9 **Abstract.** Flood events are the most frequent cause of damage to infrastructure compared to any other natural hazard, and
10 global changes (climate, socio-economic, technological) are likely to increase this damage. Transportation infrastructure
11 systems are responsible for moving people, goods, and services, and ensuring connection within and among urban areas. A
12 failed link in this system can impact the community by threatening evacuation capability, recovery operations and the overall
13 economy. Bridges are critical links in the wider urban system since they are associated with little redundancy and a high
14 (re)construction cost. Riverine bridges are particularly prone to failure during flood events; in fact, the risks to bridges from
15 high river flows and bank erosion have been recognized as crucial at global level. The interaction among flow, structure and
16 network is complex, and not fully understood. This study aims to establish a rigorous, multiphysics modelling approach for
17 the assessment of the hydrodynamic forces impacting inundated bridges, and the subsequent structural response, while
18 understanding the consequences of such impact on the surrounding network. Objectives of this study are to model
19 hydrodynamic forces as demand on the bridge structure, to advance a performance evaluation of the structure under the
20 modelled loading, and to assess the overall impact at systemic level. The flood-prone city of Carlisle (UK) is used as case
21 study and a proof of concept. Implications of the hydrodynamic impact on the performance and functionality of the
22 surrounding transport network are discussed. This research will help to fill the gap between current guidance for design and
23 assessment of bridges within the overall transport system.

24 **1 Introduction**

25 Bridges are crucial elements of the transport network given their high construction costs and the lack of alternatives routes.
26 Man-made and natural events are a threat to bridge safety and network serviceability (Yang and Frangopol, 2020). Bridges
27 act as bottlenecks for surrounding roads, and thus any service disruption can knock-out communities' access and
28 connections, impair emergency planning and evacuation routes, as well as impact economies and businesses.

29 Some disruptive events are growing in frequency and severity. In particular, the impacts of flooding have been exacerbated
30 in recent years by urbanisation (e.g. increase of impermeable surfaces), inappropriate land use in flood-prone areas and
31 climate change. Rainfall events that lead to flooding are becoming more frequent and intense (Solomon et al., 2007),
32 triggering bridge incidents and failures all over the world (Cumbria, UK, 2009; Drake, Colorado, 2013; Texas, 2018; Greece,
33 2020). As recent examples, Grinton Bridge in Yorkshire (North-West UK) and Keritis Bridge in Crete (Greece) were both
34 washed away by floodwaters in 2019.

35 Riverine bridges are intrinsically vulnerable to flooding, as they are located in the area of the riverbed. Flood and scour
36 represent one of the most frequent causes of bridge failures (Hunt, 2009; Wardhana and Hadipriono, 2003; Khan, 2015;
37 Ahamed et al., 2020). Although, scour is recognized as the biggest threat for bridges over water (and available scour-related
38 literature is much more robust), hydrodynamic forces could be as critical for bridge piers on bedrock (where scour is
39 unlikely), and for the decks of all flooded bridges (Kim et al., 2017; Oudenbroek et al., 2018). In terms of consequences,
40 natural hazards can damage bridges structurally (thus causing direct physical damages), but these events can also result in

41 functional failures that cause travel time delays and rerouting that lead to indirect losses (Alabbad et al., 2021). Any bridge
42 failure, whether structural or functional, has the potential to impose heavy consequences to owners or responsible authorities,
43 as well as dire expenses. Therefore, understanding the potential impact of flooding to bridges is a compelling need of
44 communities in areas of high flood risk.

45 Currently, a limited number of studies investigated the consequences of extreme flooding to bridges and the surrounding
46 network (Yang and Frangopol, 2020). Practical application and case studies of real bridges tend to be focused on other
47 natural hazards (e.g. earthquakes: Kilanitis and Sextos, 2019, Ertugay et al., 2016; Zhou et al., 2010). This study aims to
48 establish a rigorous, multiphysics modelling approach for assessing hydrodynamic forces on inundated bridges, subsequent
49 structural response, and consequences of such impact on the surrounding network. Objectives of this study are to model
50 hydrodynamic forces as demand on the bridge structure, to advance a performance evaluation of the structure under the
51 modelled loading, and to assess the overall impact at systemic level. Implications of the hydrodynamic impact on the
52 performance and functionality of the surrounding transport network are discussed. This research will help to fill the gap
53 between current guidance for design and assessment of bridges within the overall transport system.

54 **1.1 Background**

55 Transport networks are formed by multiple links (i.e. roads), and their performance relies on a number of parameters, such as
56 availability of alternative routes (redundancy), road capacity, or traffic demand, among others. A bridge failure often means
57 a critical link been taken out of service. Bridges are usually costly assets to be repaired, have little redundancy and are likely
58 to be crossed by a high number of users, especially if belonging to strategic road networks (e.g. highways). Therefore, bridge
59 closure or failure can impact the overall performance of the road network and the failure consequences have to be
60 investigated from a system-perspective (Yang and Frangopol, 2020). The assessment of the systemic impact is a complex
61 and multi-disciplinary problem, at the interface of hydrology, fluid dynamics, structural analysis and transport modelling.

