Abstract

As Europe is faced with increasing droughts and extreme precipitation, countries are taking measures to adapt to these changes.

- 20 It is challenging, however, to navigate through the wide range of possible measures, taking into account the efficacy, economic impact and social justice aspects of these measures, as well as the governance requirements for implementing them. This article ~~describes and evaluates an~~ presents the approach ~~to of~~ selecting and analysing ~~climate change~~ adaptation measures to increasing extreme weather events caused by ongoing climate change that was developed and applied ~~at six research sites across Europe~~. ~~It describes the steps that were taken in~~ collecting the H2020 project BINGO (Bringing Innovation to Ongoing Water
- 25 Management). The purpose of this project is (a) to develop an integrated participatory approach for selecting and ~~analysing~~ evaluating adaptation measures, ~~in a process with local stakeholders, with concrete examples from the~~ (b) to apply and evaluate the approach across six case studies, ~~study river basins across Europe, and (c) to support decision-making towards~~ adaptation capturing the diversity, the different circumstances and challenges river basins face across Europe. It combines three analyses: governance, socio-economic and social justice The governance analysis focuses on the requirements associated
- 30 with the measures and the extent to which these requirements are met at the research sites. The socio-economic impact focuses on the efficacy of the measures in reducing the risks and the broad range of tools available to compare the measures on their societal impact. Finally, ~~the~~ a tentative social justice analysis focuses on the distributive impacts of the adaptation measures. ~~In the summary of results, we give an overview of the discussion, we identify some key findings with regard to outcome of~~ the different ~~kind of measures analyses~~. In the conclusion, we briefly assess the main pros and cons of the different analyses
- 35 that were conducted. The main conclusion is that although the research sites were very different in both the challenges and the institutional context, the approach presented here yielded decision relevant outcomes.

Along the process of adapting to climate change, finding and defining appropriate adaptation measures is ~~an obvious but at the same time a~~ complex task. Moreover, it is the key activity to increase the resilience to future climate change induced risks (Dogulu and Kentel, 2015). In addition, good practice in selecting adaptation measures is a fundamental task in adjusting water infrastructure to climate change, which is globally needed (Wilby, 2019). Part of this good practice is to analyse the impact of potential adaptation measures, not only in terms of hazard risk reduction, but also in terms of socio-economic effects, social justice or governance needs for implementation. For example, Zhou et al. (2012) combine climate modelling and an economic cost-benefit assessment in analysing climate adaptation measures for pluvial flooding in urban areas. Harrison et al. (2013) combine climate change scenarios with socio-economic scenarios in a digital platform to allow stakeholders to explore adaptation options within the context of varying futures. European research projects such as ECONADAPT and BASE have also focused on the economics of climate adaptation to support adaptation planning (Watkiss et al. 2015, Garotte et al. 2016, Meyer et al. 2015)).

Another part of this good practice is to involve stakeholders in selecting and analysing these adaptation measures. Involving local stakeholders in these analysis, not just through consultation, but through co-production, enhances their relevance, usability, legitimacy and credibility (Palutikof et al. 2019). For example, Bhave et al. (2014) combine top-down climate modelling with bottom-up (involving stakeholders) prioritization of adaptation measures, but do not analyse socio-economic effect of measures, nor governance requirements for implementation. Andersson-Sköld et al. (2015) use focus group interviews with stakeholders to gauge the perceptions of adaptation measures, as part of a broader integrated framework to analyse the impact of climate adaptation measures. On the other hand, Singh et al. (2020) develop and apply a broad framework to assess the feasibility of adaptation measures, including political, economic and social indicators, but not specific to local conditions and not as part of a participatory framework. This study contributes to the literature by integrating three different analyses (governance, socio-economic, and social justice) in a participatory framework, where most other studies capture only one or two of the above-mentioned dimensions (Verkerk et al. 2017; Bojovic et al., 2018; O’Sullivan et al., 2020).

This article presents the approach of selecting and analysing adaptation measures to increasing extreme weather events caused by ongoing climate change, that was developed and applied in the H2020 project BINGO (Bringing Innovation to Ongoing Water Management). The purpose of this project is (a) to develop an integrated participatory approach for selecting and evaluating adaptation measures, (b) to apply and evaluate the approach across six case-study river basins across Europe, and (c) to support decision-making towards adaptation capturing the diversity, the different circumstances and challenges river basins face across Europe. The project was conducted by over 20 project partners at six research sites in Europe, ranging from the island of Cyprus to the: (1) The city of Badalona (Spain), which faces the risk of flash floods and combined sewer overflows (CSOs) due to increased precipitation; (2) The city of Bergen, (Norway-The), also facing the risk of floods and CSOs due to

increased precipitation; (3) The Veluwe (Netherlands), a Natura 2000 site where long term drought may affect the groundwater system; (4) the Troodos mountains (Cyprus), where decreasing precipitation causes water shortages for farmers and municipalities; (5) The Wupper River Basin, which is divided in two sub cases, one about flood risk due extreme weather events and one about decreasing water levels in the main water reservoir due to decreasing precipitation; and (6) the Sorraia Valley (Portugal) where farmers are confronted with water shortages due to decreasing precipitation.

The BINGO project followed a comprehensive approach from decadal predictions of weather events, hydrological analysis of the impact of the weather events on water systems, to risk analysis and risk treatment. The work presented in this ~~paper~~article focuses on the treatment of risks following extreme precipitation or drought. Risk treatment in project BINGO was organised as a collaborative process between scientists and local stakeholders, through ~~the so-called~~ Communities of Practice (CoPs) (Freitas et al., 2018). These CoPs consisted of representatives of local and regional governments, organisations involved in climate adaptation and research partners.

Based on the risks that were identified and analysed in the risk analysis, the CoPs selected and analysed adaptation measures, with the goal of informing decision makers about the expected efforts and gains ~~for~~from the implementation of these measures. The approach applied in the BINGO project is in line with steps formulated in the Adaptation Support Tool developed as part of the Climate-ADAPT initiative of the European Union (<https://climate-adapt.eea.europa.eu/knowledge/tools/adaptation-support-tool>). More resources from the BINGO project can be found on the project website (www.projectbingo.eu).

The next ~~paragraphs~~sections describe the process of selecting and ~~analyzing~~analysing promising adaptation measures in the ~~logic~~ order as ~~conduced~~conducted within the BINGO project for all cases: (1) ~~Collecting~~collecting and selecting adaptation measures, (2) governance analysis of selected adaptation measures (3) analysis of socio-economic implications (4) social justice analysis. These steps are illustrated with examples from the case study in the city of Badalona, ~~Spain~~ as well as from other sites in brief. A summary of the results of the analysis is provided, comparing different types of measures. Finally, ~~in the discussion, we will draw some general conclusions basedare drawn on the results from all six cases~~application of the different methods.

2— Collecting and selecting adaptation measures

Two approaches were ~~taken~~applied to collect potential adaptation measures suitable to the climate change risks identified at the six research sites, namely a desk study of previous adaptation research and consultation of stakeholders involved in the local CoPs. ~~With regard to~~For the desk study, the primary sources for adaptation measures were two previous EU research projects CarpathCC (<http://www.carpathcc.eu/>) and PREPARED- (<http://www.prepared-fp7.eu>). From both projects databases were available with adaptation measures, including a brief analysis of their potential impact and risk reduction potential. From

105 these databases the BINGO research partners selected measures that were (a) potentially relevant for the hazards the research sites are facing (based on initial hazard and risk identification analyses also performed within BINGO), and (b) relevant for the main characteristics of the research site (e.g. urban area, agricultural area, natural area).

