54 Abstract

55 This study focuses on a single Mediterranean hurricane (hereafter medicane), to investigate its
56 response to global warming during the middle of the 21st century and assesses the effects of a
57 warmer ocean and a warmer atmosphere on its development. Our investigation uses the state-of-the-
58 art regional climate model WRF to produce the 6-member, multi-physics ensembles. Results show
59 that our model setup *simulates* a realistic cyclone track and the transition from an initial disturbance
60 to a tropical-like cyclone with a deep warm core. *However*, the *simulated* transition *occurs* earlier
61 than for the observed medicane. *The* response of the medicane to future climate change *is*
62 *investigated with* a pseudo global warming (PGW) approach. This is the first *application* of the
63 PGW framework to *medicanes*. The PGW approach adds a climate change delta (*defined as*
64 *difference between future and present climate*) to WRF's boundary conditions which is obtained for
65 all prognostic variables using the mean change in an ensemble of CMIP5 simulations. A PGW
66 simulation where the climate change delta is added to all prognostic variables (PGW_{ALL}) shows that
67 most of the medicane characteristics moderately intensify, e.g., surface wind speed, uptake of water
68 vapour and precipitation. However, the *minimum sea level pressure (SLP)* is almost identical to that
69 under present climate conditions. Two additional PGW simulations were undertaken; One
70 simulation adds the projected change in sea surface and skin temperature only (PGW_{SST}) while the
71 second simulation adds the PGW changes to only atmospheric variables (PGW_{ATMS}) i.e. we use
72 present *day* sea surface temperatures. These simulations show *opposing responses of* the medicane.
73 In PGW_{SST}, the medicane is more intense than PGW_{ALL} as indicated by lower SLP values, the
74 stronger surface wind, and the more intense evaporation and precipitation. In contrast, the medicane
75 in PGW_{ATMS} still transitions into a tropical-like cyclone with a deep warm core, but the PGW_{ATMS}
76 *medicane* weakens considerably (SLP, surface wind and rainfall decrease). This difference can be
77 explained by an increase in water vapour driven by the warmer ocean surface (favourable for
78 cumulus convection). *The* warmer and drier atmosphere in PGW_{ATMS} tends to inhibit condensation
79 (unfavourable for cumulus convection). *The warmer ocean and warmer atmosphere have*
80 *counteracting effects which leads to only a modest enhancement of the medicane by global*
81 *warming*. The novel approach in this study provides new insights *into* the different roles of
82 *warming of* the ocean and atmosphere in medicane development.

1. Introduction

It is well known that severe cyclonic storms occur in the Mediterranean Sea, in particular, from September to March (e.g., Cavicchia et al., 2013). They generate large amounts of precipitation and intense winds that severely damage regional economies and infrastructure over the coastal areas in the Mediterranean (e.g., Bakkensen, 2017). A high number of cyclonic storms may occur during a year. However, it is only few of them that qualify as medicanes. This is mainly due to phenomenological criteria used to identify e.g. a cloud-free “eye”, which is just one of characteristics of tropical cyclones.

These tropical-like cyclones are called Mediterranean hurricanes or medicanes (this term is used hereafter). Although there are many similarities between medicanes and tropical cyclones, there are also clear differences between them. Firstly, the lifetime of medicanes is shorter than most tropical cyclones. Secondly, the development of tropical cyclones generally requires that sea surface temperatures (SSTs) exceed the empirical threshold of 26°C. However, SSTs in the Mediterranean Sea are almost never this warm with autumn and winter SSTs varying from around 18°C to 23°C in the current climate (e.g., Shaltout and Omstedt, 2014; Fig. 2a). This is much lower than the empirical threshold of 26°C for tropical cyclone formation and the occurrence of tropical cyclones over such cold SSTs is very rare even in the tropics (cf. Pacific and Atlantic cold tongue, e.g., Jin 1996; Caniaux et al., 2011). Another difference between medicanes and tropical cyclones is that the formation of medicanes is generally triggered by an intrusion of trough-like systems or cut-off lows over the Mediterranean (Fita et al., 2006; Chaboureaud et al., 2012; Fita and Flaounas, 2018; Bouin and Lebeaupin Brossier, 2020). Notably, Fita and Flaounas (2018) suggested that some medicanes show hybrid features of tropical and extratropical cyclones, which is more similar to subtropical cyclones (cold core and shallow convection at the mature stage). Consequently, they are subjected to baroclinic forcing like extratropical cyclones (Fita et al., 2006; Chaboureaud et al., 2012). As such, it is expected that the formation of medicanes is not different from other intense Mediterranean cyclones (Flaounas et al., 2015), and it should be noted that there is no physical criterion for classifying a Mediterranean cyclone as a tropical-like system.

The mechanism of medicane development has been investigated in previous studies. A cut-off low and a potential vorticity anomaly are pre-conditioning factors for medicane initiation (e.g., Miglietta et al., 2016). This triggers deep cumulus convection resulting in the formation of a deep warm core and consequently, a tropical transition of the initial perturbation occurs (Mazza et al., 2017) due to the warm seclusion. Miglietta and Rotunno (2019) investigated two medicanes and showed that each had a different development mechanism. Air-sea interactions were important for one medicane but not for the other which was maintained mainly by a mid-latitude baroclinic

environment (air-sea fluxes and latent heat flux still help to develop the medicane). This development mechanism is also suggested by Carrió et al. (2017).

While the mechanism of medicanes differ to a large extent from that of tropical cyclones, understanding the response of the medicane features to anthropogenic global climate change is important for mitigating future risks associated with natural hazards. According to Shaltout and Omdtedt (2014), the Mediterranean SST is expected to increase by 2.6°C per century. This warming in the ocean can be a potential source of enhanced moisture to the atmosphere. In fact, significant changes in medicanes e.g., frequency and intensity associated with global warming have been reported in previous studies. Cavicchia (2014) used coupled global climate models to show that medicanes can moderately intensify but their frequency tends to decrease. Tous et al. (2016) also suggested similar future changes in frequency and intensity of medicanes. Their study also revealed that the location of medicane formation is expected to change (more frequent over the Gulf of Lion-Genova and South of Sicily). González-Alemán et al. (2019) concluded that associated with medicane intensification, the structure of tropical-like cyclones is more robust and their lifetime as tropical-like cyclones is longer-lasting compared to medicanes under current climate. Consequently, this leads to more hazardous situations in the projected future.

Most of the aforementioned studies on the future climate of medicanes are based on results obtained from global coupled models (CGCMs). However, in long climatic simulations performed with CGCMs, the typical grid spacing varies between 100km and 25km. Even simulations at 25km have still an insufficient resolution to resolve the fine-scale structure of medicanes e.g. the cyclone core and the associated rain bands. Consequently, the intensity of medicanes is underestimated in most coupled regional models (Gaertner et al. 2018). Therefore, it is most likely that CGCMs also underestimate future changes in medicanes. One possible solution to this problem is to dynamically downscale the global models with a regional climate model (RCM) at finer resolutions (e.g., Cavicchia and von Storch, 2012; Cavicchia et al., 2014). Alternatively, a pseudo global warming method (PGW, e.g., Schär et al., 1996; Rasmussen et al., 2011; Parker et al., 2018; Mooney et al., in review) can be used to assess more explicitly the impacts of future climate change on medicanes. PGW is an advantageous method for characterising the response of a given medicane to climate change by imposing the future changes in atmospheric and ocean variables estimated by CGCMs to boundary conditions of a high-resolution RCM (see details in Section 2). This approach permits a more direct assessment of the impacts of future climate change on an extreme weather event (e.g., Parker et al., 2018). Additionally, the PGW method enables investigations of the relative roles of a warmer atmosphere and a warmer ocean in the response of medicanes to climate change.

In this study, we use a PGW framework to investigate the impacts of global warming on the development and intensity of medicane Rolf (Miglietta et al., 2013; Ricchi et al., 2017; Dafis et al.,

2018). Rolf occurred from 6th to 9th November in 2011 and affected the Balearic Islands, Italy and southern France due to longer persistence of tropical-cyclonic features. Since Rolf was a highly destructive medicane for coastal communities in many Mediterranean countries and is one of the most intense medicanes (e.g., Dafis et al., 2018), it is important to assess how these types of medicanes will respond to climate change in the near future. Medicane Rolf generated the deep cumulus convection and persisted with tropical cyclone-like characteristics (deep warm core) longer than other Mediterranean storms and vortices (e.g., Miglietta et al., 2013). Moreover, according to Miglietta et al. (2013), Rolf occurred around the Balearic Islands, which is a hot spot of medicane genesis. Therefore, it is interesting and important to investigate the impacts of climate change on this type of Mediterranean storm. We perform additional idealised experiments in which only the atmosphere or the ocean, respectively, experience global warming to elucidate the roles of a warmer atmosphere and a warmer ocean on the medicane. This study is structured as follows. In Section 2, details of the reanalysis data, RCM and experimental designs are provided. An evaluation and assessment of the simulation of medicane Rolf under current climate conditions with respect to a state-of-the-art reanalysis is presented in Section 3. The results of the PGW experiments are given in Section 4. Additionally, we analyse the possible future changes of the medicane. A more insightful discussion on the competing roles of a warmer atmosphere and ocean in the medicane is examined in Section 5. Finally, the concluding remarks of this study is provided in Section 6.