62 Scour damage is a significant concern for many bridge structures and has been extensively studied (e.g. Pregolato et al.,
63 2021a; Wang et al., 2017; Hung and Yau, 2017; AASHTO, 2002); the more common methods include using the HEC-18
64 (Arneson et al., 2012) or CIRIA scour equations (Kirby et al., 2015; HE, 2012). however, it is not the main focus of this
65 paper

66

67 On the contrary, literature about modeling the hydrodynamic forces of the fluid on bridges due to riverine floods is limited,
68 especially concerning fragility models or reliability analysis (Pregolato, 2019; Gidaris et al., 2017). Existing research
69 investigated tsunami impact to bridges (e.g. Motley and al., 2016; Lomonaco et al., 2018; Qin et al., 2018; Winter et al.,
70 2017), where Computational Fluid Dynamics (CFD) techniques are used to compute hydrodynamic forces on bridges and
71 components. [Li et al. \(2021\) advanced a CFD-based numerical study on the tsunami-induced scour around bridge piers.](#)
72 [Kerenyi et al. \(2009\) applied CFD to compute hydrodynamic forces on inundated bridge decks, however the analysis was](#)
73 [limited to the evaluation of drag and lift forces, without investigating impact and consequences.](#) [Bento et al., \(2021\)](#)
74 [suggested CFD as a more sophisticated technique for modelling flow depth and velocities at sites.](#) Multi-hazard studies have
75 investigated the interaction and implication of multiple hazards acting on a single structure (Gidaris et al., 2017; Carey et al.,
76 2019), especially between earthquake and tsunami. Other studies (Mondoro and Frangopol, 2018; Liu et al., 2018; Yilmaz et
77 al., 2016) that tackled flood impact to bridges generally expressed the hazard through flood hazard curves, generated via
78 flood-frequency analysis; however, a detailed hydraulic analysis was beyond the scope of their work. While tsunami loading
79 of bridges will often result in much higher forces than riverine flows, the prevalence of riverine flooding relative to tsunami
80 events necessitate further study and could have a far-reaching effect.

81 1.2 Motivation and aim

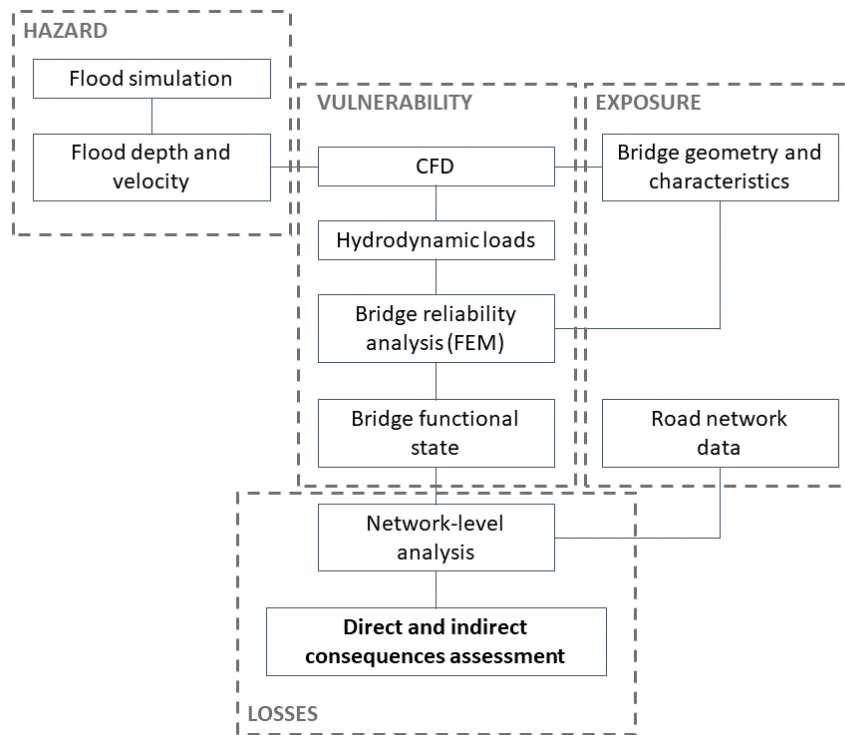

82 To the authors' knowledge, no study has comprehensively investigated the impact of high-river flows on bridges accounting
83 for the complexity of the hydrodynamic forces to which the bridge is subjected and the associated structural and functional
84 response. Moreover, the impact of the reduced service on a bridge on the surrounding network is rarely addressed in the
85 literature. Given this limited availability of models, this paper aims at establishing a multilevel modeling framework to
86 address these issues in one combined approach. This aim is achieved by developing an integrated framework to assess the
87 flooding impact on riverine bridges from the structural- to the network-level (Pregolato et al., 2021b) and applying it to a
88 real case study in the UK. This research tackles varying flow conditions (velocity and depth) to understand the structural
89 response across given simulated flooding conditions. This work is novel since it represents a first attempt to couple CFD
90 analysis with both Finite Element (FE) and network analysis for bridges subjected to flooding, in an effort to capture both
91 the cause and effect of flooding. It is expected that this approach will be useful for understanding structural damage and
92 functional loss for a range of bridges, and ultimately to assess risk for any coastal or riverine structure where large-scale
93 water inundation is expected.

94 2 Method

95 This paper adopts a risk-based framework to assess the impact of high river flows to bridges and surrounding roads (Figure
96 1). The framework proposes a comprehensive method that encompasses the traditional four risk modules (hazard, exposure,
97 vulnerability and consequences; Grossi and Kunreuther, 2005) and includes hydrodynamic force modelling, bridge
98 susceptibility to the hazard, performance evaluation and network-level impact assessment. This study adopts specific
99 models/software, but the precise chosen sub-models are not critical. In fact, all models/software are interchangeable, and it is
100 reasonable to expect that the presented approach would be appropriate for software packages that ensure similar
101 configuration.