At the same time, in each of the six research sites the first CoP meeting was organised. In this meeting, local stakeholders discussed and identified potential future climate hazards as a result of climate change for their research site and identified ~~adaptation~~ measures that were either already planned or considered suitable. These measures were collected as part of ~~the~~ workshop reports (Van Alphen et al., 2017a) and compiled, together with the measures collected in the desk research, as the in a portfolio of adaptation measures (Van Alphen et al., 2017b). The Portfolio of Adaptation Measures is now available as an online tool, which is accessible to anyone who is interested in adaptation measures to extreme weather events. ([http://beta.tools.watershare.eu/bingo/\\$/](http://beta.tools.watershare.eu/bingo/$/)). In the portfolio, different types of measures are distinguished. Informational measures (such as e.g., raising awareness for behavioral/behavioural change), financial measures (such as e.g., insurance and subsidies), regulatory measures (such as e.g., standards and legal bans) and infrastructural measures (technical e.g., flood control infrastructure). The complete set of measures can be filtered by type of risk, sector, or adaptation objective. Since the portfolio was first created to support the work in BINGO, the broad risk categories reflected the risks first identified in the six case studies (1) decrease of water quantity due to decrease precipitation; (2) decrease of water quality due to decreased precipitation; 115 (3) floods due to increased precipitation; (4) decrease of water quality due to increased precipitation. The sectors reflected the sectors represented in the case studies: (1) agriculture; (2) flood management; (3) public water supply; (4) urban drainage (5) water governance (6) water resource management. This design was chosen so project partners and bio-physical changes)-future users can easily find measures suited to their own circumstances. For each measure an overview of the governance needs for implementation was given, based on the Three Layer Framework presented below.

125 ~~A first~~After compiling this broad portfolio, a more specific assessment of potential risks at the research site was ~~then~~ made and discussed with stakeholders. Local stakeholders could make a ~~first closer~~ selection of adaptation measures from the longlist provided by the project team and ~~for~~ the measures that were developed locally. This first selection of measures was ~~done~~ accompanied by focusing a discussion on the following governance aspects related to the measures: (1) responsibility for implementation, (2) participation/division of roles, (3) availability of necessary resources; (4) potential challenges. During the 130 CoP meetings at the six research sites, these issues/aspects were discussed for the different measures and a selection was made either through scoring or through voting. The measures were selected for the purpose of further analysis. For instance, in the case of Cyprus, measures were first scored ~~in on~~ relevance and feasibility and then voted on by the stakeholders. Table 1 shows the selection of measures for each research site.

Table 1: Overview of adaptation measures selected by the research sites

<u>Research site</u>	<u>Climate risk</u>	<u>Technical infrastructure measures</u>	<u>Blue/green measures</u>	<u>Behavioral measures</u>

3 Governance analysis of selected adaptation measures

3.1 Three Layer Framework

The Three Layer Framework for Water Governance, a tool for assessing water governance practices (Havekes et al., 2016), was used ~~for analyzing~~ to analyse the governance needs of the adaptation measures. The framework builds on the work done

140 by the Organization for Economic Co-operation and Development (OECD 2011) on governance gaps in water governance, and elaborates on these gaps with ~~the~~ building blocks for good water governance identified by the Dutch Water Governance Centre. The framework distinguishes between three layers of governance: the *content layer*, the *institutional layer* and the *relational layer*. ~~For the purpose of this study, the framework has been adapted to assess the governance requirements for the implementation of the adaptation measures.~~

145 First, the *content layer* looks into the substance of adaptation measures. Measures are characterized by the risk that they address (such as from floods, ~~combined sewer overflows~~CSOs or droughts) and the type of intervention (informational, financial, regulatory, infrastructural). Also, the content layer addresses the type of knowledge and expertise needed to implement the measure (technical knowledge, administrative knowledge, knowledge about interest and preferences). Second, the *institutional layer* deals with the broad range of organizational requirements for the implementation of adaptation measures. This entails:

150 (1) the involvement of the necessary actors and a clear division of roles and responsibilities between them; (2) the administrative resources to implement the measure, such as staff, accounting and monitoring capacities, regulatory capacity and knowledge infrastructure; (3) the legal requirements and the connection with EU regulation, policy and directives; and finally (4) the financial requirements and the way these funds can be generated. Third, the *relational layer* of the framework refers to the requirements placed on the wider governance context of adaptation to climate change. This entails: (1) the potential

155 cultural or ethical issues that may support or obstruct implementation of adaptation measures; (2) the requirements with regard to public accountability, communication and participation.

Based on this Three Layer Framework, a questionnaire was developed to assess each individual measure selected by the ~~research sites partners~~.CoPs. ~~The questions address the different layers and their elements. Examples of questions are: which~~

160 ~~(constellation of) actors should be involved in the development and implementation of the adaptation measure? Are the necessary actors currently involved sufficiently? Which cultural or ethical issues either support or obstruct the implementation of the adaptation measure?~~ The questionnaires were filled in by the research partners or in a collaborative effort with experts and local stakeholders.

3.2 Application in the Badalona case

165 Following the methodology outlined above, three adaptation measures were selected for the Badalona research site with the objective of ~~minimizing the impacts~~reducing of urban floods and ~~combined sewer overflows~~.CSOs or ~~reducing the impact thereof~~. These include: ~~an increase of inlets,conventional urban~~ drainage ~~and retention capacity;grey~~ infrastructure (e.g., ~~new or larger drainage conduits, new detention tanks, new surface drains, etc.~~); the development of ~~Sustainable Urban Drainage Systems~~ (SUDS) and the implementation of an Early Warning System (EWS).

170 For each one of the adaptation measures a ~~thorough analysis of the~~ governance assessment was performed by following the expert analysis of the three-layer-framework. The results of the analysis demonstrate that: (1) the structural measure (increase of sewer capacity) meets the knowledge and legal requirements (this measure was already included in the Drainage Master Plan Badalona of 2012) but does not have the financial, organizational and relational requirements for its implementation; (2) the SUDS development meets the technical and relational requirements (it has quite support given it is a “green solution”) but
175 does not meet the financial, legal and organizational requirements to foster its implementation; (3) the Early Warning System meets almost all the requirements except from the relational layer regarding public accountability, communication and participation.

This governance assessment (together with the socio-economic assessment explained next) has allowed the Badalona City Council to have a clear roadmap to support decisions towards urban adaptation.

180 4 Analysis of socio-economic implications

~~4.1 Challenges in analysing socio-economic implications of climate change adaptation measures~~

4.1 Guidance in selecting fitting analysis frameworks

To achieve a viable adaptation to climate change ~~adaptation~~ is a complex task that is highly dependent on factors such as the financial means of involved stakeholders and the social impacts ~~that of~~ the implementation of a measure. For decision makers
185 ~~it is accompanied by. A variety of potential adaptation measures exists, with various costs~~ key to define all necessary indicators and benefits of implementation. The availability of acquire the necessary data to analyse and compare alternative solutions poses a challenge to the decision-maker. This issue is also linked to the decision-making process as different decision criteria are available for the evaluation. Guidance is needed to find the framework that best fits the specific case, depending on the need to different stakeholders. These range from financial criteria (include e.g. tangible costs and benefits), to not only
190 monetary but also non-monetary criteria, such as technical effectiveness, co benefits or welfare implications. All of this indicates that finding a suitable analytical framework to assess the socio-economic implications for decision making in climate change adaptation is a major challenge decision indicators (Markanday et al., 2019; Dogulu and Kentel, 2015).

~~4.2 Guidance in selecting fitting analysis frameworks~~

Within the BINGO project a ~~so-called~~ toolbox was compiled that summarizes the state-of-the art of suitable methods for
195 evaluating and comparing alternative strategies and measures for climate change adaptation (Koti et al., 2017). This toolbox has been used as a background framework to analyse and prioritize fitting risk reduction measures for the six research sites, customized to local stakeholders’ needs. ~~The experiences made during this process can be generalized for future applications, giving the analyst a straightforward guideline which evaluation approach to choose.~~ The work conducted in the BINGO project inter alia resulted in the preparation of a decision tree that supports stakeholders to identify suitable assessment methods,

200 respectively depending on their requirements and preferences to the analysis process. Complementing the comprehensive BINGO-toolbox, the decision tree in fig. 1 focuses on those analysis frameworks applied in the BINGO-case studies.