2. Model and Methodology

2.1 WRF Simulation of Rolf under present climate

The model setup consists of two nested domains as shown in Fig.1. Both domains have 52 vertical layers and the horizontal grid spacing is 15km and 5km for the outer and inner domains respectively. The Weather Research and Forecasting (WRF; Skamarock et al., 2008) model version 3.9.1 is used to simulate a 6-member ensemble for Rolf. Ensemble members are created using different combinations of physical parameterisations in the WRF model. Previous studies (e.g., Miglietta et al., 2015; Ricchi et al., 2017; Mooney et al., 2018) have shown that simulated medicanes and tropical cyclones are highly sensitive to different combinations of physical schemes. Based on their results, we form our ensemble by varying the microphysical and planetary boundary layer (PBL) parametrisations. The microphysics selected were 1) WSM5 (Hong et al., 2004), 2) WSM6 (Hong and Lim, 2006), and 3) Thompson (Thompson et al., 2008). The PBL schemes used were 1) Mellor-Yamada-Janjic (MYJ, Janjic, 1994), and 2) Mellor-Yamada-Nakanishi-Niino (MYNN; Nakanishi and Niino, 2006; Nakanishi and Niino, 2009; Olson et al., 2019). In order to choose a convective scheme, we simulated Rolf with three commonly used convective schemes:

193 Kain-Fritsch (Kain 2004), Betts-Miller-Janjic (Janjic, 1994), Tiedtke (Tiedtke, 1989; Zhang et al.,
 194 2011). The assessment study used single WRF domain with 10km grid spacing forced by ERA-
 195 Interim (Dee et al., 2011) reanalysis data ($0.75^{\circ} \times 0.75^{\circ}$, 6 hourly). Each simulation has different
 196 combinations of microphysics, (WSM5 WSM6, and Thompson) and PBL (MYJ and MYNN).
 197 According to this assessment simulation, most of simulations with the Tiedtke scheme tend to
 198 produce more realistic medicane tracks, making landfall over southern France while simulations
 199 with other two convection schemes fail to make a landfall over southern France, make an incorrect
 200 landfall over the Sardinia Island or decay over the Mediterranean Sea without landfall (not shown).
 201 Based on the results of this assessment, we performed WRF simulations with the Tiedtke convection
 202 scheme. Table 2 lists the combinations of parameterisation schemes and the name of each
 203 simulation or ensemble member. The purpose of this ensemble is to increase the robustness of our
 204 results. This is important as a single tropical cyclone simulation contains substantial uncertainty in
 205 its intensity and development (e.g., Torn, 2016). All simulations use the longwave and shortwave
 206 radiative schemes of the Rapid Radiative Transfer Model (Mlawer et al., 1997) and the NOAH 4-
 207 layer land surface model (Chen and Dudhia, 2001a, b). Initialization and lateral boundary
 208 conditions are taken from ERA-Interim 6-hourly reanalysis data ($0.75^{\circ} \times 0.75^{\circ}$). The lower boundary
 209 condition of sea surface temperature (SST) is obtained from daily OISST data with $0.25^{\circ} \times 0.25^{\circ}$
 210 horizontal resolution. The simulations are integrated from 0000UTC on 05-November-2011 to
 211 0000UTC on 10-November-2011. Hereafter, these simulations are referred to as PRS, which stands
 212 for present-day climate condition. ERA-Interim is selected as the driving data for our WRF
 213 simulations to maintain consistency between the spatial resolutions of the PGW delta calculated
 214 from the CMIP5 ensemble and the reanalysis data used for the initial and boundary conditions (in
 215 particular for atmospheric variables). We also investigated the representation of the medicane Rolf
 216 in ERA-Interim and found a cyclone track similar to ERA5 (see Section 3 and Fig. S1 for details).

217 In this study, ERA5 reanalysis data (Copernicus Climate Change Service, 2017) is used to
 218 benchmark the simulation of medicane Rolf. ERA5 is a state-of-the-art reanalysis system with a
 219 high spatio-temporal resolution ($0.25^{\circ} \times 0.25^{\circ}$ and 1 hourly). The trajectory of Rolf was estimated
 220 from ERA5 by identifying the location of the minimum SLP value at 3-hourly intervals. This track
 221 is regarded as the reference track in this study (see Fig. S1). Additionally, we use observational data
 222 of the cyclone track produced by the US National Oceanic and Atmospheric Administration
 223 (NOAA) using the Dvorak Technique (see Fig. S1). This data is available only from 1200UTC on
 224 07-November-2011 to 1200UTC on the 09-November-2011
 225 (<https://www.ssd.noaa.gov/PS/TROP/DATA/2011/tdata/med/01M.html>).

227

2.2 WRF simulation of Rolf under warmer climate

To investigate how future global climate change influences the medicane, a pseudo global warming (PGW, e.g., Parker et al., 2018; Mooney et al., in review) experiment is employed. In the PGW framework, boundary conditions of WRF are perturbed by the monthly-mean values of global climate change (Δ). This is estimated by simulations of climate projections from CGCMs. In other words, we can simulate the medicane Rolf under a virtually warmed climate. In this study, we obtain the PGW Δ from the ensemble mean (see Table 1) of 19 simulations used in the Coupled Model Inter-comparison Project 5 (CMIP5, Taylor et al., 2012) between 2036-2065 and 1976-2005. These periods were chosen on the basis of data availability for CMIP5 CGCMs and to represent 1.5°C of global warming in the middle of this century. The advantage of using an ensemble mean of 19 GCM realizations over a single GCM realization is that it minimises the influence of unforced natural climate variations and model-errors in quantifying the forced climate response to future GHG warming (Changhaï et al., 2017). The PGW Δ contains perturbed values for zonal and meridional winds, temperature, relative humidity, geo-potential, SLP, SST, and skin temperature. The new boundary conditions including the global warming can be expressed as,

$$BC_{PGW} = BC_{PRS} + \Delta \quad (1),$$

where BC_{PGW} represents future boundary conditions and BC_{PRS} represents present day boundary condition from ERA-Interim. Both BC_{PGW} and BC_{PRS} are 6-hourly values, while Δ is a monthly mean value for November. Δ is the PGW perturbation and is defined as follows:

$$\Delta = CMIP5_{2036-2065} - CMIP5_{2005-1976} \quad (2),$$

These equations are applied to each of the following variables: zonal and meridional winds (U and V), temperature (T), relative humidity (RH), geo-potential (z), SLP, SST, and skin temperature (TSK). In the PGW experiments, we perform three different simulations where the perturbation Δ is added to: (1) all variables at the boundary conditions (PGW_{ALL}), (2) only SST and skin temperature (PGW_{SST}), and (3) only the atmospheric variables (PGW_{ATMS}). This enables an investigation of the relative roles of projected future changes in the atmosphere and ocean in the development and modification of the medicane. Other experimental configurations of PGWs are the same as those in PRS (see section 2.1). Figures 2b and c provide the PGW Δ for SSTs and a vertical profile of atmospheric temperature and relative humidity (averaged over the 5km-mesh domain in Fig. 1) for the PGW experiments in this study. In the Mediterranean Sea, the PGW delta increases SSTs by approximately 2°C (see Fig. 2b and also shown by Somot et al., 2006) and the troposphere is warmed by 2 to 3°C (Fig. 2c). In contrast, projections of the relative humidity in the troposphere tend to be reduced under global warming. This projected thermodynamical response to global

warming can lead the Mediterranean climate to be warmer and drier (e.g., Giorgi and Lionello, 2008). To the best of our knowledge, the present study is the first investigation to employ the PGW method to a tropical-like cyclone in the Mediterranean Sea.

2.3 Estimation of the Cyclone Phase Space (CPS)

For a trajectory of observed and simulated medicanes, the minimum SLP is tracked from 0000UTC on 06-November-2011 until 1200UTC on 09-November-2011. If the medicane makes a landfall before 1200UTC on 09-November-2011, the tracking is ceased. While not all Mediterranean storms with a warm core undergo a tropical transition (e.g., Fita and Flaounas, 2018), one remarkable characteristic of many medicanes is the transition of the cyclonic system transitions from extratropical to tropical (e.g., Gaertner et al., 2018). Hart (2003) proposes an objective measurement of cyclone phase space defined as,

$$\frac{\partial(\Delta Z)}{\partial \ln p} \bigg|_{900\text{hPa}}^{600\text{hPa}} = -|V_T^L| \quad (2) \quad \text{and} \quad \frac{\partial(\Delta Z)}{\partial \ln p} \bigg|_{600\text{hPa}}^{300\text{hPa}} = -|V_T^U| \quad (3)$$

where,

$$\Delta Z = Z_{\max} - Z_{\min} \quad (4).$$

Z_{\max} and Z_{\min} denote the maximum and minimum geopotential height at a pressure level within 2.5° (for ERA5) and 250km (for WRF simulations) radius around the medicane centre. The upper- and lower- tropospheric thermal wind relation is estimated by equations (2) and (3), respectively. As shown by Hart (2003), in the extratropical phase, the cyclone has a deep cold core and the values of (2) and (3) are negative. In addition, the tropical cyclone has a deep warm core with positive values for (2) and (3). In this study, the thermal wind relation is estimated every 50 hPa from 900 to 300 hPa and the cyclone phase indices of (2) and (3) are defined as the mean of the values every 50 hPa between 600 and 300 hPa and between 600 and 900 hPa.

3. Simulation of Medicane Rolf under present climate

In this section we examine the results of PRS to assess the ability of our WRF setup to simulate Rolf. The cyclone track of PRS is given in Fig. 3a. In the PRS ensemble simulation, the medicanes have very similar tracks from 0000UTC on 06-November-2011 to 0000UTC on 09-November-2011 shown in Fig. 3a even though there is a spread in the track: firstly, the medicane moves southward and crosses around the Menorca Island. After that, it turns northward and finally makes landfall around southern France. This cyclone track reproduces the observed track well (Fig.