102 The first step is to determine the intensity measures of flooding in terms of flow depth and velocity (see Section 2.1). For
103 modelling fluvial flooding, most 2D hydrodynamic models can simulate flood depths and flow velocity, e.g. *LISFLOOD-FP*
104 (<https://bit.ly/3lstd4j>) or *TELEMAC* (<http://www.opentelemac.org/>). Bridge information, such as geometry and design, can
105 be retrieved through publicly available databases (e.g. the US National Bridge Inventory) or by coordination with local
106 infrastructure managers and authorities; such information includes (but is not limited to) bridge dimensions, number of piers,
107 material, design principle, foundation type. Unsurprisingly, the availability and accuracy of data vary from bridge to bridge
108 and can influence the modelling outputs.

109 The second step consists of modelling the interaction between the water and the bridge, as well as the subsequent flood-
110 induced loads. A simplified vulnerability and criticality assessment (Johnson and Whittington, 2011) include the evaluation
111 of the local flow conditions and corresponding hydrodynamic forces that represent the load on the bridge structure using
112 Computational Fluid Dynamics (CFD) techniques. Here, the C++ toolbox *OpenFOAM* is the adopted software, being open-
113 source and particularly versatile for the development of customized numerical solvers (<https://www.openfoam.org/>).

114

115 **Figure 1: The proposed risk-based methodological flowchart to integrate modelling of hydrodynamic forces, performance and**
 116 **network-level analysis. Acronyms: CFD - Computational Fluid Dynamics; FEM – Finite Element Model.**

117 The third step is to determine the response of the bridge subjected to flood through an advanced structural analysis approach
 118 such as Finite Element (FE) analysis. There are many available FE models, such as Abaqus FEA (www.3ds.com), ANSYS
 119 (<https://www.ansys.com/en-gb>), SAP2000 (<https://www.csiamerica.com/products/sap2000>) or the *OpenSees* software
 120 framework (McKenna et al., 2010). Mondoro and Frangopol (2018) described salient limit states for bridges subjected to
 121 hydraulic loads, and the subset studied in this paper (shown in Figure 2) includes yielding of the girders or piers, unseating
 122 or uplift of the girders, failure of the bearings, and excessive global displacement of the superstructure at which transient
 123 fluid-structure interaction is important (i.e., the CFD modeling approach is limited).

124

125 **Figure 2: Bridge failure states investigated due to flood loading.**

126 The general limit-states philosophy considers that specifications should satisfy “specified limit states to achieve the
 127 objectives of constructability, safety and serviceability” (AASHTO, 2017). In this work, the failure of a bridge is seen as
 128 twofold: (i) structural (also strength limit state), when the bridge deck, piers or foundation reach the ultimate limit state or
 129 permanent deformations; (ii) functional (also service limit state), when the bridge cannot perform its service as usual. A
 130 structural failure directly leads to a functional failure, e.g. the bridge collapses; preventive closure could also take place
 131 when bridge conditions are considered unsafe. Nevertheless, a bridge could be unserviceable but still structurally sound, e.g.

132 when floodwater or debris cover the deck. Hydraulic pressures (drag, lift and overturning moment) are assessed for
133 potentially dislodging the deck from piers, when submerged or partially sub-merged, and overtopping of the deck is
134 evaluated qualitatively from the CFD model. Though these limit states have significantly different long-term consequences,
135 both result in potential functional failure. The importance of long-term effects should be defined based on local
136 transportation needs.

137 The last step is to assess consequences, by including the impact of the bridge failure on the wider transport network.
138 Transport models such as *ESRI™ ArcGIS Network Analyst* (<https://bit.ly/2GPMknl>), *SUMO* (<http://sumo.sourceforge.net/>) or
139 *MatSIM* (<https://www.matsim.org/>) are suitable for computing routing and delays associated with a disrupted network link
140 (such as a closed bridge). Road network data are publicly available from sources such as Digimap®
141 (<https://digimap.edina.ac.uk/>), which provides Ordnance Survey road maps. These contain topographic information of roads
142 including name, location, length, capacity and type. After configuring the transportation network model with the collected
143 data, routing and accessibility can be investigated using network-based spatial analysis and transport appraisal techniques
144 (Arrighi et al., 2020; Pregolato et al., 2016). This impact analysis links the structural damage of a bridge due to flooding
145 with the reduced performance of the local road network the bridge serves for, approximating the wider consequences.

146 **2.1 Fluvial flooding simulation**

147 Ideally, boundary conditions should be provided by gauging stations; however, no river gauges are present near the bridge of
148 interest, as is often the case in practical scenarios. This study adopted the 2D hydrodynamic model *LISFLOOD-FP*, which
149 allows to simulate flood depths and flow velocity to set up CFD boundary conditions for a flood scenario and from available
150 gauge data.

151 *LISFLOOD-FP* is a two-dimensional, spatially distributed, grid-based hydrodynamic model for simulating channel and
152 floodplain flows (Neal et al., 2009). The model dynamically simulates flood propagation in each grid cell at each time step,
153 on the basis of the local inertial formulation of the shallow water equations and an explicit finite difference method.
154 Numerically, this process involves calculating the momentum equation (the flow between cells given the mass in each cell)
155 and the continuity equation (the change in mass in each cell given the flows between cells) (Neal et al., 2018). The equations
156 underpinning the model, including their derivation, can be found in Bates et al. (2010) and de Almeida et al. (2012).

157 As input data, *LISFLOOD-FP* requires a DEM (Digital Elevation Model) of the area, channel and boundary condition
158 information (e.g. channel friction, width and depth, hydrograph and evaporation). Flow depth and velocity (for each cell) are
159 the output considered, since they represent the intensity measures of the hazard adopted by this study. The impact of bridges
160 on flow is not explicitly represented in this particular application.

