than the sum of the drag force (upward force by infiltration
217 pressure during water supply) and the gravity (downward force), despite the application of a higher hydraulic
218 pressure in Test 2 as compared to that in Test 1.

219 **3.2.2 Water drainage stage**

220 During the water drainage stage of Test 2, no vertical displacement was observed on the surface of the model
221 ground. The displacement of the soil element according to the development of the underground cavity was
222 observed by the PIV technique. Figures 7, 8, and 9 show the displacement increment vectors, incremental
223 volumetric strain distribution, and incremental shear strain distribution, respectively; the analysis was
224 conducted in four phases: (a) 0–30 s, (b) 30–60 s, (c) 60–90 s, and (d) 90–120 s (the displacement ended within
225 120 s).

226 In the initial phase of the water drainage stage (0–30 s), the soil was discharged through the slit, causing an
227 internal collapse near the slit. Thus, an underground cavity was formed (Figure 7a), differing from that in
228 Test 1 in terms of shape as well as location; it was located close to the maximum groundwater level (about
229 60 cm from the bottom plate). These results indicate that the hydraulic pressure (related to rainfall intensity)
230 affects the shape and location of the underground cavity in the water drainage stage. In Test 1, the eroded

231 zone was formed up to about 89 % of the maximum groundwater level. In Test 2, it developed up to about
232 86 %. When a poorly-graded non-cohesive soil was used under the same experimental conditions, the cavity
233 developed up to 107 % of the maximum groundwater level (Kwak et al., 2019). This shows that the well-
234 graded cohesive soil used in this study has a greater resistance to soil erosion. In addition, during the initial
235 stage (0–30 s), the incremental volumetric and shear strains were found to be concentrated in the upper area
236 of the underground cavity (Figure 8a and Figure 9a).

237 During the 30–90 s phase, downward displacement was no longer observed at the top of the cavity;
238 displacement in the slit direction occurred only in the left and right areas adjacent to the cavity (Figure 7b
239 and c). The volumetric and shear strains also showed a tendency to be concentrated in the left and right areas
240 where the displacement occurred, indicating that the cavity gradually increased laterally (Figure 8b, c, Figure
241 9b, and c). In the process of forming a cavity, the downward infiltration pressure was low, and the soil that
242 had lost strength accumulated near the slit. On the other hand, when the downward infiltration pressure was
243 higher, all the soil that had lost strength escaped, resulting in the formation of an oval cavity. After 90 s, as
244 the groundwater level was exhausted, the unsaturated strength of the ground was restored, and no further
245 displacement or deformation were observed inside the ground (Figure 7d, Figure 8d, and Figure 9d).

246 **3.3 Test 3: Extremely heavy rainfall intensity (90 cm hydraulic head)**

247 **3.3.1 Water supply stage**

248 Test 3 was conducted to simulate the intensity of an extremely heavy rainfall that causes the groundwater
249 level to rise up to the surface of the ground. In the water supply stage of Test 3, significant displacements
250 were measured on the surface (LVDTs) and inside the model ground (PIV). Figure 10 shows the surface
251 displacement over time, with a gradual subsidence after approximately 2400 s. The ground displacements
252 identified by the PIV technique from 0–2000 s also showed no specific behaviors. Therefore, the internal
253 displacement vectors identified as a result of the PIV technique after 2000 s are shown in Figure 11, overlaid
254 onto the final photograph of each step: (a) 2000–2400 s, (b) 2400–2800 s, (c) 2800–3200 s, and (d) 3200–
255 3600 s.

256 As the groundwater level reached about 75 cm (83 % of ground height), soil particle displacement was
257 observed in the soil from 2000–2400 s. This result indicates that, owing to the strength of the soil, the
258 resistance factor becomes smaller as the model ground is saturated, and the weight of the soil in the saturated
259 region cannot be supported. Since the soil in the upper part of the groundwater level still maintained its
260 unsaturated strength, the downward displacement appeared only in the area adjacent to the groundwater level.
261 There was still no subsidence observed on the surface (Figure 11a).

262 From 2400–2800 s, downward displacement towards the slit was observed throughout the soil area. In
263 particular, a larger downward displacement was observed in the inverted triangle region above the slit, which
264 was significantly affected by the inflow of groundwater (Figure 11b). As the groundwater level rose, the
265 matric suction expressed in the unsaturated region of the ground decreased. Therefore, the subsidence on the

266 ground surface was also measured from this phase. From 2800–3200 s, the groundwater level reached 80 cm
267 from the bottom (89 % of ground height), and the maximum downward displacement of the entire water
268 supply stage was observed during this phase (Figure 11c). This indicates that infiltration occurs when the
269 groundwater level approaches the ground surface, and the soil structure is no longer supported as there is no
270 longer sufficient matric suction in the ground directly above the groundwater level. After 3200 s, downward
271 displacement occurred continuously throughout the soil area until groundwater level reaches the target level
272 (Figure 11d).