305 S1a). The phase shift of the cyclone of PRS ensemble is shown in Figure 3b using cyclone phase
306 space defined by Hart (2003) (see the details of definition in section 2.3). In the beginning, the
307 cyclones of all ensemble members already develop with a shallow warm core (Fig. 3b). This
308 shallow warm core develops into deep warm core at 0000UTC on 07-November-2011 (that is
309 earlier than ERA5 in Fig. S1b). At 0000UTC on 08-November-2011, the simulated cyclone forms a
300 completely deep structure of a warm core. After that, the structure of the deep warm core gradually
301 weakens in all ensemble members. This shift of cyclone phase is approximately consistent with that
302 from ERA5. Thus, PRS can reproduce Rolf in a way that cyclone phase match accordingly the one
303 by ERA5 (Figs. 3 and S1).

304 Along this cyclone track, a time sequence of SLP of the ensemble-mean cyclone centre is
305 given in Fig. 4. The SLP drops down to 992 hPa at 0600UTC on 06-November-2011 during the
306 preconditioning period of the tropical-like cyclone. Similar to ERA5 (see Fig. S1c), the SLP of the
307 cyclone increases to 996 hPa until 0000UTC on 07-November-2011, decreases again, and
308 consequently the deepening of the low pressure reaches 992 to 993 hPa between 0000 and
309 0300UTC on 08-November-2011 (Fig. 4). After this peak, the cyclone's ensemble-mean SLP
310 increases rapidly as it approaches southern France (the depression is weakened to 1006 hPa after
311 22UTC on 08-November-2011). The development of the cyclone can be partially linked with the
312 water vapour gained by the cyclone as shown in Fig. 4. The latent heat flux gained by the cyclone
313 increases from the beginning until 0600UTC on 07-November-2011 (from 160 to 280 Wm⁻²) even
314 though this is stronger than in ERA5 (Fig. S1). After this peak, the latent heat flux begins to
315 decrease and is slightly enhanced at 0000UTC on 08-November-2011. The latent heat flux drops
316 again until the landfall over southern France. Surface flux and the diabatic heating is responsible
317 partially for transition tropical-like cyclones (e.g., Emanuel, 2005; Qutián-Hernández et al., 2020).
318 Rolf also obtains a large amount of water vapour from the underlying sea surface during its phase
319 transition and development. The maximum value of latent heat flux reaches 740W/m² in one grid
320 cell at the cyclone peak, while this value is less than two cases of Mediterranean storms (Miglietta
321 and Rotunno, 2018). In that study, the two Mediterranean storms were closer to the African
322 Continent than the Rolf and therefore, dry air from the African Continent and warmer SST could
323 enhance evaporation compared to the case of Rolf. In the PRS simulations, the precipitation
324 associated with the cyclone is intense at 0000UTC on 06-November-2011 and decreases until
325 1200UTC on 06-November-2011 in Fig. 4. That can be associated with deep cumulus convection
326 due to the initial disturbance (not shown). After 1200UTC on 06-November-2011, the precipitation
327 remains in a relatively small amount with some fluctuations before increasing again at 1200UTC on
328 07-November-2011 reaching a peak around 2000UTC to 2100UTC on 07-November-2011, which
329 is somewhat earlier than the peak of SLP depression. Coinciding with the reduction in the SLP

depression, the precipitation decreases again after the peak. The red contour shows an averaged wind speed exceeding the 95th percentile (referred to as maximum wind speed, MWS, hereafter) within 250km radius around the cyclone in each simulation. The MWS is defined as an averaged value of 10m-wind speed at a grid box where the wind speed exceeds 95th percentile every hour within 250km radius of the cyclone. In PRS, from 0000UTC on 06-November-2011 until 1200UTC on 07-November-2011, the MWS does not show a clear variation (18m/s to 21m/s). After that, MWS increases until 0800UTC on 08-November-2011, reaching to 24m/s. This variation is roughly consistent with that in the SLP (Fig. 4a) even though the timing is relatively delayed in the MWR compared to SLP.

The difference in intensity and transition timing between ERA5 and PRS may be caused by the difference in evaporation and condensation gained by the cyclone. Nonetheless, PRS is able to realistically reproduce the medicane Rolf and the impact of climate change on Rolf will be described in the next section.

4. Simulation of Medicane Rolf under 1.5°C global warming

As explained in Section 2, we explore how Rolf is affected by the future climate change (middle of the 21st century), which corresponds to global warming of 1.5°C using the pseudo global warming (PGW: e.g., Schär et al., 1996; Rasmussen et al., 2011; Parker et al., 2018) technique. In addition to the effects of climate change, the relative roles of the atmosphere and the ocean in the modulations of medicane Rolf are also investigated separately in this section. Note that we omit the number of years for describing the time and date in this section.

Figure 5 shows the simulated cyclone tracks of Rolf in the PGW experiments for a 6-member multi-physics ensemble. PGW_{ALL} reproduces a very similar cyclone track to that in PRS (Fig. 3a). From the beginning, the cyclone moves southward approaching the Balearic Islands. After that, the cyclone progresses northward and makes landfall over southern France. While this behaviour is not considerably different from that in PRS, a few other differences can be detected. Under the future climate change, no simulated Rolfs makes landfall over Menorca while some of PRS medicanes hit Menorca (Fig. 3a). This indicates that the latitude where the cyclone shifts its direction from south to north tends to be relatively higher than that in PRS (Figs. 3a and 5a). Some of the ensemble members make landfall slightly earlier than PRS. These modifications in the cyclone track are more remarkable in PGW_{SST} shown (Fig. 5b). The simulated medicanes change their marching direction to the north at a much higher latitude (higher than 40°N) in all ensemble members, far from the Balearic Islands, at 0000UTC on 07-November. After this shift, the cyclone moves northward similar to PRS and PGW_{ALL}, but its direction shifts more westward than PRS and PGW_{ALL}. Due to those modifications, the simulated medicanes make landfall (one medicane of

365 TD_TP_MJ disappears over the Mediterranean Sea) over southern France at 3.8°E, which is more
 366 western than PRS and PGW_{ALL}, and the landfall is much earlier than PRS and PGW_{ALL}, which is at
 367 1200UTC to 1800UTC on 08-November. Interestingly the PGW_{ATMS} simulations of Rolf exhibit a
 368 response that contrasts to PGW_{ALL} and PGW_{SST} in Fig. 5c. Many of ensemble members have a
 369 cyclone that strike Menorca like PRS, but afterwards the cyclones in PGW_{ATMS} progresses more
 370 southward while the cyclone in PRS moves eastward after this landfall on Menorca (Figs. 5c). The
 371 cyclones in PGW_{ATMS} continue eastward after 0000UTC on 07-November and finally change its
 372 direction to north around 1200UTC on 07-November, which is later by 6 and 12 hours than PRS or
 373 PGW_{ALL} and PGW_{SST}. Instead of moving westward, the cyclone in PGW_{ATMS} orientates to the
 374 northeast and approaches southern France around 7°E at 0000UTC on 09-November shown in Fig.
 375 5c. The response of the cyclone tracks to climate change seems different between PGW_{ALL}/PGW_{SST}
 376 and PGW_{ATMS} and we examine the response of other cyclone features in the PGW experiments.

377 Figure 6a gives a time series of the ensemble-mean SLP in the cyclone centre of PGWs
 378 along the cyclone tracks in Figs. 5. Rolf in PGW_{ALL} develops the SLP centre in quite a similar way
 379 to Rolf in PRS. In the beginning, the SLP decreases once to 991 hPa at 0700UTC on 06-November
 380 and once again increases until 0000UTC on 07-November before decreasing again to 991hPa
 381 between 2200UTC on 07-November and 0000UTC on 08-November. This SLP depression is
 382 slightly lower in PGW_{ALL} than in PRS. While the difference of SLP depression between PRS and
 383 PGW_{ALL} is small, the SLP gradient around the centre is different. Figure 7 shows the scalar of SLP
 384 gradient for PRS and PGW_{ALL} at the maximum of SLP depression. It is obvious that the SLP
 385 gradient is much stronger in the PGW_{ALL} than in the PRS around the peak time (PRS is 0.0004
 386 hPa/m and PGW_{ALL} is 0.0007 hPa/m) indicating that the warmer climate induces the stronger wind
 387 in the centre, which could be linked to changes in precipitation (this aspect is described later).
 388 Compared to PRS, the cyclone in PGW_{ALL} decays relatively rapidly after the peak at 0600UTC on
 389 08-November, in particular, after 1200UTC on 08-November. This is likely to be due to the earlier
 390 time of landfall of some of the PGW_{ALL} cyclones over southern France (Figs. 3b and Fig. 5a).
 391 Inversely, the SLP of the PGW_{SST} cyclone drops down intensively to 987 hPa from 0000UTC to
 392 1000UTC on 06-November. The SLP centre in the PGW_{SST} generally continues to decrease until
 393 2100UTC on 07-November reaching 982 hPa. This is a slightly earlier peak time and much lower
 394 SLP in the cyclone centre than those in PRS and PGW_{ALL}. After this peak, the cyclone in the
 395 PGW_{SST} decays quite rapidly (approximately 20 hPa per 24 hours between 2100UTC on 07-
 396 November and 2100UTC on 08-November). This is associated with the earlier landfall time
 397 compared to PRS and PGW_{ALL} (Figs. 3b, 5a and 5b). It is noteworthy that in the PGW_{ATMS}, the SLP
 398 generally increases throughout cyclone tracking. While initially, the ensemble-mean SLP of the
 399 PGW_{ATMS} cyclone centre is almost identical to those of PRS and PGW_{ALL}, the second depression of

the cyclone centre after 0000UTC on 07-November is much weaker than PRS and PGW_{ALL}. The second reduction in SLP is detected at 2100UTC on 07-November (slightly earlier than PRS), but it reduces only to 997 hPa. The cyclone begins to decay gradually after this. Interestingly, this result suggests that the role of future climate change in the atmospheric and oceanic background have competing effects on the medicane development.