161 **2.2 Computational fluid dynamics (CFD) analysis**

162 Three-dimensional (3D) CFD software is capable of resolving fine details of flood flow around bridges on a local scale such
163 as splashes, eddies, or flow separation, which cannot be captured by depth-averaged methods (such as *LISFLOOD-LP*).
164 Also, bridges present a problem for depth-averaged tools since the computational mesh is two-dimensional and cannot be
165 discretized vertically, which does not allow for a gap underneath a bridge superstructure. To accurately model such
166 behaviors is crucial when estimating flow-induced force demands, which requires the use of a fine, three-dimensional mesh.
167 Additionally, using higher fidelity, three-dimensional models allow for localized loads to be measured on individual faces of
168 a structure, which may be used to determine whether or not individual components fail versus entire structures (Winter et al.,
169 2017).

170 For this study, the three-dimensional CFD code *OpenFOAM* was selected. Flood flows were modelled using the *interFoam*
171 solver, which is a two-phase solver that relies upon Volume of Fluid (VoF) method (Tryggvason et al., 2011) to track the
172 interface between water and air phases. The underlying governing equations that are implemented in *interFoam* are the

173 Reynolds-averaged Navier-Stokes (RANS) equations, which are solved using a predictor-corrector or projection type of
 174 method to solve for velocity and pressure fields, and advection equations for the volume fraction introduced by the VoF
 175 method. More specifically, pressure-velocity coupling was achieved using the PIMPLE algorithm, which is a combination of
 176 the Pressure-Implicit Split-Operator (PISO) and Semi-Implicit Method For Pressure-Linked Equations (SIMPLE). Since the
 177 RANS system of equations does not constitute a well-posed system due to the so-called Reynolds stress tensor that arises
 178 from the Reynolds-averaging process, a suitable turbulence model that introduces additional equations must be chosen to
 179 close the system. For this study, the $k-\omega$ Shear Stress Transport (SST) model was used due to its ability to handle severely
 180 separated flows near sharp corners better than other similar models such as the Standard, Renormalization Group (RNG), or
 181 realizable $k-\epsilon$ models.

182 2.3 Structural analysis

183 A structural analysis approach is functional for: (i) simulating relevant structural response mechanisms, which differ based
 184 on bridge type, and (ii) characterizing loading derived from the associated CFD model. Finite element (FE) analysis is
 185 commonly employed in structural engineering to simulate the response of bridges to natural hazards for the purpose of
 186 design and performance evaluation. Modern reinforced concrete and steel bridge structures are commonly formed of girders,
 187 cap beams, and pier walls or columns which can be modeled as assemblages of line and spring elements; this approach is
 188 common in practice and can be implemented in a wide variety of structural analysis programs. To model nonlinear response,
 189 which is especially important when considering extreme loads associated with natural hazards, line elements may employ
 190 concentrated or distributed plasticity formulations that make use of nonlinear hinges or fiber sections. Rotational, shear,
 191 and/or axial spring elements can be used to simulate the response of discrete components such as connections and bearings.
 192 Alternatively, continuum finite-element analysis can be employed for members if complex local response of components
 193 (e.g. local buckling and/or deformation) is of interest; this approach is significantly more computationally expensive,
 194 however. Other approaches, such as the discrete-element method, may be well suited for masonry bridges.
 195 In this work, modeling with line and spring elements is performed, so this approach will be discussed in greater detail. The
 196 considered bridge consists of a girder superstructure supported on reinforced concrete piers. *OpenSees* (McKenna et al.
 197 2010) was selected as the analysis software due to its robust nonlinear modeling and scripting capabilities. This latter
 198 capability is beneficial for performance evaluation using a suite of input parameters (in this case, a parameter sweep
 199 characterizing different flood conditions). Moreover, the software is open source and therefore suitable for adaptation in
 200 envisioned future work to enhance interactivity with *OpenFOAM*.

201 Component response and demands based on the structural analysis can be used to assign a damage state for the bridge. Here,
 202 the structural damage is evaluated as slight, moderate, extensive, or complete damage based on the FEMA Hazus manual
 203 (FEMA, 2003). Each of these damage states is associated with level of functionality and repair effort. The qualitative
 204 description of damage states and average repair cost per m^2 (ft^2) is available in literature for hurricanes (Padgett et al., 2008)
 205 and earthquakes (Hazus manual - FEMA, 2003); Gehl and D'Ayala (2018) offered a qualitative damage scale of potential
 206 damage state and failure modes for the bridge components, which could be associated with functionality losses and remedial
 207 actions. Table 1 adapts such literature to riverine flooding using additional works and expert opinion: it lists four identified
 208 damage states (from slight to complete), and associated average repair cost and days of closure due to remedial works
 209 (Werner et al., 2008; Gardoni, 2018; Lam and Adey, 2016).