273 **3.3.2 Water drainage stage**

274 The water drainage stage of Test 3 was divided into four phases for the analysis: (a) 0–30 s, (b) 30–60 s, (c)
275 60–90 s, and (d) 90–120 s. The displacement increment vectors, incremental volumetric strain distributions,
276 and incremental shear strain distributions of each stage are shown in Figures 12, 13 and 14, respectively,
277 overlaid onto the photograph of the target ground taken at the end of each phase.

278 In the initial phase (0–30 s) of the water drainage stage of Test 3, the groundwater was rapidly discharged
279 into the slit owing to high downward infiltration pressure. As the soil particles escaped along with the
280 groundwater discharge, the upper ground collapsed, forming an anthropogenic sinkhole similar in shape to
281 the punching shear failure (Figure 12a). In the previous tests, the cavities formed up to about 86 % and 89 %
282 of the maximum groundwater level. The shape of the formed anthropogenic sinkhole indicated significant
283 downward displacement (of the soil that had lost strength) towards the slit. The sudden collapse of the ground
284 clogged the slit, which in turn prevented soil discharge. At this time, the shear deformation also showed a
285 tendency to be concentrated around the collapsed soil (Figure 14a). After the soil was completely drained,
286 no significant deformation inside the ground and on the ground surface were observed via the PIV technique
287 and the LVDTs after 30 s, as the matric suction allowed the ground to recover its unsaturated strength.

288 **3.4 Comparative Study**

289 To quantitatively analyze the effect of rainfall intensity on ground cavity and sinkhole development, the
290 evolution of the cavity size with time in the water drainage stage was obtained for each test, and the time at
291 which the water was completely drained was also displayed, as shown in Figure 15. For the hydraulic pressure
292 of 45 cm and 70 cm, the time taken for the groundwater to drain completely was 70 s and 90 s, respectively.
293 However, in Test 3, although the groundwater level was higher, the soil collapsed instantly, resulting in an
294 anthropogenic sinkhole, and the time taken for complete drainage was 80 s, which was faster than that in Test
295 2. After the drainage was completed, the cavity sizes measured in Test 1 and Test 2 were 497 cm² (66 % of
296 the final cavity size of 742 cm²) and 1286 cm² (87 % of the final cavity size of 1482 cm²), respectively. In
297 both Tests 1 and 2, the cavity expanded for about 30 s after the drainage was completed, at which time its
298 size tended to stabilize. In Test 3, where the anthropogenic sinkhole occurred, a cavity of 1207 cm² (56 % of

299 the final cavity size of 2171 cm²) was formed after the drainage was completed, after which the cavity
300 continued to expand for approximately 200 s.

301 Table 4 shows the ratio of the weight of the total soil volume to the weight of the discharged soil volume, the
302 volume ratio of the area corresponding to the cavity, and the weight ratio of the loosening zone, respectively.
303 The size and internal density change of the loosening zone were calculated by the following method. (1)
304 After completion of the test, the discharged soil was dried to measure the weight. (2) The weight of the area
305 corresponding to the cavity was calculated by multiplying the calculated volume of the cavity by the initial
306 density of the soil. The soil weight corresponding to the loosening zone was calculated through the difference
307 between the results of steps (1) and (2). (3) The size of the loosening zone was calculated by excluding the
308 area corresponding to the cavity from the area overlapping with the volumetric strain calculated in each step.
309 (4) The internal density change was confirmed using the results of steps (2) and (3).

310 As shown in Table 4, the size and density change of the loosening area were found to be nearly identical in
311 the three tests. On the other hand, as the hydraulic head increased, the weight and volume of the eroded zone
312 and the average width of the cavity relative to the slit width increased linearly. However, recalling the fact
313 that the hydraulic head increased drastically when the rainfall intensity exceeds a certain threshold, it can be
314 inferred that the volume of the discharged soil and the size of the eroded zone may also increase exponentially
315 with rainfall intensity. The threshold value is definitely specific to a given sewer-system. Thus the
316 experimental results of this study suggest that to prevent sinkholes caused by pipe defects, sewage pipe
317 network facilities need to be expanded to inhibit the rapid rise of groundwater levels in preparation for
318 increased torrential rain caused by climate change.