Figure 6b shows a time series of latent heat flux gained (averaged) by the simulated cyclone within a radius of 250 km. The evaporation in PGW_{ALL} is marginally larger than that in PRS, especially from the beginning at 0000UTC on 06-November to 1200UTC on 07-November (approximately 50 W/m² higher at largest). During this period, the temporal variation in evaporation along the cyclone track is almost identical between PRS and PGW_{ALL}. In PGW_{SST}, the simulated cyclones obtain much more water vapour from the underlying warmer SST. Initially, the latent heat flux is about 1.5 times more in PGW_{SST} than that in PRS and increases up to 450 W/m² until 1200UTC on 07-November. The uptake of water vapour drops suddenly after 2000UTC on 07-November and becomes less than that in PRS at 0700UTC on 08-November and is diminished to a few tens of W/m² after the earlier landfall. Inversely, the evaporation in PGW_{ATMS} is less than that in PRS during the entire period of cyclone tracking. However, the temporal variation in evaporation is quite similar to that in PRS having a peak between 00UTC to 0600UTC on 07-November. The decreasing rate of the evaporation after the peak in PGW_{ATMS} is relatively more moderate than those in PGW_{ALL} and PGW_{SST} probably due to the later time of the landfall (Fig. 5c). While the uptake of water vapour differs among PGWs, its peak leads the maximum of the medicane similarly by 6 to 12 hours (Figs. 6a and 6b).

The precipitation in PGW_{ALL} shows a similar variation to that in PRS until 0900UTC on 07-November (see Fig. 6c) although the precipitation is slightly stronger. While the precipitation in PGW_{ALL} increases at almost the same time as PRS, its maximum value around 1900UTC on 07-November is larger than that in PRS (PGW_{ALL} is 1.8mm/h and PRS is 1.4mm/h). This implies that the simulated cyclone in PGW_{ALL} can obtain more energy from diabatic heating than PRS, which could result in a stronger SLP gradient shown in Fig. 7. This stronger precipitation can be associated with an enhanced uptake of the water vapour in PGW_{ALL} as shown in Fig. 6b. In PGW_{SST}, the precipitation is very similar to that in PRS and PGW_{ALL} at the beginning. However, the precipitation keeps its relatively strong intensity and consequently, the difference from PGW_{ALL} and PRS is large during the cyclone lifetime. After 0000UTC on 07-November, precipitation increases and its peak increases and peaks at 2.6 mm/hour before 2100UTC on 07-November. This value is 31.2mm/12h of PGW_{SST} (within 250km radius) that can be classified to the extremely intense precipitation event in the Mediterranean Sea according to Fig. 8 of Flaounas et al. (2019). After this, the precipitation is abruptly reduced due to the earlier timing of the landfall (Fig. 5b).

435 This intense rainfall can be associated with the increased water vapour available in PGW_{SST} (Fig.
 436 6b). The precipitation of PGW_{ATMS} also shows an identical variation with PRS in the beginning of
 437 the track. Associated with the moderate latent heat flux in Fig. 6b, the precipitation is less during
 438 the whole lifecycle of the cyclone and does not show a clear peak (two small peaks at 1700UTC on
 439 07-November and 0600UTC on 08-November) with a smaller amount than those in PRS and other
 440 PGWs.

441 Figure 6d illustrates a time series of MWS for the PGW experiments. In PGW_{ALL}, the
 442 hourly changes in MSW are similar to those in PRS, but that is stronger than in PRS through most
 443 of its lifecycle (at largest, 6m/s higher in PGW_{ALL}). The maximum value of MWS reaches 26m/s at
 444 0000UTC on 08-November. After 0600UTC on 08-November, the MWS in PGW_{ALL} gradually
 445 reduces and eventually its value becomes smaller than that of PRS. This could be caused by the
 446 slightly earlier landfall in PGW_{ALL} than PRS (Fig. 5a). In PGW_{SST}, the MWS is almost identical to
 447 that in PGW_{ALL} until 0000UTC on 07-November. After this time, the MWS in PGW_{SST} gets
 448 stronger than that in PGW_{ALL} and an increase rate of in MWS is about 8 m/s between 1200UTC on
 449 07-November and 0000UTC on 08-November reaching 30 m/s at 0000UTC on 08-November. The
 450 MWS falls down rapidly (from 28m/s to 12 m/s per 14 hours) after 0500UTC on 08-November
 451 probably due to the earlier landfall (Fig. 5b). In PGW_{ATMS}, during 06 and 07-November, the MWS
 452 is stronger than that in PRS. However, after 0000UTC on 08-November, the MWS in PGW_{ATMS} is
 453 weaker than that in PRS resulting in a smaller maximum amplitude of MWS during the cyclone
 454 tracking in PGW_{ATMS} is smaller than in PRS (21m/s for PGW_{ATMS} and 24m/s for PRS). In addition,
 455 as seen in Fig. S2, the ratio of grid boxes with weaker wind speeds (category of 5 to 10m/s) is larger
 456 in PGW_{ATMS} than in PRS (in particular, 1200UTC on 07-November and 0800UTC on 08-
 457 November). That is, the area of strong winds is much smaller in PGW_{ATMS} than in PRS (the
 458 horizontal distribution of winds will be given in Fig. 9).

459 Figure 8 illustrates a diagram of the cyclone phase space in PGWs. Whilst the phase shift
 460 from a shallow to a deep warm core is almost identical in the PRS and PGW_{ALL}, the warm core of
 461 PGW_{ALL} simulated cyclone is relatively stronger, especially, in the lower troposphere (Fig. 8a).
 462 Towards the end of tracks, the structure of the deep warm core in some members of the PGW_{ALL}
 463 (TD_W6_MN and TD_TP_MJ) are diminished substantially and this is due to the earlier landfall
 464 than PRS. In PGW_{SST}, the simulated cyclones change their phase from shallow to deep warm core
 465 in a similar way to PRS and PGW_{ALL} (Fig. 8b). However, once the cyclone shifts to a deep warm
 466 core, the structure of the deep warm core is strengthened and consequently, some ensembles of
 467 simulated cyclones reach much larger values of deep warm core (the values in both troposphere
 468 reach more than 200) than PRS and PGW_{ALL}. Due to the much earlier landfall, the structure of the
 469 deep warm core of some ensembles members shrinks abruptly after its mature state and eventually

470 the cyclone is reduced to one with a cold core at the end of track. The phase shift of the cyclone in
471 PGW_{ATMS} is also similar to those in PRS and PGW_{ALL} in Fig. 8c. In contrast, after the cyclone is
472 converted into a tropical-like cyclone, the maximum value of the deep warm core phase is smaller
473 than those of PRS and other PGWs. There is no rapid reduction of warm core in PGW_{ATMS} since the
474 cyclone achieves landfall later than other PGW simulations (Fig. 5c).

475 Under global warming, the development of the medicane is modified with respect to that of
476 the present climate (in particular, a moderate intensification as aforementioned from Figs. 6 to 8).
477 Here, we explore the horizontal structure of the medicane. The wind speed of PRS exceeds 24 m/s
478 at the peak of SLP depression (based on Fig. 5a) in Fig. 9a. Within 100km radius, the wind speeds
479 are 20 m/s. In PGW_{ALL}, while the radius of high wind speeds appears to be slightly smaller, the
480 wind speed is 24 m/s over a large part within the radius of 100km (see Fig. 9b) and the maximum
481 values (faster than 26 m/s) is larger than that of PRS. This result is consistent with the stronger SLP
482 gradient around the cyclone centre in PGW_{ALL} as shown in Fig. 7. Regarding the intensification in
483 the SLP depression, the surface wind speed is much stronger in PGW_{SST} than PRS and PGW_{ALL} in
484 Fig. 9c. The wind speed exceeds 30 m/s in most areas within the radius of 100km (except for the
485 centre). In contrast, wind speeds for the cyclone in PGW_{ATMS} are substantially lower. Its MWS is
486 22 to 24 m/s, which is equivalent to that in PRS (as shown Fig. 7d, the hourly MWS in PGW_{ATMS} is
487 larger than that in PRS), but the area of high speed winds is obviously diminished in Fig. 9d and the
488 strong wind speed is limited only in the northern sector around the centre.

489 Figure 10 illustrates the rainband structure of each simulated cyclone during the
490 precipitation peak given in Fig. 6c. In PRS, the cyclone has a spiral band of precipitation around the
491 centre (Fig. 10a). In particular, the precipitation is active (up to 9-10 mm/h) in the northern sector of
492 the cyclone and the strong rainfall extends to the northeast direction within a radius of 150 km.
493 There is little rainfall in the centre area, which could be cloud-free “eye”; this can be easily
494 detected, and it is also a key feature of tropical-like cyclones. As seen in Fig. 6c the precipitation of
495 PGW_{ALL} intensifies during its peak in Fig. 10b. Whereas the spiral band of precipitation is likely to
496 be similar to that in PRS in the northern sector, the precipitation is intense than PRS around the
497 centre (reaches 16mm/h) and the southern sector. It seems that the spiral rainband of the medicane
498 is reinforced due to projected global warming. The eye of the medicane is larger than that in PRS.
499 The warmer SST enhances the spiral band more effectively in Fig. 10c as shown in Fig. 6c. The
500 precipitation around the centre exceeds 16 mm/h in the southern sector and the northeastward
501 rainband is elongated with intense rainfall. In the far side of the southern sector, the rainband is
502 more activated (up to 8 mm/h) compared to PGW_{ALL}. This is associated with the much deeper
503 depression of SLP and stronger wind in PGW_{SST} (Figs. 5a and 9c). Corresponding to the
504 deactivated precipitation due only to the warmer atmosphere (Fig. 7c), the rainband around the

505 cyclone centre in PGW_{ATMS} is reduced significantly as shown in Fig. 10d. While the maximum
506 rainfall is still more than 14 mm/h near the centre, the rainband almost loses its spiral structure and
507 the area of intense rainfall is limited only around the cyclone centre.