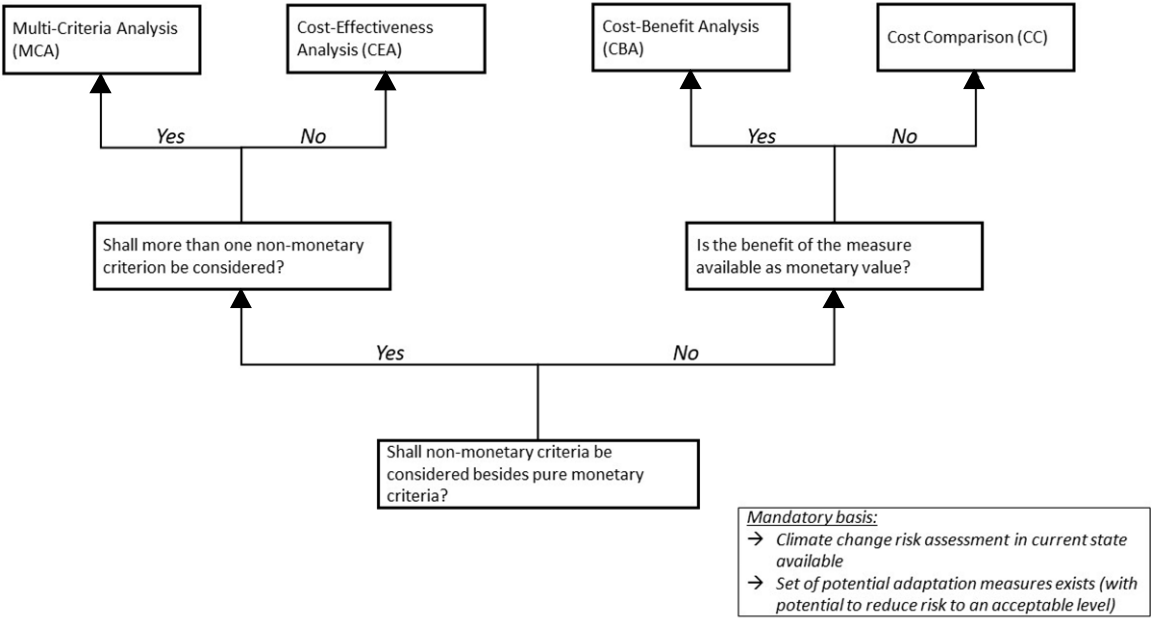

Figure 1: Decision tree supporting the definition process of a fitting analytical framework to evaluate socio-economic implications of climate change adaptation measures

205 The application of the decision tree presupposes the definition of potential adaptation measures. This is due to the fact that the provided methods aim to support the analyst in prioritizing a set of potential adaptation measures ~~instead of giving the analyst a support in finding measures from scratch.~~ The work conducted in the BINGO case studies showed that the nature of potential adaptation measures (e.g. infrastructural measures, behavioural measures, etc.) ~~might~~can have a major influence on the requirements of the analysis methods and relevant indicators, ~~underlining~~underlying the ~~importance of determining the set of~~
 210 ~~adaptation measures before the definition of a suitable~~need for a case specific analysis method. ~~The methodology described in part 1 represents a suitable approach for this presupposed step.~~ Furthermore, a risk assessment ~~in the current state must of~~
~~expected climate change hazards and their magnitude needs to~~ be conducted before ~~the analysis to enable the decision maker to check if the different measures have the potential to reduce the existing risks to an acceptable level. The case study of the~~
 215 ~~Große Dhünn reservoir might serve as an example to indicate this importance. Here efforts were made to analyse the cost-effectiveness of the~~hand. This is important in formulating a base line (expected future without any adaptation measure “water savings”, although in a later stage this measure turned out to be insufficient to reduce). ~~In this way the risk to an acceptable level. In case of a preliminary and rough examination of the respective measures’ reduction potential compared to that base~~

line can be assessed for all alternative adaptation measures, in order to evaluate the ~~potential~~ risk reduction ~~potential~~, many efforts in later stages can potentially be saved. If both requirements are fulfilled, the analyst may follow the procedure of the decision tree. To do so, the question of the box at the bottom of the tree has to be answered of each measure. This is a mandatory data set to compare alternative adaptation measures with yes or no. Depending on the given answer, the analyst is led to the next box via one of the two arrows labelled with yes and no. This procedure is repeated one stage methods presented in the framework above, finally leading the analyst to one of four analysis frameworks. These frameworks are Multi-Criteria Analysis (MCA), Cost-Effectiveness, ~~This risk reduction potential should be used as a primary indicator. For example, in the application of a cost-effectiveness analysis (CEA), Cost-Benefit Analysis (CBA) and Cost-Comparison (CC).~~ it can serve as input to compare the costs to the risk reduction effectiveness.

~~For the selection process on which~~In selecting an evaluation framework ~~will be applied and thus for the use of~~by using the decision tree, the ~~integration~~participation of all ~~relevant~~ stakeholders that are affected by the adaptation measures turned out to be of high importance. These stakeholders might be water boards, ~~relevant~~ authorities, ~~local or regional governments~~, NGOs, farmers, ~~or~~ local residents ~~or similar~~. The ~~experiences made in the~~BINGO case studies showed ~~clearly that all the importance of stakeholders have to get~~getting the chance to express their points of view and major concerns. This holistic integration of ~~stakeholder perspectives~~ enabled the definition of sets of ~~criteria that were considered in the~~indicators for prioritization of adaptation measures and that ensured the ~~final~~eventual acceptance of the results ~~of~~by all stakeholders. ~~In turn, an~~An omission of this broad stakeholder ~~integration~~participation might lead to a lack of stakeholders' acceptance of the analysis results and thus to ~~potential~~major barriers in the ~~realization~~implementation of the ~~finally chosen~~adaptation measures.

Limitations in the final choice of an evaluation framework ~~are possible~~may arise due to insufficient data availability, e.g. because required data does not exist or because the efforts to get the required data is incommensurate with the ~~gained~~benefits ~~gained~~.

The following sections briefly highlight ~~the decision support frameworks as proposed in fig. 1. Moreover, they indicate why and in which case studies of the BINGO project the decision support frameworks have been successfully applied. This is not a comprehensive presentation of the analysis results, since an extensive presentation this would be out of the exceed limits of this article. Details can be found throughout the documentation in BINGO project reports (current webpage: (http://www.projectbingo.eu/resources and after migration soon: http://bingo.web.spi.pt/-).~~

4.32 Cost-Benefit Analysis

A CBA ~~is a valuable framework~~helps to obtain a rank of available options in monetary terms. It is a commonly used approach to prioritize flood risk reduction measures for climate change adaptation (Penning-Rowsell et al. 2010, Zhou et al. 2012). Costs represent the resources necessary to implement a certain measure. In this context, benefits account for the expected reduction of monetary damages brought by the measures implementation. In addition, co-benefits can be included for measures that

improve ecosystem services provision, such as green infrastructure, which are evaluated in monetary terms by available valuation methods (OECD 2018, Gerner et al. 2018, Hanley and Barbier 2009).

A CBA was conducted for the Badalona case study, due to suitability with the data available and general interest among stakeholders. The costs of the measures under assessment contain: (1) initial investments, included gradually in a linear trend following the assumptions of future implementation times, (2) operating costs for the time horizon of the analysis (set until 2100), (3) rehabilitation and disposal costs, considering technical assumptions on the duration of the assets.

Benefits were assessed using the avoided cost methods, consisting ~~in~~of the estimation of the difference between estimated damages in the baseline scenario and in each of the alternative scenarios. Expected Annual Damage (EAD) ~~is~~was used as ~~the~~an indicator (Martinez-Gomariz et al., 2019), ~~developed previously~~ for flood damages, ~~calculated~~ for Badalona ~~risk assessment~~ ~~from~~using historical ~~flood damage~~ data ~~of~~provided by the National Reinsurance Consortium (Consorcio de Compensación de Seguros). In addition, for the green roof and other green areas proposed as measures, ecosystem service benefits were identified as regulating (air quality and temperature control), supporting (habitat creation), and cultural (aesthetic) services. Monetization of the changes on the environmental variables were estimated using market prices for the marketed items -(e.g. reduction of electricity consumption from temperature control), and also non-market prices for those items that do not have a market for trade (e.g. increase of property value after green roof implementation). For non-market prices, benefit transfer method has been applied, using reference studies and adapting the values in economic and size terms. For more details on the methodologies and results, please refer to the deliverable D5.3 of the project- (Strehl et al. 2019a).