210 **Table 1. Bridge damage states (Gehl and D'Ayala, 2018) associated to average repair cost per m^2 (Padgett et al., 2008; FEMA,**
 211 **2003) and average days of closure due to repair (Werner et al., 2008; Gardoni, 2018; Lam and Adey, 2016).**

Damage state	Description	Average repair cost (£/m ²)	Days of closure
Slight	Minor damages such as cracking (shear	£1.45/m ² (\$0.25/ ft ²)	0-5

	keys, hinges, deck) and spalling (hinges, columns) that require no more than cosmetic repair. Negligible scour. Some water and/or debris on deck. Full service, likely speed reduction of travelling vehicles.		
Moderate	Moderate experience of shear cracks and spalling that still leave columns structurally sound. Moderate scour and moderate movement of the abutments. Significant water and/or debris on deck. The bridge is partially serviceable (e.g. alternating circulation, reduced capacity and load), but safe to use by emergency vehicles.	£36.54/m ² (\$6.28/ft ²)	5-12
Extensive	Degradation of columns without collapse, shear and cracking leading to structurally unsafety. Significant residual movement at connections or major settlement approach. Delamination failure of individual bearings. Extensive scour of abutments. The bridge is closed to traffic.	£308.66/m ² (\$53.05/ft ²)	13-49
Complete	Collapse of columns or connection losing all bearing support. Imminent deck collapse. Unseating of girders. Scour leading to foundation failure. The bridge is unserviceable.	£1102.77/m ² (\$189.43/ft ²)	>50

212

213 2.4 Fluid-structure coupling

214 The relationship between the CFD and structural analysis is critical to the implementation of the proposed framework as
215 outlined in the vulnerability analysis block in Figure 1. Both analyses must adequately represent the bridge geometry, and
216 the CFD output and structural analysis input loading must be compatible. Here, the coupling approach between *OpenFOAM*
217 and *OpenSees* is discussed, but the methodology is applicable to other software. It is noted that *OpenSees* alone is seldom
218 used to model structural response to fluids because of the complexity of the fluid loading and the required coupling
219 mechanism between fluid and solid solvers. As such, the present work is among the first of its kind using *OpenSees*. Other
220 recent research has sought to implement coupling between these multi-physics models. For example, Stephens et al. (2017)
221 demonstrated how *OpenSees* can be “loosely coupled” (i.e., with no interaction between CFD and FE models) with
222 *OpenFOAM* to characterize structural response due to sequential earthquake and tsunami loading. A similar loosely coupled
223 scheme is used here, where:

- 224 i. the bridge superstructure (deck and girders) is modeled as a rigid, 2D cross section with a unit length out of plane
225 and subjected to steady-state flow at different water depths and velocities in *OpenFOAM*;
- 226 ii. the steady-state reactions (output from *OpenFOAM*) on the cross section are recorded; and
- 227 iii. the gravity loads and the steady-state reactions from *OpenFOAM* are applied as distributed, external loads on girder
228 line elements in a 3D *OpenSees* model of the full bridge.

229 It is noted that the bridge superstructure is rigid in the computational fluid dynamics model (an important simplification to
 230 facilitate the analysis) but not in the finite-element model.

231 2.5 Impact assessment

232 The impact of a bridge failure in terms of consequences (C) includes direct consequences (C_{dir}) and indirect consequences
 233 (C_{ind}), which relate the surrounding transport network (Argyroudis et al., 2019; Kim et al., 2018). The total costs C is
 234 computed as (Eq. 1):

$$C = C_{dir} + C_{ind} = C_{repair} + C_{cleaning} + C_{detour} + C_{delay} \quad \text{Eq. 1}$$

235 where C_{repair} is the cost associated with repair or replacement of the bridge, C_{clean} is the cost associated with the debris
 236 removal (due to flooding), C_{detour} is the additional vehicle operating due to the detour and C_{delay} is the cost associated with trip
 237 delays of normal traffic. Indirect costs may also include a fee for closing the bridge that the bridge owner has to pay to
 238 transport operators/agencies (e.g. for railways, highways).

239 Table 1 (Sec. 2.3) was functional to compute C_{repair} . Average days of closure due to repairs are obtained via discussion with
 240 national operators and existing literature (Werner et al., 2008; Gardoni, 2018; Lam and Adey, 2016). Values for C_{clean} can be
 241 researched among historic data of bridge owners, e.g. records from bridge inspection reports. C_{detour} and C_{delay} depend on the
 242 network, type of vehicle and traffic flow; this study is limited to consider private cars and HGVs (Heavy Goods Vehicles, i.e.
 243 over-3.5-tonnes-gross vehicle weight, including both articulated and rigid body types), for the sake of a contained
 244 demonstration. According to standard transport appraisal procedures (e.g. DfT, 2009), the parameters are computed with Eq.
 245 2 and Eq. 3 respectively. Considering an origin i , a destination j and a vehicle type z :

246

$$C_{detour} = \sum_i \sum_j \sum_z q_{i,j,z} l_{i,j,z} VOC_z \quad \text{Eq. 2}$$

$$C_{delay} = \sum_i \sum_j \sum_z q_{i,j,z} d_{i,j,z} VTT_z \quad \text{Eq. 3}$$

247

248 q is the volume of traffic, l is the incurred additional length, d is the incurred additional time (delay), VOC is the extra
 249 Vehicle Operating Cost (including fuel, tear and wear) and VTT is the Value of Travel Time, i.e. the non-monetary costs
 250 incurred along the journey as time spent on transport. The additional length and travel time due to the detour are computed
 251 using *ESRI™ ArcGIS Network Analyst*, setting the origin and the destination of the trip in opposite sides of the river as
 252 demonstration (Pregolato et al., 2016).

253 3 Application and results

254 The city of Carlisle is a flood-prone city (area: 1,040 km²; 2018 population: 108,387) located in the Northwest of England
 255 (UK) (Fig. 3). Three road bridges connect the two parts of the town over the river Eden from North to South (the A689, A7
 256 and M6 bridges) and a fourth one from West to East (Warwick bridge). The 2D hydrodynamic model *LISFLOOD-LP* was
 257 set up to simulate a 1-in-500-year flooding scenario (Fig. 3b) for a domain covering 14.75 km² of Carlisle, at 5 m of
 258 resolution. This simulation provided flow velocity and inundation height data.