508

509 **5. Discussion on different roles of warmer atmosphere and ocean in medicane development**

510 In the previous section we showed that the warmer climate leads to a moderate medicane
511 intensification in agreement with previous studies (e.g., Cavicchia et al., 2014; Tous et al., 2016;
512 González-Alemán et al., 2019). The results also showed more enhanced precipitation, surface wind
513 speed and a SLP deepening around the medicane. Interestingly though, the warmer atmosphere
514 inhibits the medicane development substantially, while the warmer ocean enhances the medicane
515 considerably. In this section, we discuss the roles of the atmosphere and the ocean in the
516 medicane's response to future warming.

517 Figure 11a gives a time function of convective available potential energy (CAPE) averaged
518 within the 250km radius around the cyclone centre. CAPE in PRS increases from the beginning and
519 reaches its peak (400 J kg^{-1}) around 1000UTC on 07-November. This peak occurs earlier than the
520 maximum of precipitation as shown in Fig. 6c. In the remaining time, CAPE decreases
521 corresponding to the decay of the cyclone. PGW_{ALL} has a slightly larger CAPE than PRS. CAPE
522 becomes smaller in PGW_{ALL} than PRS after the peak probably because the cyclones in PGW_{ALL}
523 tend to make a slightly earlier landfall. Such a difference is most obvious in PGW_{SST}. CAPE in
524 PGW_{SST} becomes much larger at 1200UTC on 06-November (250 J kg^{-1}) and the timing of its peaks
525 is at 0700UTC on 07-November, which is relatively earlier than PRS. After the peak, CAPE
526 decreases much more abruptly than PGW_{ALL} partially due to the earliest time of landfall. Inversely,
527 CAPE in PGW_{ATMS} is smaller than PRS during the almost entire cyclone track. Figures 11b-e give
528 CAPE of each WRF simulation at its maximum in Fig. 11a. Between PRS and PGW_{ALL}, the
529 simulated cyclones gain more energy in PGW_{ALL} (at maximum, 800 J kg^{-1} for PRS and more than
530 1000 J kg^{-1} for PGW_{ALL}, Figs. 11b and 11c) resulting in the enhanced precipitation. In PGW_{SST}, the
531 simulated medicanes also obtain a lot of energy like PGW_{ALL} and the area of large CAPE (more
532 than 1000 J kg^{-1}) spreads more widely around the cyclone centre than PRS and PGW_{ALL} (Fig. 11d).
533 In addition, the CAPE is larger in the northern sector of the PGW_{SST} medicane than other simulated
534 medicanes (800 to 900 J kg^{-1}). This wider area of high CAPE is consistent with the larger area of
535 intense precipitation (Fig. 10c). Contrastingly, CAPE in PGW_{ATMS} shrinks extensively and its size
536 of high CAPE is much smaller than PRS.

537 Figure 12 gives the outgoing longwave radiation (OLR) as a proxy of cumulus convection
538 during the time of maximum rainfall (see Fig. 6c) in each experiment. In PRS, the deep cumulus
539 convection is well developed (the OLR is $140\text{-}150 \text{ W m}^{-2}$) around the medicane centre during the

rainfall peak (Fig. 12a). Inversely, the high OLR ($240\text{-}260\text{Wm}^{-2}$) is detected in the centre, which could be a cloud-free area. In PGW_{ALL} , the low OLR ($140\text{-}160\text{Wm}^{-2}$) is extended more to the northern sector of the simulated medicane than PRS (Fig. 12b). The cloud free area in the centre seems to be larger than PRS. Due to the warmer SST, the deep cumulus convection is reinforced indicating by the much lower OLR around the medicane centre in PGW_{SST} ($130\text{-}140\text{Wm}^{-2}$, Fig. 12c). The cloud free area is quite similar to that in PGW_{ALL} . In PGW_{ATMS} , contrastingly, the low OLR area reduces considerably and the southern sector of the medicane is covered with high OLR (240Wm^{-2}). While the cloud free area in the centre has a same size as that of PRS, the OLR is relatively lower than that of PRS (210Wm^{-2}), indicating that the feature of tropical-like cyclone is weakened in PGW_{ATMS} . These CAPE and OLR differences are consistent well with the results of precipitation differences (Figs. 5c and 10).

In PGW_{SST} , the warmer underlying SST **enhances** the latent heat flux and the atmospheric conditions **are more favourable for** cumulus convection. In addition to the evaporation, surface wind associated with the medicane is also substantially enhanced during the cyclone's lifetime (especially before and at the peak). This possibly indicates that the **wind-induced surface heat exchange** (WISHE) mechanism is enhanced in PGW_{SST} . Conversely, in PGW_{ATMS} , the background troposphere is warmed and drier through the entire troposphere compared to PRS (Fig. 2c). Even though the ocean forcing is similar in PRS and PGW_{ATMS} (since the SST boundary condition does not differ), the warmer temperature and the lower relative humidity due to global warming (Fig. 2c) is unfavourable for condensation. This means that CAPE is reduced resulting in reduction in deep cumulus convection (Fig. 12d). That is, the diabatic heating is less effectively generated and the WISHE mechanism and SLP depression are also reduced in PGW_{ATMS} . The moderate intensification of the medicane in PGW_{ALL} is a consequent of the competition between enhancement due to the warmer SST and suppression due to the warmer/drier atmosphere.

However, we need to consider the role of SST change due to surface wind and evaporation. When evaporation is more effective in PGW_{SST} and less effective in PGW_{ATMS} , the underlying SST can be cooled down and warmed up. Due to the regional climate model used in this study, our result does not consider the two-way interactions between the atmosphere and ocean, and how this impacts the response of medicane characteristics in a warmer climate. Future work will investigate these impacts on the medicane with a coupled atmosphere-ocean regional climate model (e.g., Akhtar et al., 2014; Mooney et al., 2016; Ricchi et al., 2019) to increase robustness of our results in this study.

572

573 6. Concluding Remarks

574 In this study we investigated the impacts of future climate change on a tropical-like cyclone
575 (medicane) formed in the Mediterranean Sea in a PGW framework with the WRF regional climate
576 model. The main novelty of this work is the investigation of the relative roles of the atmosphere and
577 ocean, respectively in the medicane's response to projected global warming.

578 We performed 6 physical ensemble simulations of the medicane Rolf under present (PRS)
579 and future warming conditions of 1.5°C by applying the PGW method for RCP8.5 according to the
580 middle of the 21st century (e.g., Parker et al., 2018; Mooney et al., in review). Compared to the
581 reference track of ERA5 reanalysis, PRS of WRF simulates Rolf realistically making a landfall over
582 southern France. While the SLP depression of Rolf is stronger in PRS than in ERA5 partially
583 because of difference in grid size, the SLP deepening decreases to 992 hPa in PRS, which is
584 consistent well with previous studies (e.g., Miglietta et al., 2013). PRS also represents well the
585 phase transition to a tropical-like cyclone with a deep warm core.

586 The PGW experiments revealed obvious changes in medicane structure associated with
587 global warming. Firstly, there are clear impacts on the cyclone track: in PGW_{ALL} and PGW_{SST}, the
588 medicane tends to move into more northern and western pathway and its timing of landfall becomes
589 earlier than PRS (in particular in PGW_{SST}). Conversely, the medicane in PGW_{ATMS} shifts more
590 southward and eastward. This difference in cyclone track might not be a random response, but it
591 seems to be associated with changes in the intensity of the medicane. In PGW_{ALL} and PGW_{SST}, the
592 medicane is more enhanced in terms of surface wind and precipitation around the cyclone centre
593 (e.g., Cavicchia et al., 2014; González-Alemán et al., 2019) and the degree of intensification is
594 much stronger in PGW_{SST} and PGW_{ALL} (e.g., the hourly maximum wind speed reaches 30 m/s in
595 PGW_{SST} in Fig. 6d). The cyclone track of the stronger medicane in PGW_{SST} is more to the north
596 and, consequently, makes an earlier landfall than in PGW_{ALL}. Inversely, the medicane in PGW_{ATMS}
597 reduces its intensity to a large extent with a smaller size of region with high wind speed. The
598 northward shift in position of the maximum wind speed associated with the medicane is also
599 detected in a climate projection by Tous et al. (2016). The changes in cyclone track shown in this
600 study might be indicative for the results of Tous et al. (2016). However, since our simulations
601 address only one medicane with 6-member multi-physical ensembles, we will need to investigate
602 the changes in cyclone track due to global warming in other case studies, so that the implication for
603 medicanes more generally becomes more robust.

604 Our PGW simulations elucidated the counteracting individual contributions of a warmer
605 atmosphere and a warmer ocean to the development of medicanes associated with global warming.
606 Since the warmer and drier atmosphere reduces cumulus convection indicated by weaker CAPE and
607 larger OLR, the energy due to diabatic heating is not sufficient. This situation can be ineffective to
608 drive the WISHE mechanism (hourly maximum wind speed is approximately equivalent between

609 PRS and PGW_{ATMS} , but the area of high wind speed is much smaller in PGW_{ATMS} than in PRS).
610 Consequently, the transition from a cut-off low into a tropical-like cyclone tends to be degraded.
611 Conversely, the warmer ocean surface enriches the medicane with moisture, which allows cumulus
612 convection to develop more effectively (Figs 11c and 12c). With a more efficient energy gain, the
613 medicane growth is enhanced and WISHE (e.g., Emanuel, 1986) can be also activated, as indicated
614 by the results of PGW_{SST} . Consolidating these reversal effects of warmer (and drier) atmosphere
615 and ocean (through nonlinear processes), the medicane intensifies to a moderate extent by global
616 warming. While the medicane under global warming shows a modest intensification (e.g.,
617 Cavicchia et al., 2014) in terms of wind speed and SLP deepening, precipitation presents radical
618 changes during the peak of intensity. This suggests that the medicane could be more hazardous due
619 to global warming as concluded by González-Alemán et al. (2019).