4.43 Cost-Effectiveness Analysis

The core idea of a CEA is to relate the costs of a measure to its effectiveness, like the technical performance (Levin and McEwan, 2001). Both key figures, the costs as well as the effectiveness, which is measured with a suitable indicator, need to be quantified to calculate the ratio. Within BINGO, a CEA was used in the case study of the ~~so-called~~ Große Dhünn reservoir ~~in the western part of Germany-(Wupper River Basin)~~. The reservoir, operated and owned by the Wupperverband (regional water board), usually stores up to 81 ~~M-m~~Mm³ of water ~~especially~~used for drinking water production, supplying up to ~~4~~ ~~M-1M~~ people. In this case the risk assessment conducted in the project pointed out the potentially hazardous event of more than 1,000 days with an insufficient reservoir water storage (defined as less than 35 ~~M-m~~Mm³ water storage) in the worst case decadal climate change projections. Therefore, the focus of this case study was to explore infrastructural and non-infrastructural adaptation measures that reduce the risk to an acceptable level. ~~The most important indicator to assess a potential measure was~~

~~In this particular case, effectiveness was measured by~~ a non-monetary indicator, namely its technical performance which was defined as the additional amount of available water per anno. The Wupperverband had the ~~capacities~~capacity to simulate the additional amount of water ~~by simulating a~~based on the reduction of the low water elevation (non-infrastructural measure) and

280 by ~~simulating~~ a transfer pipeline from the so called Kerspe reservoir to the Große Dhünn reservoir (infrastructural measure). Moreover, the additional water availability by a new horizontal well (infrastructural measure) and by water saving devices coupled with water use restrictions as emergency action (non-infrastructural measure) could be estimated. The data availability allowed a cost estimation for all four measures. Thus, a cost-effectiveness analysis was the best fitting decision support method in this case, offering the possibility to rank technically and/or organizationally feasible risk reduction measures by their cost-effectiveness ratio, advising the Wupperverband and other regional stakeholders in the prioritization of climate change adaptations for their regional situation. More details can be found in Strehl et al. (2019a).

4.54 Multi-Criteria Analysis

An MCA describes a class of analysis methods that consider a variety of different ~~parameters~~criteria (synonym: indicators) to achieve a prioritization of the potential measures. ~~One very~~A common ~~manifestation~~application is the weighted sum method. 290 ~~To apply this method~~Here, first the stakeholders affected by the potential adaptation measures have to agree on a set of relevant indicators to evaluate the impacts of the different measures. Afterwards the stakeholders have to give a ~~weighting~~weight to each indicator. In the subsequent step each indicator is evaluated by the stakeholders with respect to its manifestation for each respective measure, e.g. by applying a scale from 1 (negative manifestation) to 5 (positive manifestation). ~~It is crucial that this evaluation is normalized for each indicator so that no additional, unintended weighting is given to the indicators.~~ Finally, the 295 score for each measure is determined by summing up the products of the weighting and the evaluation score of each measure. These final scores serve as ranking of the measures (Carrico et al. 2014).

~~An application example for this methodology is given by~~This method was applied in the Veluwe case study. The Veluwe is a region in the Netherlands dealing with hazards of long-term droughts and warming/heat stress. To reduce the risks connected to these hazards, three potential adaptation measures were identified, namely the reduction of areas covered by pine-trees, the 300 implementation of ~~artificial~~surface water infiltration and ~~a limitation of sprinkler irrigation~~agricultural water restrictions. As a separate cost-effectiveness analysis was conducted in the Veluwe case, an MCA was chosen as second decision support that focused on 19 different non-monetary ~~criteria~~indicators that the group of relevant stakeholders agreed on. This methodology enabled a focused investigation of the manifestation of different non-monetary ~~criteria~~indicator besides the cost-effectiveness analysis, allowing to take a well-founded and holistic decision for or against the respective adaptation measures. ~~For detailed~~ 305 ~~information, please refer to deliverable 5.3 of the BINGO project~~ (Strehl et al. 2019a).

4.65 Cost Comparison

Cost comparison (CC) is a dynamic approach used to compare the costs. Investment expenditures as well as operational expenditures for implementing and operating an adaptation measure are accounted for along the lifetime of a measure, also minding discounting. ~~From a finance mathematical point of view two ways are common in literature and practice: either~~ 310 ~~accounting and comparing costs for measures by the present value or by annual costs, calculated by applying the annuity~~

~~method~~ (Götze et al. 2015, DWA 2012). The advantage of a CC in general is that it allows a straightforward comparison of adaptation measures by one single common ~~criteriaindicator~~. Thus, this method is a viable approach to support decision making in climate change adaptation if only cost data is available for potential adaptation measures, or if the costs are the most important ~~criteriaindicator~~ and other ~~criteriaindicators~~ are negligible.

315 Within the BINGO case studies, no solely CC was conducted as the data availabilities in all case studies allowed a more complex analysis, incorporating more than one single ~~criteriaindicator~~ for decision support analysis. However, the underlying methodology for a CC was used in many of the case studies, e.g. in the case study for the Große Dhünn reservoir (Wupper River Basin) to calculate the annual costs for adaptation measures ~~in the case study for the Große Dhünn reservoir~~.

4.76 Combining frameworks

320 The decision tree explained above serves as a guidance that is suitable for a variety of cases where decisions for or against certain adaptation measures need to be taken. However, sometimes a combination of analysis frameworks might be necessary or desired. Within the BINGO project, this was essential for the case study in the German city of Wuppertal, located in the western part of Germany of the Wupper River Basin. The spatial boundaries of that case study covered an area of approx. 8 km² around a small urban water course called the Mirke creek. The area is known as endangered flood zone (MKULNV 2015) and recent flood damage events triggered the urgency of involved stakeholders to act since flood risk might also aggravate with further climate change in the future. The aim of the case study was to compare potential flood risk reduction measures at several so called critical hotspots along a 6 km long course of the creek. The explored measures needed to be ranked by their cost-effectiveness, in order to advise stakeholders where to spend time and financial resources first (Strehl et al. 2019b).

330 To capture all relevant socio-economic details, the customized approach for Wuppertal had to combine some of the frameworks mentioned in fig 1 above. ~~Spoken in generic terms, the decision tree framework does not have to be followed strictly in any case, ending in one exclusive method to follow for the desired decision support. Anyhow it is a guideline supporting the user to determine a fitting analysis path and sometimes results in the identification of different methods which are more useful in a combined approach.~~

335 In the WuppertalWupper River Basin case, stakeholders stated from the beginning of the project that non-monetary indicators are also relevant for this case study. However, as stated above, the primary aim was to rank the solutions in order to guide stakeholders how to spend time and financial resources wisely, beginning at a hotspot with the best cost-effectiveness. This is why a CEA was combined with an MCA framework. ~~Additionally, to calculate the costs for the CEA, the same basic methodology as used for a CC was followed.~~

340 The MCA framework followed in the WuppertalWupper River Basin case study was aligned to the so called Analytical Hierarchy Process (AHP) based on Saaty (2008) and Saaty (1987). Here, at first the importancea weighing of the investigated

~~parameters is determined~~~~indicators was given~~ by the stakeholders ~~in~~by pairwise comparisons ~~of the indicators~~, followed by an evaluation of the ~~parameters'~~~~indicators'~~ manifestations themselves. Both values per ~~parameter~~~~indicator~~ were afterwards combined to a final value that indicates the respective measure's effectiveness in non-monetary terms. The resulting single value was related to the costs for each measure (as calculated by the principles of a CC). ~~In other words, the result was a calculation of a cost effectiveness ratio for each risk reduction measure that is in turn based on information gained from an AHP analysis.~~ Details on the followed approach and results of the case can be found in the BINGO D5.3 report (Strehl et al. 2019a).