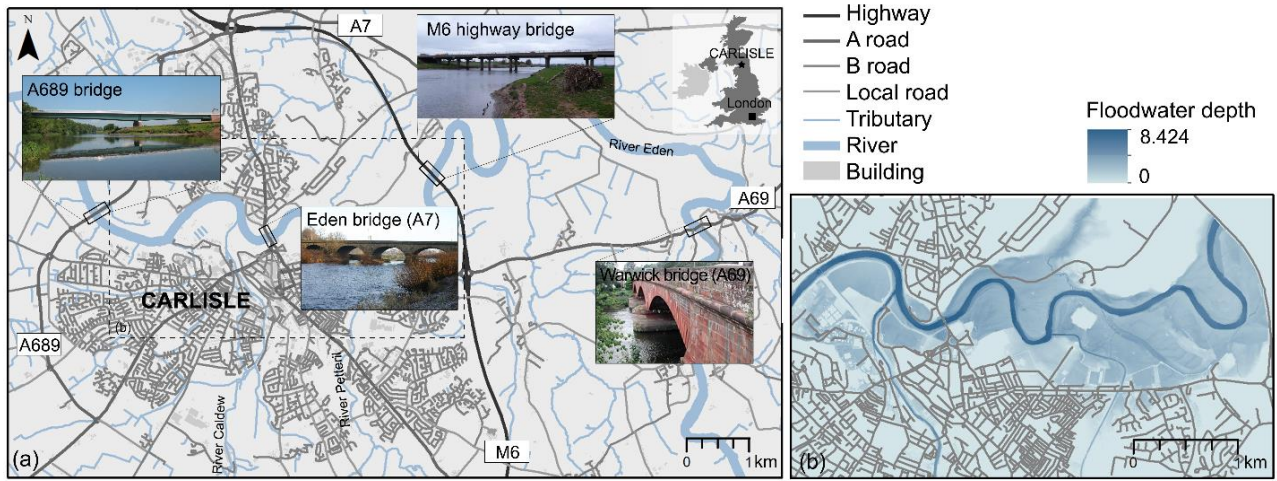

Figure 3. The case study is the city of Carlisle, UK: (a) general overview of Carlisle upon the river Eden, connected North-South by three road bridges (the A689, A7 and M6 bridges) and West-East by the Warwick bridge (A69); (b) flood hazard map for Carlisle, as simulated with LISFLOOD-LP for a 1-in-500-year flood event.

259 As a proof of concept, the M6 highway bridge over the River Eden was considered. The bridge is comprised of a girder
 260 superstructure supported by hammerhead piers. A schematic model of this bridge is shown in Figure 4 with approximate pier
 261 column (reinforced concrete), girder (concrete-encased steel), and bearing pad dimensions.
 262

263 (a) Bridge model and typical member cross sections (b) Typical hammerhead pier and superstructure model with elastomeric bearing dimensions
 264 Figure 4. Approximate geometry of M6 bridge as modeled in *OpenSees* including pier column, girder, and bearing dimensions
 265 shown (not to scale).

266 The pier columns are elliptically shaped and oriented to reduce hydraulic drag. The columns taper to a width of 4134 mm
 267 and depth of 1676 mm at the base. The girders are supported on fixed, laminated elastomeric bearing pads with dowels at the
 268 southern end of each span and free spherical bearings at the northern end. Salient bridge and flow input data are summarized
 269 in Table 2.

270
 271 Table 2. Input data of this study for the exemplary CFD analysis of the M6 bridge (Carlisle, UK).

VARIABLE	DATA	SOURCE
Span length	27.4 m	Drawings provided by Highways England
Superstructure width	17.3 m	Drawings provided by Highways England
Superstructure weight (deck, girders, and diaphragm beams)	514 kN/m	Derived from drawings
Flow Velocity	1, 2, and 3 m/s	Modelled (LISFLOOD-LP)
Inundation Height	12.5, 13.0, 13.5, 14.0, 14.5, 15.0, 16.0, 17.0, 18.0 m (from datum; +3.2 m)	Modelled (LISFLOOD-LP)

273 **3.1 CFD simulation and analysis**

274 The CFD simulation was initiated at given inundation heights and flow velocity, as modelled by the *LISFLOOD-LP* model
 275 for a 1-in-a-500-year flood event at the site. The *OpenFOAM* model was set to simulate a range of flow velocity and depth
 276 values above and below the calculated 500-year flood results in order to assess how varying the depth and velocity affected
 277 the resulting bridge performance. Flow velocities and depths were extracted from *LISFLOOD-LP* in proximity of the bridge,
 278 and also compared with historical data (e.g., the peak flow recorded at Sheepmount, UK in December 2015 was equal to
 279 $1680.0 \text{ m}^3/\text{s}$; EA, 2016) and inspection reports. The statistics for the velocity (both in its actual flood flow direction and also
 280 normal to the bridge) were computed from the *LISFLOOD-LP* velocity vector (V_x , V_y) and maximum water depth data,
 281 considering maximum values for both quantities over the whole flood simulation. The 500-year return period flood showed
 282 velocity values up to roughly 3.5 m/s and max flood depth up to 17 m near the M6 Bridge. These statistics motivated using a
 283 range of steady-state velocities of 1-3 m/s and inundation elevations of 12.5-18 m above datum in the *OpenFOAM*
 284 simulations. The bridge superstructure was positioned such that the bottom of the bridge's lowest girders and the highest
 285 point of the top of the bridge deck were at elevations of 12.375 m and 14.425 m respectively, relative to the datum, which
 286 was 3.2 m below the riverbed's lowest point. Flow rates corresponding to the range of selected flow velocities and depths
 287 were specified at the inlet boundary of the *OpenFOAM* model, using the `variableHeightFlowrate` boundary condition. To
 288 model the free-surface flow of the Eden River interacting with the M6 bridge in *OpenFOAM*, the `interFoam` multiphase fluid
 289 flow solver which utilizes the Volume of Fluid method for interface tracking was used along with the $k-\omega$ SST turbulence
 290 model to resolve turbulent flow behaviors. Default *OpenFOAM* values for air-water physical fluid properties (densities: $\rho_{\text{air}} =$
 291 1 kg/m^3 , $\rho_{\text{water}} = 1000 \text{ kg/m}^3$; kinematic viscosities: $\nu_{\text{air}} = 1.48(10^{-5}) \text{ m}^2/\text{s}$; $\nu_{\text{water}} = 1.0(10^{-6}) \text{ m}^2/\text{s}$; surface tension: $\sigma = 0.07$
 292 N/m) and turbulence model coefficients were used for all simulations. A full summary of all *OpenFOAM* boundary
 293 conditions is provided in Table 3.