319 **4 Conclusions**

320 In this study, model tests were used to analyze the effects of rainfall intensity on the formation of the eroded
321 zone and the occurrence of sinkholes caused by soil erosions due to groundwater infiltration through pipe
322 defects. The model tests were conducted to simulate the actual site conditions as far as possible by using the
323 soil used around sewer pipe networks and the sewer pipe landfill standards as well as a large-scale soil
324 chamber. The groundwater level was applied to the model tests by setting three hydraulic heads based on the
325 heavy rainfall characteristics of South Korea: (1) heavy rainfall intensity (47 cm hydraulic head); (2) very
326 heavy rainfall intensity (70 cm hydraulic head); and (3) extremely heavy rainfall intensity (90 cm hydraulic
327 head). Throughout the model tests, the groundwater level changes and the ground surface displacements were
328 measured continuously from the start to the end of the tests. In addition, the PIV technique, which can
329 continuously measure and analyze the displacement of the entire ground, was applied to quantify the ground
330 deformation (volumetric strain and shear strain), generation, and expansion of the underground cavity. Based
331 on the results of the three tests, the following observations were drawn:

332 (1) The rainfall intensity considerably affected on the ground deformation during and after a rainfall.

333 (2) Under heavy and very heavy rainfall intensity conditions, no internal soil deformation occurred while the
334 groundwater level was rising. However, under extremely heavy rainfall intensity conditions, ground
335 subsidence was observed. This result indicates that the resistance factor (due to the soil strength parameter)
336 becomes smaller than the sum of the drag force (upward force by infiltration pressure during water supply)
337 and the gravity (downward force) when the rainfall intensity exceeds a certain threshold, which was found
338 to have a hydraulic head between 70 cm and 90 cm under the given system.

339 (3) After heavy rainfall (that leads to the rise of the groundwater level due to the infiltration of groundwater
340 through the sewer pipe defects), the soil was discharged from the area above the slit with the rapid outflow
341 of groundwater, where there was no active restraining pressure. During the formation and development of
342 cavity along with the drop in the groundwater level, the incremental volumetric and shear strains were
343 concentrated in the vicinity of the underground cavity.

344 (4) The height and average width of cavities increased linearly with the applied hydraulic head, and notably,
345 sinkhole opened under extremely heavy rainfall intensity. Referring the previous study which showed the
346 relationship between the hydraulic head and rainfall intensity, the discharged soil and the size of the eroded
347 zone may increase exponentially with rainfall intensity.

348 It should be noted that the hydraulic head-rainfall intensity relationship used in this study is site-specific. The
349 induced hydraulic head under the same rainfall intensity can be different site to site. Nevertheless, the
350 experimental observations of this study confirm the influence of rainfall intensity on the soil erosion near the
351 sewer pipe defects as well as sinkhole occurrence and suggest a necessity of sewage pipe network facilities
352 rehabilitation in preparation for increased torrential rain caused by climate change.

| Test No. | Soil type | Slit size | Degree of compaction D_C (Relative density D_R) | Burial depth | Maximum groundwater level |
|----------|----------------------|-----------|---------------------------------------------------------|--------------|---------------------------|
| #1 | Adjusted Gwanak soil | 2 cm | 93 % (78 %) | 90 cm | 47 cm |
| #2 | | | | | 70 cm |
| #3 | | | | | 90 cm |

550

551 **Table 4: Comparative studies of the model tests.**

| Test | Test 1 (47 cm G.W.L) | Test 2 (70 cm G.W.L) | Test 3 (90 cm G.W.L) |
|-----------------------------------------------------------------------------------------------------------------|-------------------------|-------------------------|-------------------------|
| Percentage of the weight of the discharged soil in the total initial weight of the model ground | 6.4 % | 12.9 % | 18.3 % |
| Percentage of the volume of the eroded zone(cavity or sinkhole) in the total initial volume of the model ground | 5.9 % | 12.5 % | 18.2 % |
| Ratio of average cavity width* to slit width | 11.5 (22.9 / 2 cm) | 13.1 (26.2 / 2 cm) | 16.4 (32.8 / 2 cm) |
| Average density change in the loosening zone | -3.1 kN/m ³ | -3.7 kN/m ³ | -2.9 kN/m ³ |

552 * Calculated by dividing the cavity size (via Image J software) by the height of cavity.