5 Social justice analysis

5.1 Why a social justice analysis?

350 Social justice and equity principles have been highlighted by the IPCC (2018) as key aspects of a climate-resilient development of societies. Adaptation to climate change is difficult to regulate because the causes and effects of a changing climate are spread both geographically and in time. For policy-making on climate adaptation to be legitimate and effective, it has to take justice and equity principles into account (Gupta 2005, Caney 2005b). Adaptation policies also contribute to human well-being and social capital, and increase the overall adaptive capacity of societies (Reckien et al. 2018).

355 Until today, the debate on social justice and climate change has mainly centred on the recognition of responsibility for global climate change (Pielke et al. 2007), inter-generational justice (Caney 2005a) as well as distributional justice, especially in the context of vulnerability to impacts of climate change (Adger 2006, Breil et al. 2018). It is only recently that social justice is emerging as a central concept to guide decision making for adaptation policy. In the face of climate change, the scope of the transition ahead calls for a high degree of support from all parts of society. The successful implementation of adaptation action
360 thus depends on transparent and legitimate decision making processes as well as a systematic consideration of equity principles (Patterson et al. 2018). A social justice analysis of adaptation measures ~~can serve, especially with an advanced methodology to introduce the topic into adaptation decision making, has great potential~~ to assess the probable acceptability of proposed measures, ~~can~~to inform their context-adequate design and ~~enhance~~~~to enhance~~ the legitimacy of the planning process with a view to the long-term support by the wider public.

365 5.2 The concept of social justice in BINGO

There is not a commonly agreed definition of social justice or equity in the context of adaptation (Breil et al. 2018), and the prioritization of principles and values varies according to the specific regional context (EEA 2018). In essence, social justice theorizes about fair allocations of burdens and benefits among different members of a society (Rawls 1971). According to Miller (1999) social justice thus concerns the question of “how the basic structure of a society distributes advantages and
370 disadvantages to its members”. These distributions are often based on, and legitimized through, “distributive” or “equity” principles (Buchanan 1972, Cook 1987). The BINGO social justice analysis seeks to map the distributions of costs or negative

impacts and benefits of the adaptation measures among different actors or groups in society in the specific context of each research site. This was done using a standardized questionnaire (see fig. 2). Participants also received a short introduction paper, highlighting the concept of social justice to them as well. The questionnaire was developed based on three equity principles generally distinguished in the environmental-philosophical literature (Shue 1999, Low and Gleeson 1998, Paavola & Adger 2002, Ikeme 2003, Anand 2004): (1) the egalitarian principle is based on Mill's and Bentham's utilitarian "greatest happiness principle". Distributions aim to maximize the positive effects and minimize the negative effects for society as a whole. An example of this principle in adaptation governance are the upcoming international weather insurances and bonds, which pay out after a certain weather disaster irrespective of the needs of the victims (Dlugolecki & Keykhah 2002); (2) the solidarity principle aims to neutralize "involuntary inequalities" between people. Distributions follow Rawls' "maximin" principle which involves maximizing the well-being of those who are worst-off. A practical example of the operation of this principle in adaptation governance is the United Nations Adaptation Fund that finances adaptation projects in developing countries (Person & Remling 2014); (3) the deontological principle is based on Kant's notion that people are rational and act ~~intentional~~intentionally, and can therefore be held responsible for their choices and actions. Nozick's elaborated on this notion in his "entitlement theory", which holds that any "patterned" redistributions focused on outcomes are unjust and (re)distributions should always put individual rights and liberties at the basis. The "polluter pays" principle is a practical example of this principle (Tol & Verheyen 2004).

As the evaluation of social justice is highly context dependent, the analysis does not present a conclusive result for each measure but rather presents a qualitative summary of distributional impacts for decision makers to consider in addition to the rating which is produced in the socio-economic assessment.

Analysis of social justice

1. How are costs for the implementation and upkeep of this measure shared between parties?
2. Does the adaptation measure incur any negative side-effects (indirect/social costs)? If so, what kind of effects?
 - a. If yes: To what extent and how are these side-effects mitigated, and by whom (who is paying for the mitigation)?
 - b. If no: Who will carry the burden of the negative side-effects?
3. Which actor(s) will directly benefit from this measure, e.g. in terms of economic revenue, or access to products or services created by the measure? Or does the measure benefit the general public?
4. Does the adaptation measure incur any positive side-effects (additional social benefits)? If so, what kind of effects?
5. Which actor(s) will enjoy these indirect benefits?
6. Considering the answers to the questions above, which equity principles do you recognize in these distributions?
7. To what extent and in what way does the adaptation measures reduce or strengthen existing social (in)equalities?

Figure 2: Questionnaire for social justice analysis.

5.3 ~~Application~~ The application of social justice analysis in BINGO - the Badalona case study

In the BINGO case study of Badalona, the application of the social justice analysis for the three selected adaptation measures shows that (1) all adaptation measures will have positive impacts on Badalona's citizens. The general public will benefit from the reduction of flooding and combined sewer overflows and the social perception in the municipality's efficiency will increase; (2) none of the adaptation measures will are likely to incur negative side-effects; on the contrary, the implementation of nature-based solutions will incur social co-benefits such as: enhanced public amenity, enhanced air quality, increase of ecosystem services and the reduction of the "heat island effect"; (3) regarding equity principles, both the deontological and egalitarian principles may apply in the case of climate change adaptation given that, on the one hand, Badalona's citizens are paying for the proper performance of the urban drainage system and at the same time the society as a whole receives the positive consequences of such adaptation.

5.4 Limitations

Pre-existing inequalities or specific vulnerabilities of certain groups of the respective municipalities could only be considered to a limited extent (question 7 of the questionnaire). However, the analysis of specific social vulnerabilities at the level of the municipality is advisable when designing adaptation measures as well as the participation of vulnerable groups in the planning process to ensure that the contextual and procedural equity are also taken into account (Breil et al. 2018).

6 Discussion

When looking at the 6 Summary of results

410 In total, 22 measures were selected by the research sites, a strong focus on and analysed using the methods described above
(Table 1). A majority of measures are technical infrastructure or 'grey' measures (table 1) can be identified. This may be
explained by the familiarity of the stakeholders and end users with these types this type of measures. Often, The governance
analysis shows that the knowledge and administrative resources for implementation of these measures are present at the sites,
and implementation generally does not require the involvement of a broad range of stakeholders. Also, the effectiveness of
415 these measures can often be modelled and is less uncertain than for instance behavioral measures, behavioural measures. This
is in line with Dhakal & Chevalier (2017) who find that, in the case of urban storm water management, technical solutions
remain preferred throughout the world.

However, it shows in the socio-economic and governance needs analysis shows that these technical infrastructure measures
are often expensive and can take a long time, particularly when compared with blue-green solutions or behavioural measures.
420 In the case of Badalona, the grey infrastructure proposed has the highest level of risk reduction, but is also much more
expensive than the SUDS and the EWS. In fact, the cost benefit analysis shows that the investment and operational costs are
not compensated by the socio-economic benefits considered. The proposed SUDS have a lower potential for flood and CSO
risk reduction (also because the measures analysed only covered a small area of the city), but the improvements they bring for
instance to habitat creation and enhanced aesthetic and recreational value (Locatelli et al., 2020), gives them a higher net
425 benefit. The EWS was the most cost-effective measure, significantly reducing flood risk.