294 **Table 3. *OpenFOAM* model boundary conditions.**

295

296 To reduce computation time and provide conservative results, a unit width segment of the bridge superstructure located
 297 above the deepest point of the Eden River beneath the M6 Bridge was analyzed in *OpenFOAM*, which resulted in a 2D
 298 simulation that drastically reduced the mesh cell count compared to a full 3D simulation of the entire bridge. Additionally,
 299 the out-of-plane direction components of the flow were neglected in all simulations by using the empty type of *OpenFOAM*
 300 boundary condition, ensuring the simulations were truly 2D. This setting allowed for more simulations to be run using a

301 wider range of flooding conditions in less time while conducting the parametric study. As shown in Fig. 5, the model
 302 measured forces on 20 individual components along the cross-section of the bridge superstructure segment corresponding to
 303 each girder and its tributary width of the bridge deck.

304
 305

306 **Figure 5. OpenFOAM model geometry and boundary conditions**

307

308 Fig. 6 shows converged OpenFOAM fluid load outputs for each bridge component at all inundation levels, providing an
 309 example for an initial flow velocity of 3 m/s, which corresponds to the worst-case scenario simulated in this study. Since the
 310 simulations were 2D, load values are expressed in units of force or moment per meter of bridge deck width.

311 The horizontal forces presented in Fig. 6a show significant peaks at the bridge deck edges for components 1 and 20, due to
 312 the asymmetric pressure distributions that these components experienced when comparing their upstream and downstream
 313 faces than the interior components (which were shielded from higher velocity flows by the exterior components).
 314 Additionally, the exterior components included the traffic barriers, which significantly increased their surface area on which
 315 fluid pressure acted compared to the interior components.

316 At the upstream edge of the deck, component 1 absorbed the primary impact of the incoming flood flow at its peak velocity
 317 since it was on the upstream side of the deck, resulting in it carrying the largest positive horizontal forces. At the
 318 downstream edge of the deck, component 20 was initially subjected to positive horizontal forces due to the flow impacting
 319 its bottom flange and the lower portion of its web, but for flow heights greater than 14.0 m, its horizontal force decreased
 320 until it became negative by a flow height of 16.0 m. The gradual decrease in component 20's horizontal force may be
 321 attributed to differences in the vertical surface areas of and the flow velocities near its up- and downstream sides that resulted
 322 in larger fluid pressures acting on the downstream faces than the upstream faces. The total vertical surface area of the
 323 downstream faces was larger than that of the upstream faces by an amount equivalent to the deck section, which provided
 324 additional area on which fluid pressure acted in the upstream direction. Complex flow characteristics that contributed to the
 325 velocity differences include: 1) the recirculatory flow patterns between the girders of components 19 and 20 and in the
 326 corner between the deck top and traffic barrier that led to reduced pressures on upstream faces of component 20; 2) the
 327 turbulent eddies that were shed off of the leading edge of component 20's girder bottom flange that redirected the flow
 328 toward the downstream faces of component 20; and 3) the flow over the top of the bridge deck rejoining the flow beneath the
 329 bridge at the downstream edge of the deck, which contributed to the formation of turbulent eddies in the bridge deck wake.
 330 Also, in the event that any air was trapped between girders, a lesser water level between the girders would further decrease
 331 component 20's horizontal force.