620 The PGW technique is a powerful tool to investigate the impacts of climate change on the
621 weather systems in the future. However, our results in this paper include only the climate changes
622 in background such as temperature, relative humidity, SST and etc. In this framework, any changes
623 in extratropical dynamics like wave breaking and large-scale circulation **that is an initial disturbance**
624 **for** medicanes are not directly considered. Additionally, as Flaounas et al. (2019) suggest, the water
625 vapor transport from the North Atlantic sector will be modified and significantly influences the
626 medicane frequency and intensity. The PGW approach does not reflect directly such future change
627 in water vapour transport. Nonetheless, we can conclude that the background change associated
628 with global warming will have **a moderate** impact on medicane development.

629 In this study we have presented novel findings regarding the relative roles of atmosphere
630 and ocean in the modulation of medicane development under global warming. It would be
631 interesting to see if other cases of medicanes show a similar response to the warmer atmosphere and
632 ocean. For a better quantification of changes, the simulation and investigation with a regional
633 coupled model for several cases will be desired in the future.

634

635

636

637 **Data availability**

638 The data of WRF simulations are available from the authors on request. ERA-Interim reanalysis can
639 be downloaded from <https://www.ecmwf.int/en/forecasts/datasets/reanalysis-datasets/era-interim>
640 (need to create an account). ERA5 reanalysis data can be downloaded from
641 <https://cds.climate.copernicus.eu/#!/search?text=ERA5&type=dataset> (need to create an account).
642 The best track for the medicane is available at
643 (<https://www.ssd.noaa.gov/PS/TROP/DATA/2011/tdata/med/01M.html>).

Authors contributions

SK made a plan of this work with WC. SK and PAM contributed to design the numerical simulations of WRF and PAM set the post-processing of boundary conditions for PGWs experiments. SK performed the experiments and analyzed the outputs. All the co-authors contributed to interpret the results, write the manuscript and revised the manuscript.

Competing interest

The authors declare that they have no conflict of interest.

Acknowledgement

We would like to express our grateful appreciation to Dr. **Emmanouil** Flaounas and one anonymous reviewer for their very constructive and helpful comments and suggestions so that our manuscript has been improved substantially. This study has been carried out under IBERTROPIC project (grant agreement no. CGL2017-89583-R), funded by the Spanish Ministry of Science, Innovation and Universities, the Spanish State Research Agency and the European Regional Development Fund. Koseki S. is supported by Giner de los Ríos 2018/2019 and 2019/2020, which is a scholarship grant by la Universidad de Alcalá. González-Alemán J.J. has been funded through grants BES_2014-067905 and FJC2018-035821-I by the Spanish State Research Agency. The computational resource comes from the Norwegian High-Performance Computing Program resources (NS9039K).

846 **Figures**

847

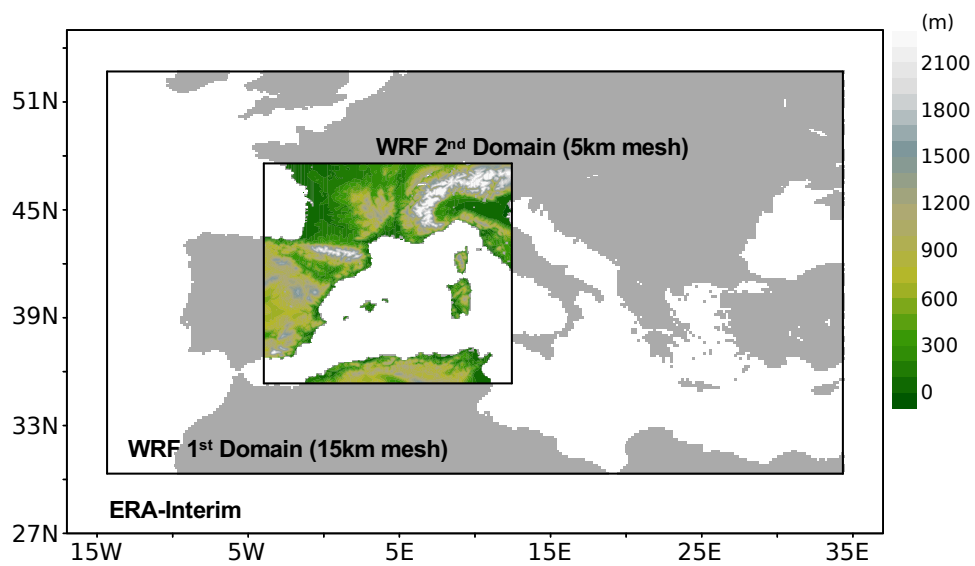

Figure 1.
Domains for WRF simulations for medicane Rolf. Shading in WRF 2nd domain is topography height from MODIS.

848
849
850

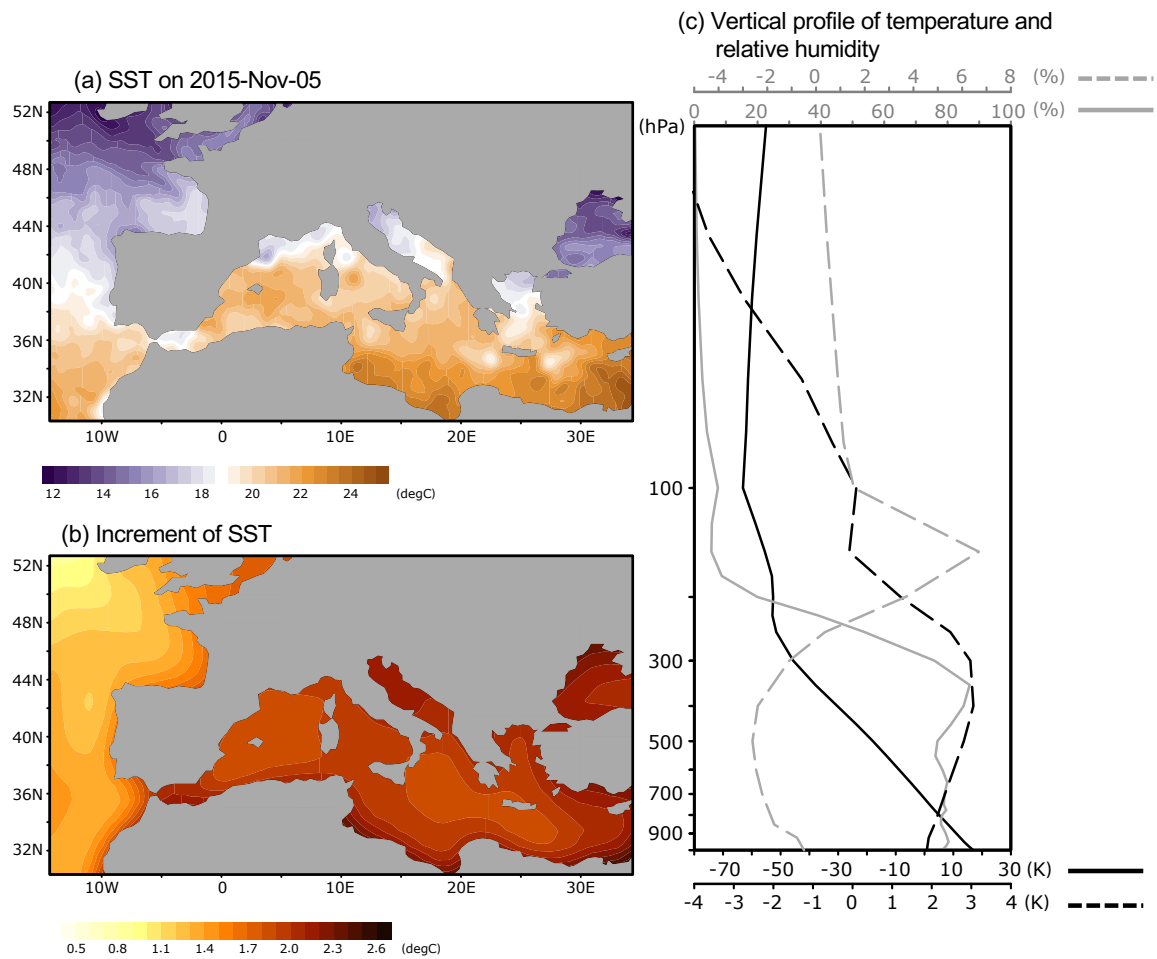

Figure 2.

(a) Sea surface temperature (SST) at 00UTC on 5th November, 2011 in OISST in WRF 1st domain.
 (b) Increment projected by 18 CMIP5 CGCMs (b) SST in WRF 1st domain and (c) vertical profiles of increment of air temperature and relative humidity averaged over WRF's 2nd domain between 2035-2065 and 1975-2006.