The case of Bergen shows similar results. The sewer separation (a traditional engineering measure), shows the highest potential
for risk reduction, particularly in cases of extreme rainfall. However, they are also very expensive in relation to the risk
reduction achievable. The proposed SUDS measures are relatively low priced compared to their overall risk reduction potential,
but do not have the potential to reduce the risk of extreme events. When combined with using the roads as safe flood ways (a
430 clever way of repurposing the grey infrastructure), they are able to handle peak flows in urban drainage at lower costs than
sewer separation. The combination of blue-green-grey measures has been proven successful in other studies as well (Alves et
al., 2020; Depietri & McPhearson, 2017).

In the Veluwe case, the artificial retention measure, which involves constructing a large water transportation pipe from a nearby
lake to the Veluwe, is the most expensive measure. It is also the measure with the highest potential for risk reduction, in this
435 case measured as the additional groundwater recharge in the Veluwe groundwater system (approximately 30 million cubic
meters per year). The additional recharge for the green measures (change in vegetation) ranges from 2-20 million cubic meters
per year, but at much lower costs. Agricultural water restrictions are less expensive than the other measures. Most expenses

go to helping farmers changes their farming practices (or buying them out), since water restrictions will force them to change crops. However, the amount of water saved is relatively small (0.2 – 0.3 million cubic meters per year).

440 When the measures are compared by their governance needs, we see a different picture. In Badalona, the measures that propose
in an increase of sewer capacity are part of an already existing Urban Drainage Master Plan. That means that the knowledge
and competences to implement. It was also found that these measures is readily available. This is labelled by Dhakal and
Chevalier (2017) as ‘pro-grey arrangements’. The main barriers to implementation are funding, political decision making and
disturbance to due to construction works–due to implementation can cause disruption to. While the SUDS require a smaller
445 budget, there is limited experience on how to implement them and technical expertise and standards/guidelines are currently
lacking, although relevant knowledge can be obtained from regional examples or local research partners. SUDS require the
collaboration of a broad range of stakeholders, which requires coordination by the Badalona City Council. This makes
implementation significantly more complicated than the proposed technical measures. These barriers are all acknowledged in
other cases as well (Dhakal & Chevalier, 2017). The governance needs for the EWS are mostly met, the main challenge is to
450 develop and implement the required protocols for the response to the ‘warnings’ that the EWS gives.

In terms of social and economic justice, as stated above, all measures have a positive impact on Badalona’s citizens due to the
decrease in the risk of floods and CSOs. The SUDS have an increased benefit, due to their many positive side effects, but some
of them are local and depend on where the measures are implemented.

In the case of Bergen, all the governance needs for implementation of sewer separation are met. With regard to SUDS, there
455 is still additional knowledge required on the performance of SUDS in cold climates. The BINGO project was instrumental in
involving the required stakeholders and so meeting the organizational needs. However, there were too few incentives for
private property owners to implement the required measures (see also Dhakal & Chevalier, 2017). This can be circumvented
by first implementing the SUDS at municipally owned properties. The implementation of Safe Flood Ways is a less traditional
technical solution. It adds a new functionality to roads that fall outside the responsibility of the road authorities and thus require
460 coordination between different municipal authorities. An example of fragmented governance (Dhakal & Chevalier, 2017).
Also, the broader impact on public safety when running water with high velocity through the streets needs to be assessed
(Skrede, 2020).

All measures in Bergen benefit the general public, because of the reduction of the risk of CSOs. As in the Badalona case, the
SUDS can provide many side benefits that have additional positive impacts. Negative side effects mostly involve construction
465 and maintenance activities and the surrounding resulting disturbances. Most measures are financed at the municipal level,
reflecting the egalitarian or solidarity principle. SUDS or sewer separation implemented at private properties has to be financed
privately, following the “polluter pays principle” (Strehl et al., 2019a)

At the Veluwe, the implementation of artificial retention is relatively easy, because the required knowledge is available and the required coordination between actors is limited and can be achieved through existing institutions. The implementation of land use change is much more complicated. It requires the collaboration between stakeholders outside of current arrangements and with diverging interests. The BINGO CoP has already been successful in establishing this cooperation. More importantly, changing land use has a huge impact on public opinion, since the Veluwe is well protected (Natura 2000) and a cherished spot for recreation. Changing its vegetation at the required scale would require a public debate on forest management at the national level (Van Alphen et al., 2019). Agricultural Water Restrictions require a locally embedded stakeholder process to be initiated, involving farmers, municipalities, water authorities and the Province. It requires farmers to change their crops and farming practices, which are often considered part of the cultural heritage as well.

Artificial infiltration improves the sustainability of the drinking water supply and helps preserving the groundwater system. These benefits are distributed equally among water users in the region, who, through fees, also bear the costs. The negative side effects are mostly decrease in attractiveness of the environment. The sewer separation proposed in Bergen and the increase of the sewer due to additional water (and energy) infrastructure. These negative effects impact disproportionally people who live nearby these infrastructures. Mitigation activities include minimization of visibility and ecological effects. Land use change has a number of positive effects (sustainable drinking water supply, preservation of groundwater system, a more diverse and robust landscape, increased biodiversity) that impact the general public. Cost for these measures are borne mostly by land owners, who will be compensated by either the province or through water fees. Negative effects mostly have to do with the loss of wild life and plants specific to pine forests (although overall bio-diversity will increase). During the transition period, tourism entrepreneurs may induce losses due to intensified foresting activities (Strehl et al, 2019a). For the measure Agricultural Water Restrictions, farmers affected by the measure would carry the major burden, but would be compensated by the regional or national government for loss of production capacity. The local groundwater supply and natural environment are positively affected which directly benefits land owners, local inhabitants and tourists.

In the case of Cyprus, the most cost effective measure is the maintenance of groundwater recharge systems capacity in Badalona both require large (in this case check dams), yielding a 1250 cubic meter (m^3) groundwater recharge per euro invested, compared to treated sewage water for irrigation ($32,6 m^3$ recycled water used per euro invested) , desalination ($1,5 m^3$ desalinated water consumed per euro invested) and irrigation scheduling technologies ($0,90 m^3$ water savings per euro invested). The implementation of this maintenance scheme mainly requires better coordination between the Water Development Department and the local community councils. Structural, institutional and political rigidities negatively affect the adoption of irrigation scheduling technologies in Cyprus. The lack of political will to charge irrigators with water prices that cover the full costs, i.e., financial, environmental and resource, does not provide an incentive to invest in water saving technologies (Van Alphen et al. 2019). Giannakis et al. (2016) suggest that the low irrigation water price elasticities, the ageing and lower training levels of farming population, the small farm size and the low level of farm investments. These funds are

500 difficult to obtain either because financial means are lacking or they are not properly allocated for, also impede the uptake of irrigation scheduling technologies. Support for farm training schemes, including issues such as water conservation and climate change adaptation—, could improve the skills of the farmers and foster the adoption of new technologies (Giannakis and Bruggeman, 2015; 2018, Van Alphen et al., 2019).

505 The use of treated sewage water for irrigation could be implemented relatively easily. However, the total benefit is small, considering that only 6% of the farmers have access to this source. Also, the long term effects of possible contaminants are yet unknown. For desalinization the key governance challenge is financial viability. Local households will pay a higher price for the desalinated water. Yet, as community councils will be responsible for selecting the source of water there are concerns regarding the prioritization of a cheaper source (Van Alphen et al. 2019).

510 All four measures proposed in the Cyprus Case Study are financed at least in part by the sectoral groups/communities that benefit directly and/or indirectly. Irrigation scheduling technologies and the maintenance of groundwater recharge systems have potential side effects which benefit the general public as they increase the qualitative and quantitative state of the groundwater system. Desalination and the use of treated sewage water for irrigation only benefit specific groups of water users. Also, they have notable negative side effects (impact of emerging contaminants, carbon emissions and brine discharges) which burden the general public and future generations (Strehl et al., 2019a)

515 In the ~~first~~ Wupper River Basin, ~~the building of a~~ case (insufficient reservoir storage due to drought), it was found that the technical infrastructure measures are very expensive compared to the behavioural measures, also in relation to the level of risk reduction. The reduction of low water elevation (which effectively reduces the outflow from the reservoir) is by far the most cost effective measure (€0.001/m³). The water saving scheme is not expensive, but the effect on the capacity of the reservoir is relatively low, and so is the cost effectiveness (€0.194/m³). Water transportation (€0.040/m³) and the horizontal well
520 (€0.054/m³) rank in between. It was noted, however, that these infrastructural measures may be needed as a risk buffer in the future, since they provide redundant capacity.

With regard to the governance needs, the reduction of low water elevation is also the easiest measure to implement, with most of the governance needs being met at the research site. The main concern is the effect on the downstream ecology when the outflow of the reservoir is reduced. The technical infrastructural measures in this case are much harder to implement. To build
525 the transfer pipe between the two catchments, water authorities and the environmental agency should be involved, as well as the property owners affected by the route. It also requires setting legal standards and assessing the technical feasibility and environmental impact. The same goes for implementing a new abstraction well (horizontal well). An additional barrier for that measure is the potential change in water quality (harder water) due to mixing of sources.

530 In terms of social justice, the measure Reduction of low water elevation enhances social justice by securing the water supply to the general public, without increasing the price of water. The main negative side effect as a reduced flow passing the dam, leading to a decrease in energy production and potential decline of ecological quality. This also affects the general public. The Substitution with an alternative water source, may increase existing inequalities since it increases the price of water, which disproportionately impacts low income groups. The same goes for the Water transport between catchment, with the addition that is negatively impacts the property owners near to the infrastructure. To the extent that these owners will be compensated
535 by the Wupper Association, the cost will be carried by the general public. Finally, the pipe/channel route can have a negative impact on the environment and landscape, which impacts the general public.

For the second Wupper River Basin case (flood risk due to increased precipitation) three technical measures were analysed. The retention basin, is the most expensive measure (88k€/y), but it also performs best in terms of risk reduction. Alignment protection (10k€/y) and protection measures for property (3k€/y) have a much smaller risk reduction effect, about 10 to 15
540 times smaller. Since these results are calculate for a specific scenario, it cannot be assumed that the just increasing the investment in the latter two protection measures will yield the same risk reduction as the retention basin.

According to the governance analysis, all requirements for implementing the retention basin are in place. With regard to the technical protection measure for property, one of the barriers for implementation is convincing the property owners to take action. Support and funding needs to be coordinated between public services and property owners. Flood protection is
545 considered a public service instead of a (partially) private responsibility. When this is the case, it does not encourage private investment (Geaves & Penning-Rowse, 2016). In the case of alignment protection and new water transportation systems also require large investments and long implementation times. Artificial retention at the Veluwe also requires large investments and may cause debate about the disruption to the natural area caused by large scale construction activities. The modernization of the irrigation system in, this is indeed a matter of public action, where land may be acquired from property owners, but no
550 investment from their side is necessary.

From the social justice analysis, it follows that the retention basin will benefit people downstream of the basin, while property owners above the endangered areas have the basin built on or near their properties. The basin will be financed by the Wupper Association, but property owners may face decreasing value of their properties because of negative environmental impact or decreasing aesthetics. This can be mitigated by an appealing design and environmental friendly construction of the basin. A
555 positive side effect of the basin that benefits the broader public is the improvement of water quality due to a reduction of direct run offs into natural streams. Protection measures for property are generally paid for by the property owners, who also reap the benefits of reduced flood risk. In case of municipal buildings, the municipality has the opportunity to embellish public spaces by choosing an appealing design. The Alignment protection will most likely be financed by the Wupper Association, as the measure benefits the general public. In case property owners will bear the costs, this will likely lead to increased social
560 inequalities.

In the Sorraia Valley is very costly and the same goes for the use of desalinated water and the uptake of irrigation scheduling technologies in Cyprus. On the other hand, three out of the four technical infrastructure measures for Cyprus are sustainable practices aiming at reducing irrigation demand (irrigation scheduling technologies); in Portugal, the technical measures involve the rehabilitation and modernisation of existing irrigation networks, that consist of a canal, a transport and distribution system and a secondary irrigation system. Improving the canal is not the most cost effective in terms of cubic meters of water saved, but it is in terms of impacted area. Improving the transport and distribution system and the secondary irrigation system only affect a small areas and need to be replicated in other areas to reach the same impact as improving local groundwater recharge, while maintaining downstream flows (groundwater recharge systems), and making use of locally available treated sewage water (use of treated sewage water for irrigation). However, it is the canal (Strehl et al., 2019a). The Tagus Water Resources Management model has the potential to be very cost effective, but this is dependent on the level of use the Water Authority will promote. This also the most important to investigate the possible long term effects of emerging contaminants such as pharmaceuticals, which are present in the treated sewage water, on soils, groundwater, ecosystems and human health. challenge with regards to the governance needs. Implementing the Water Resources Management model requires a shift from a top-down management approach to a more network oriented governance model. This requires an integrated approach to water resource management and the participation of a broad range of actors. The rehabilitation and modernisation of the irrigation networks pose no specific governance challenges, apart from acquiring funding for the investments.

A second issue with most of the technical infrastructure measures is that they are usually not very flexible. They are often literally set in concrete and built for a fixed capacity. Although the BINGO project provides decadal prediction until 2025, the life time of technical infrastructure is often much longer (30-50 years is no exception). In that time frame the extent and impact of climate change is still uncertain, which makes decisions on the capacity of the infrastructure very difficult. Building too much capacity is a waste of money, while building too little capacity is less effective in reducing the risks.

A third issue with technical infrastructural measures, is that they often serve a single purpose and do not create many side benefits. Particularly in situations where financial means and/or building space are scarce, measures that serve more than one purpose can be surprisingly efficient. However, it is often difficult to quantify these side benefits and transfer these benefits to the investors of the measures.

Table 1: Overview of technical infrastructure measures selected by the research sites

Research site	Technical infrastructure measures
Wupper River Basin, Germany	Technical protection measures for property Alignment protection Retention Basin Transition between reservoir catchments Alternative water sources

Veluwe, The Netherlands	Artificial infiltration
Sorraia Valley (Tagus basin), Portugal	Rehabilitation and modernization of irrigation networks
Troodos, Cyprus	Irrigation scheduling technologies Desalination Use of treated sewage water for irrigation Groundwater recharge systems
Bergen, Norway	Sewer separation
Badalona	Increase of sewer capacity

This is much less the case with measures that involve the combination of multiple functions and benefits, such as blue/green solutions or the multifunction use of infrastructure in Bergen, using streets additionally as safe flood way in extreme situations (Table 2). In this category of measures, changes in the natural or built environment help reduce the risk, while also performing other functions and creating potential side benefits. The land use change at the Veluwe (changing pine forests into broadleaf forests and open areas) does not only increase the groundwater recharge, it also increases biodiversity, reduces the risks of fires and creates a more varied and attractive landscape.

Table 2: Blue/green solution

Research site	Blue/green solutions
Veluwe	Land use change
Bergen	SUDS Safe Flood Ways
Badalona	SUDS

The SUDS that are analyzed by Badalona and Bergen show similar characteristics. Both measures are primarily used to decrease the risk of flash floods and CSOs by increasing the retention capacity of the built environment. These measures also have many side benefits, such as urban cooling, increased biodiversity, increased water and air quality and they can provide recreational space for citizens.

Implementing SUDS, however, is more challenging from an institutional perspective. It often requires cooperation between different sectors (urban planning, water, building & construction, etc.). If there are no institutional arrangements for these sectors to collaborate, this can be challenging. In Bergen, SUDS are now primarily planned in government owned areas, which makes coordination less difficult. If private owners need to be involved as well, things get much more complicated. Private owners need financial incentives to make changes to their property, either in the form of subsidies, or clearly identifiable

benefits, such as less flood damage, or increased energy efficiency. In the case of Badalona, SUDS have a limited effect, because of the small area (2%) that is suitable for implementation. However, due to their side benefits, they are more cost effective than the technical infrastructure measures.