851
 852
 853

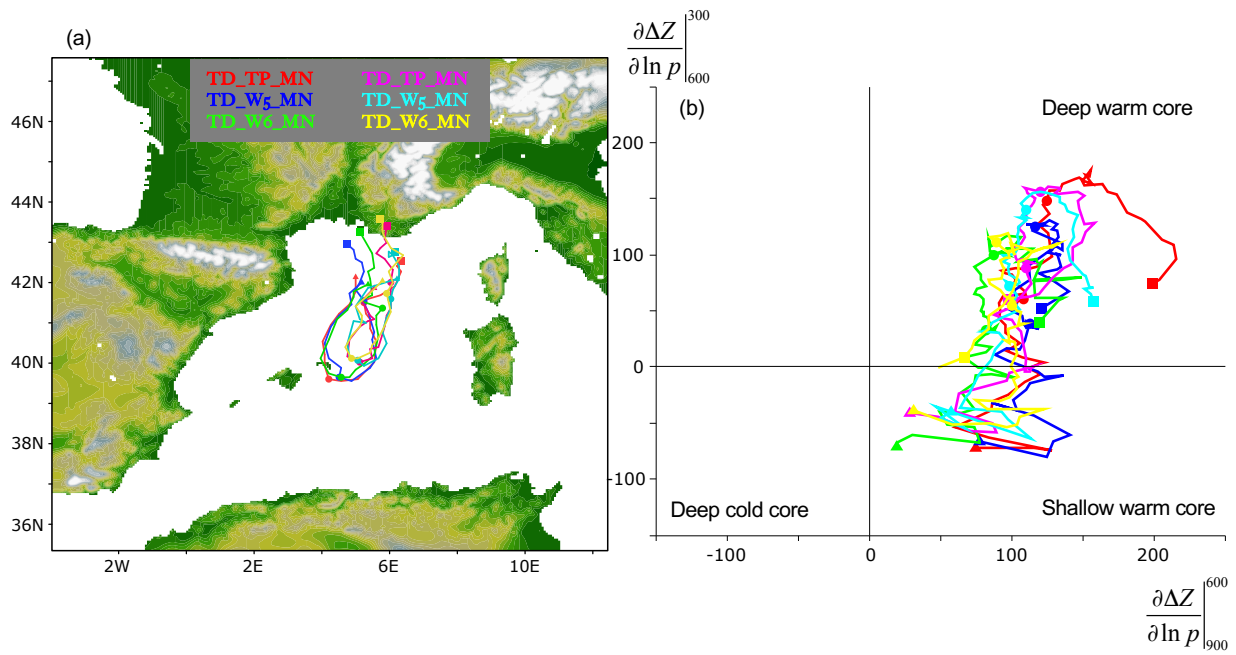

Figure 3.

(a) Trajectory of 6 ensembles of medicane Rolf PRS, from 00UTC, 6th, Nov, 2011 to 00UTC, 9th, Nov. The tracking is based on the lowest sea level pressure. The colors of red, blue, green, magenta, light blue, and yellow is for TD_TP_MN, TD_W5_MN, TD_W6_MN, TD_TP_MJ, TD_W5_MJ, and TD_W6_MJ, respectively. Note that the track of TD_W6_MJ (orange) terminates at 22UTC-08 due to the extinction of the simulated medicane. (b) Cyclone phase space of PRS ensemble.

The markers of ▲, ●, and ■ denote 00UTC-06, 00UTC-07/00UTC-08, and end of tracking, respectively.

Figure 4.

Time series of sea level pressure (SLP) at grid of cyclone centre (black line), latent heat flux (grey bar), And precipitation (blue line), and averaged wind speed exceeding 95th percentile (red line) within the 250km radius of the simulated medicane averaged within a radius of 250km.

Note that the TD_W6_MJ (orange) terminates at 23UTC-08 due to the extinction of the simulated medicane and the values of TD_W6_MJ iare excluded from the ensemble mean at 23UTC-08.

855

856

857

Figure 5. Same as Fig. 3, but for (a) PGW_{ALL} , (b) PGW_{SST} , and (c) PGW_{ATMS} , respectively. Note that the track of TD_TP_MN (red), TD_W5_MN (blue), and TD_W6_MN (green) in PGW_{SST} terminates at 15UTC-08 due to the early landfall.

858

859

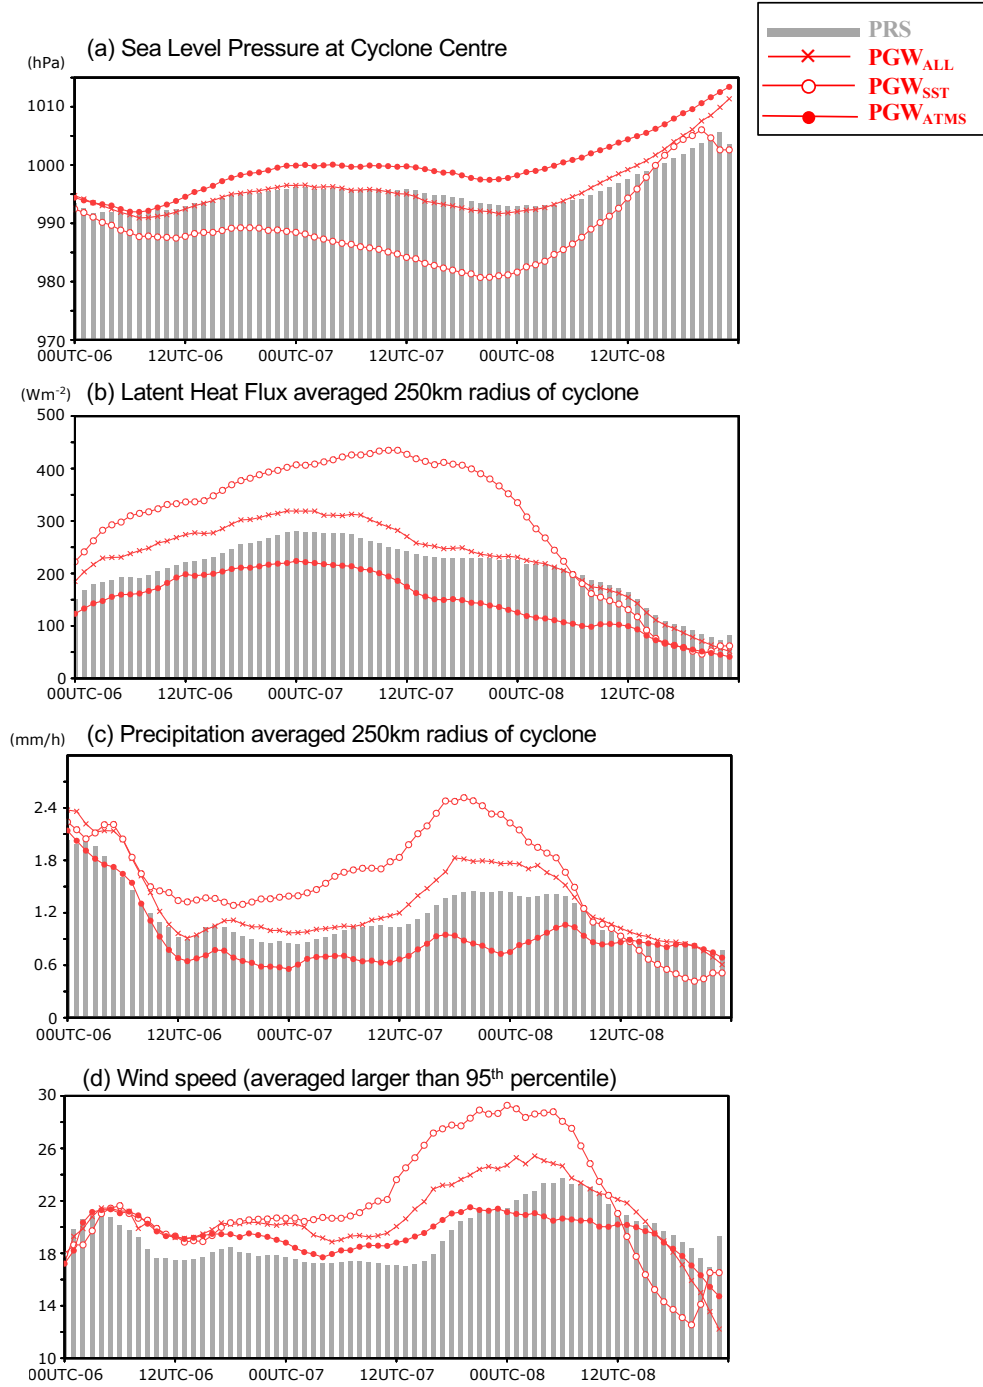

Figure 6.

Time series of ensemble of (a) SLP at grid of cyclone centre, (b) latent heat flux, (c) precipitation averaged, and (d) averaged wind speed exceeding 95th percentile within the 250km radius of the simulated medicane. (b) and (c) are averaged value within 250km radius. The gray bar and red lines denote the variables of PRS and PGWs (with different markers), respectively. All variables are ensemble-mean. Note that the values of TD_TP_MN and TD_W5_MN in PGWSST are excluded from the ensemble mean from 2000UTC-08 and 2100UTC-08, respectively, due to the extinction of simulated medicanes.