The third category of measures is aimed at behavioral change, either of individuals or institutional actors (Table 3). It is a rather broad category, but they have in common that they do not involve structural changes to the environment. In the case of Badalona, the Early Warning System provides information on expected hazards and requires a broad range of actors (emergency services, citizens, health care, police, etc.) to act on this information. It follows from the cost benefit analysis done for Badalona, that this is the most cost effective measure to reduce the impact of flash floods and CSOs. However, it is very complicated to implement. Protocols have to be set up with the involvement of a broad range of actors and once these are in place, they have to be enacted once a hazard occurs. It is always uncertain whether people will act as expected (or agreed upon) which makes this a challenging measure. Coordination of actors is also an issue in Cyprus. The institutional/governance framework for the maintenance of the check dams, which are part of the groundwater recharge systems, is not clear. Better coordination of the different levels of government involved is required to overcome these administrative obstacles. For the land use change measure at the Veluwe this is also important. A broad range of land owners need to be involved and large scale land use change in a Nature2000 area may even require the involvement of national level political actors. Coordination of different actors is also central to the Tagus water resource management model that is being developed at the Portuguese research site. It requires almost all actors involved with water use/supply in the Tagus area to be involved in the development of the framework.

Table 3: Behavioral measures

Research Site	Behavioral measures
Wupper River Basin	Water Saving Reduction of low water elevation
Veluwe	Agricultural water restrictions
Tagus	Tagus water resources management model
Bergen	Public involvement
Badalona	Early Warning System

Changing the behavior of individuals with regard to climate change adaptation is also a common challenge across the research sites. The Public Involvement measure in Bergen was considered an important measure by the Bergen research site and has been further developed in project BINGO. It proved the challenge to involve the public through a digital platform, particularly to make it appealing to different societal groups. In the Wupper River Basin, convincing individuals to take up water saving

or private property owners to apply technical protection measures was also considered a challenge. In both cases a lack of incentives can be identified (cheap water) or a lack of awareness of individual responsibility (flood protection is considered a governmental responsibility). In the case of the Veluwe it is the farmers who have to be involved to change their practices by either adopting irrigation scheduling technologies or stop using sprinkler irrigation. Reduction of low water elevation is the most special measure in this category. It does not really require behavioral change from a specific actor, but sets a different (lower) limit for discharge from the reservoir, so that water authorities have the option to keep more water in the reservoir. This does not require any infrastructural change or changes in the landscape.

The rehabilitation and modernisation of irrigation networks mainly benefits the farmers, who also pay for the measures. To alleviate the financial burden, they can apply for funding. The assured agricultural sustainability in the region benefits a broader public as well. The Water Resource Management Model helps to better plan and manage water resources in the Tagus river basin, which benefits the general public. The costs are borne by the water authorities and then allocated to all water users through a tax or a fee.

7 Conclusion

The application of the BINGO approach has been successful in generating decision-relevant outcomes for developing adaptation strategies at the research sites. The outcomes of the socio-economic analysis allowed stakeholders to prioritize measures by their cost-effectiveness, cost-benefit ratio or performance on a broader range of criteria. Sometimes this yielded surprising results, such as the high cost effectiveness of check dams maintenance in the case of Cyprus. The governance analysis allowed to stakeholders to identify gaps in the governance needs to implement measures and to prepare steps to fill those gaps. Finally, the social justice analysis can help stakeholders choosing proper financing mechanism that fits the desired principle (solidarity, egalitarian, deontological) and gives a first indication of how positive and negative impacts are distributed over different groups. Although the research sites were very different, both in their challenges as well as their socio economic and institutional context, the approach presented in this paper yielded useful results in all cases. This ~~support~~supports the transferability of the approach to other ~~case~~cases in Europe.

However, we can identify specific benefits and limitations for each of the analyses (Table 4). The main benefit of the governance analysis is that it provides a systematic overview of the requirements for implementing a certain measure, with attention to a broad range of building blocks for adequate governance. This not limited to technical and economic aspects, but also includes cultural, communicative and legal aspects. A limitation in the way that the method was applied is that it does not provide specific ~~value~~thresholds for the required level of these indicators, other than reported by the researchers and stakeholders involved.

The socio-economic analysis contributed in structuring decision relevant information on adaptation measures focusing on potential outcomes of each measure. The methods applied help to quantify and/or rank indicators affecting costs and benefits of the selected measures, from a socio-economic point of view. Moreover, the methods can be integrated in a broader, scenario-based approach to assessing adaptation strategies. Limitations of the method primarily deal with the availability of data, which
660 has a strong effect on the validity and reliability of the conclusions drawn from the analysis.

Finally, the social justice analysis gives a broader perspective than the plain focus on the outcomes of adaptation and also considers the distributional effect on different groups in society. This may result in the identification of unbalanced burdens or co-benefits which leads to better informed decisions and helps to realise climate justice. However, in the way the method was applied, the acquisition of meaningful social-justice information and derived interpretations relevant for decision makers,
665 highly relies on the interview partners. They need to have a specific knowledge of the local adaptation measures/options planned, and the socio-economic environment.

Table 4: Assessment of the applied analyses

BINGO analysis	Benefit	Limitation
Governance analysis	Provides systematic overview of requirements and whether they are met; takes into account broad range of factors, not only finances and technical capability.	Method itself does not provide standards in whether requirements are sufficiently met; relies on self-reporting by researchers and stakeholders.
Socio-economic analysis	Helps to structure decision-relevant information about adaptation alternatives, focusing on measurable outcomes of each option; applied science offers straightforward methods to quantify or at least rank relevant indicators affecting costs and benefits from a socio economic point of view; methods for a socio-economic analysis are flexible to integrate the scenario	Limitations arise with data availability; in cases with very broad decision-relevant socio-economic criteria indicators to cover, (un)reliable input data for a quantitative analysis effects the robustness of conclusions drawn from the analysis.

	based thinking of climate change projections.	
Social-justice analysis	Helps to focus not only on plain outcomes of adaptation, but also on distributional effects among society; broadens the scope of the analysis, eventually leading to identify additional co-benefits or unbalanced burdens for stakeholders of climate change adaptation measures, allowing a better informed decision.	Information acquisition for a social-justice analysis relies on qualitative input, e.g. by interviews and pre-structured questionnaires as conducted in the BINGO-project; time and financial resources and available interview partners may limit the scope of the analysis.

Code and data availability. Model files and data are not provided due to the confidentiality of the data and models.

670 Notwithstanding, in agreement with the other project stakeholders, the authors of this paper will try to address specific requests for scientific purposes.

Author contributions: HJA, CS, FV, EI, AP, SG and EB developed the methodology. All authors were involved in the research at the research sites. HJA, CS, FV, EI, AP and SG prepared the paper with contributions from all authors.

Competing interests. The authors declare that they have no conflict of interest.

675 **Acknowledgments:** The authors wish to thank all partners and stakeholders of BINGO for their input and feedback. We specifically thank Adriana Bruggeman, Christos Zoumides, Hakan Djuma, Marinos Eliades (The Cyprus Institute); Ayis Iacovides, Marios Mouskoundis (IACO); Maria Rafaela de Saldanha Gonçalves Matos, Ana Estela Barbosa, Maria João Freitas, Teresa Viseu (LNEC); Alberto Freitas (DGADR); Ana Luís (EPAL); Eduardo Martinez-Gomariz (Cetaqua); ~~Luca Locatelli~~, Beniamino Russo (Aquatec); Rita Andrade (SPI); Thorsten Luckner, Paula Lorza (Wupperverband); Suzanne Buil-
680 van den Bos (Provincie Gelderland); Jan Hogendoorn, Jolijn van Engelenburg (Vitens); Juliane Koti, Andreas Hein, Leni Handelsmann (IWW); Pedro Brito (DGADR); Robert Mittelstädt (Hydrotec); Marit Aase, Magnar Sekse (Municipality of Bergen); Ashenafi Seifu Grange, Tone Merete Muthanna (NTNU); Adriana Hulsmann; Nicolien van Aalderen (KWR)

Financial support. This research has been supported by the BINGO European H2020 project (grant no. 641739).