Figure 7.
 Scalar of SLP gradient for (a) PRS and (b) PGW_{ALL} around the cyclone centre at SLP minimum (referring to Fig. 6a)

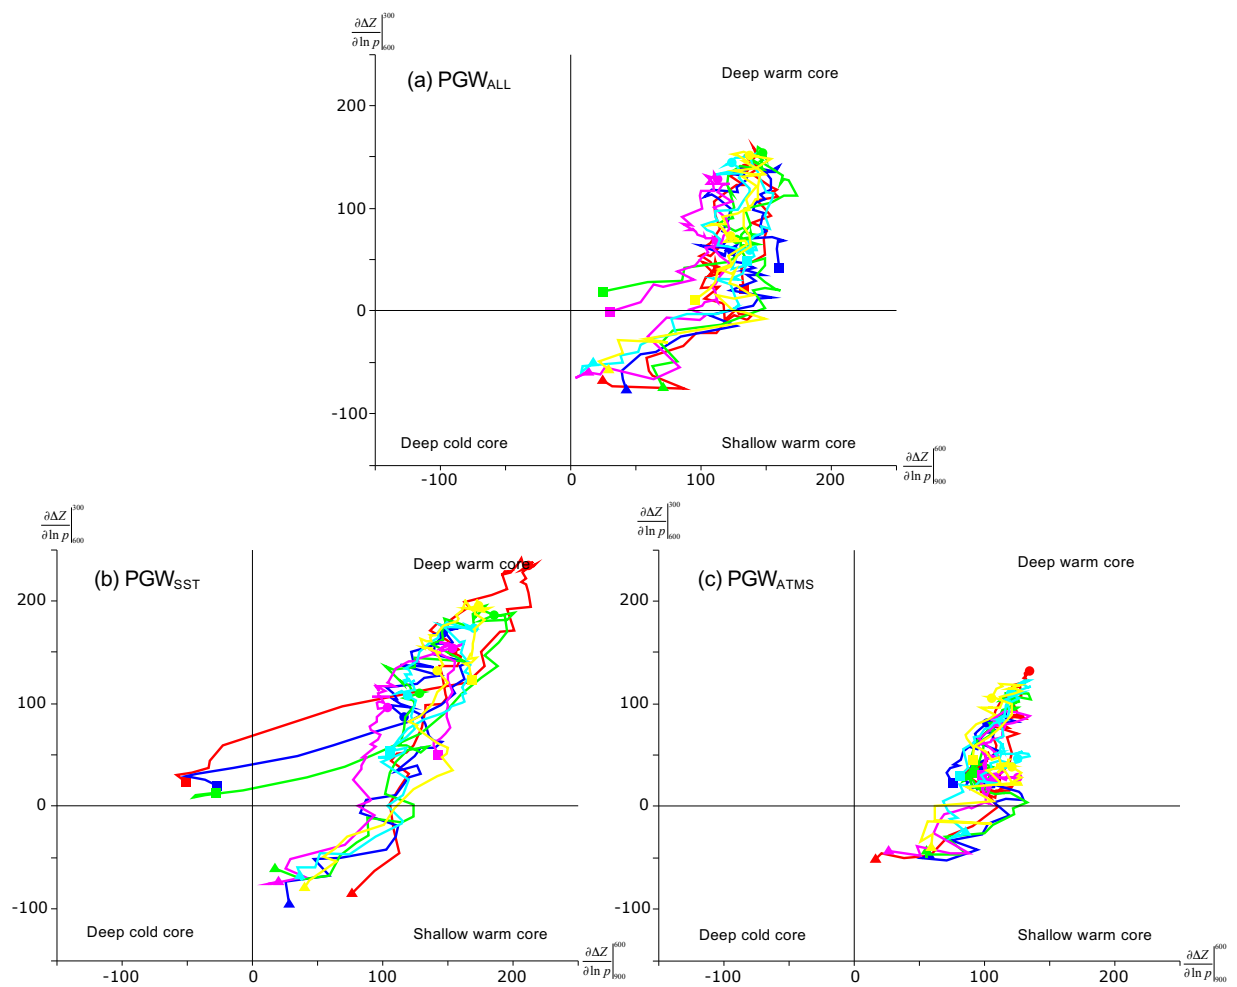

Figure 8. Same as Fig. 3b, but for (a) PGW_{ALL}, (b) PGW_{SST}, and (c) PGW_{ATMS}, respectively.

Figure 9. Surface wind speed during maximum wind speed (referring to Fig. 6d) for (a) PRS, (b) PGW_{ALL}, (c) PGW_{SST}, and (d) PGW_{ATMS} around the cyclone centre, respectively.

Figure 10.

Precipitation during its maximum (referring to Fig. 6c) for (a) PRS, (b) PGW_{ALL}, (c) PGW_{SST}, and (d) PGW_{ATMS} around the cyclone centre, respectively.

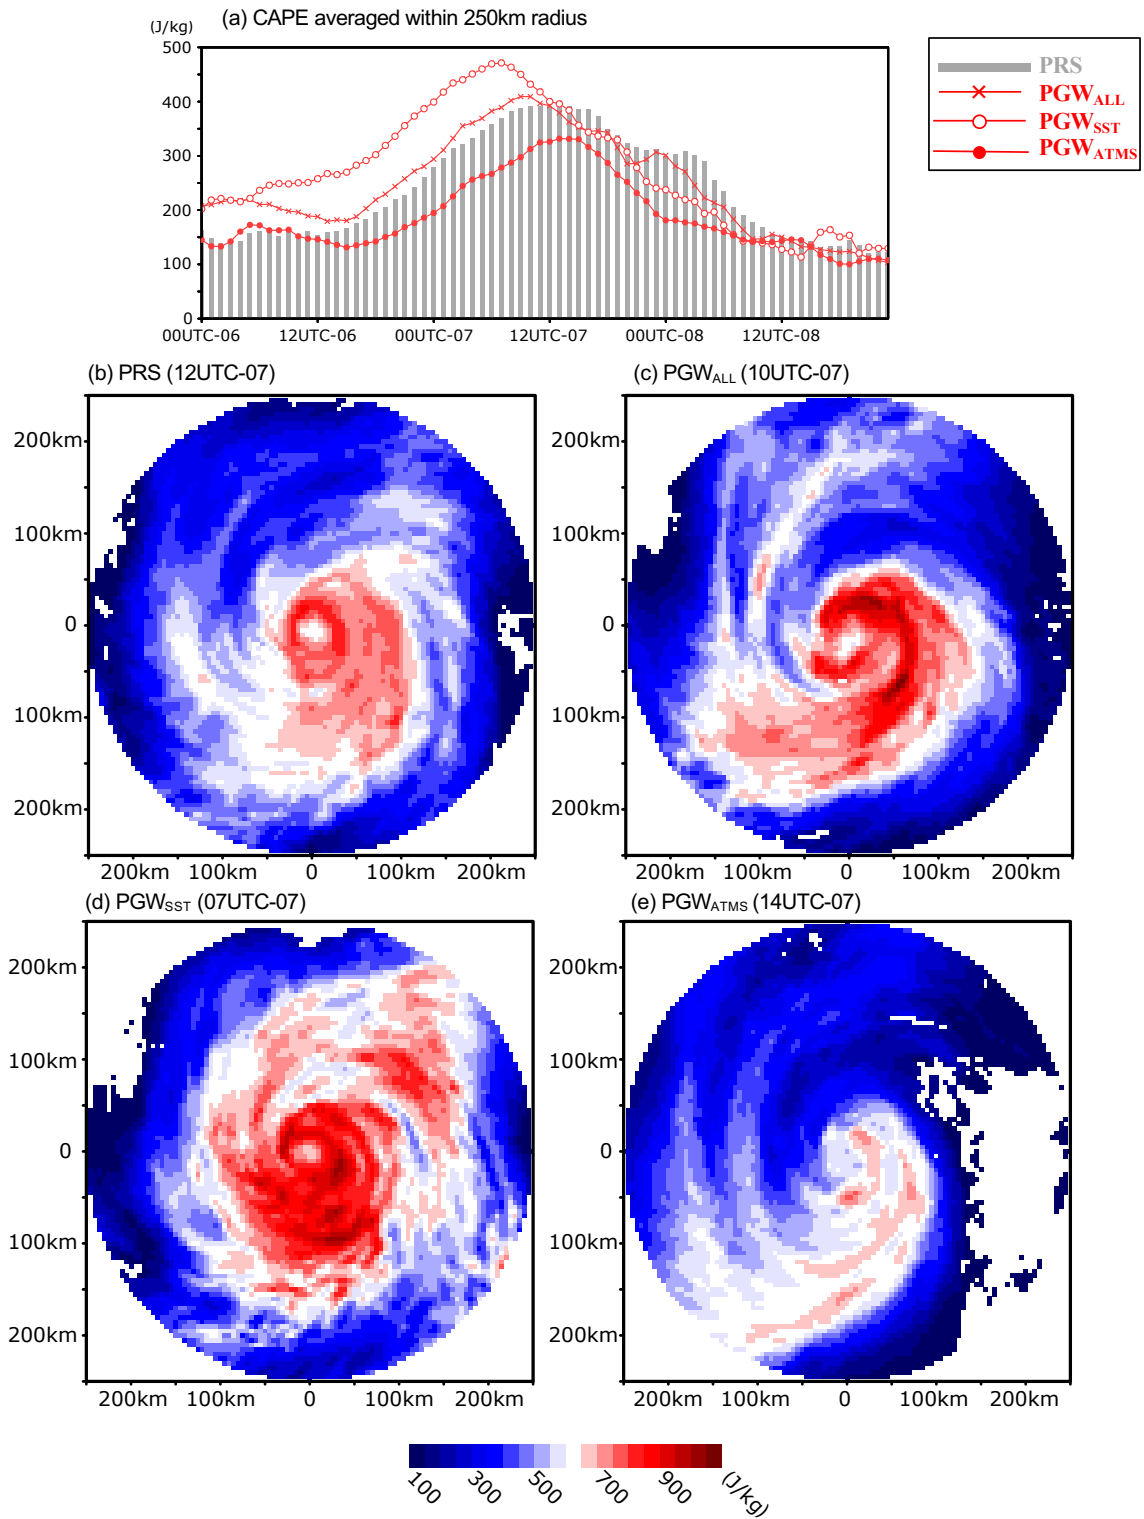

Figure 11.
 (a) Same as Fig. 6b, but for convective available potential energy (CAPE) and CAPE at its minimum (referring to Fig. 10a) for (b) PRS, (c) PGW_{ALL}, (d) PGW_{SST}, and (e) PGW_{ATMS} around the cyclone centre, respectively.

Figure 12.
Same as for Fig.10, but for outgoing longwave radiation (OLR)
during intense rainfall in Fig.6c