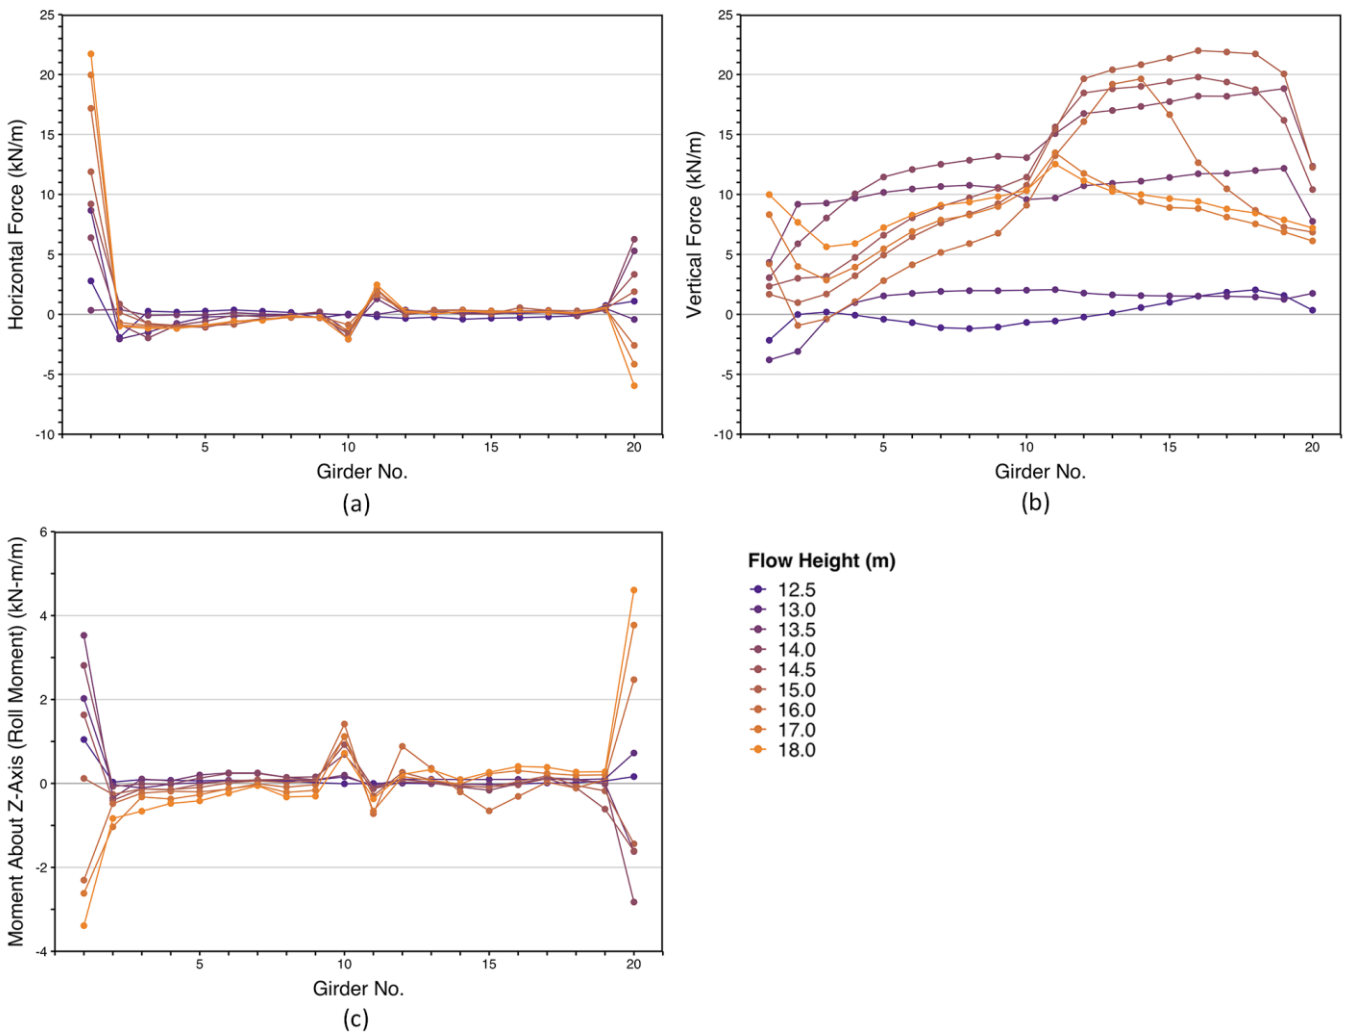

332 The vertical forces shown in Fig. 6b are of similar magnitude to the horizontal force values in Fig. 6a. When the flow height
 333 was small prior to the flood overtopping the bridge (i.e. 12.5 m to 13.0 m), the vertical forces on both halves of the bridge
 334 were roughly uniform except for the components nearest to the upstream edge of the bridge. In these cases, the vertical
 335 forces on components 1 - 3 decreased due to fluid pressure acting downward on the top of the girder bottom flanges. For

336 flow heights of 13.5 m to 16.0 m, the vertical forces on the upstream half of the bridge initially increased due to buoyancy
337 forces increasing (due to increasing flow depth), but it started to decrease at a flow height of 14.0 m as the flood began to
338 overtop the bridge. By a flow height of 17.0 m, the bridge was submerged enough that buoyancy caused the vertical forces
339 on the upstream half of the bridge to increase again.

340 For the downstream half of the bridge, uplift due to buoyancy increased until a flow height of 15.0 m. At this point, the flow
341 overtopped the superstructure crest at the midpoint of the bridge. This change in flow behaviour caused the vertical forces on
342 the downstream half of the bridge to decrease until the bridge was sufficiently submerged at a flow height of 18.0 m.

343 Overturning moment results acting about the z -axis of each bridge component are shown in Fig. 6c. Similar to the horizontal
344 forces shown in Fig. 6a, the extreme overturning moment values occurred at the edge components of the bridge deck,
345 whereas the interior components experienced much smaller overturning moments since they are shielded by the edge
346 components. At flow depths less than 14.0 m prior to the flood overtopping the barriers, increasing positive moment values
347 for the component 1 at the upstream edge indicate that a counter-clockwise rotation would occur, which would cause the
348 upstream side of the bridge component to move downwards, whereas downstream side would move upwards. This process is
349 due to the lesser depth flows only impacting the bottom flanges and lower parts of the webs of the girders. As the flow depth
350 increased, the position of the resultant horizontal force gradually increased until it moved above the centroid of the
351 component 1 girder, about which moments were summed. This effect resulted in a trend reversal such that the moment
352 decreased with increasing flood depth until for depths of 16.0 m or more clockwise rotations of component 1 occurred due to
353 flow overtopping and eventual full submersion the bridge. At the opposite deck edge, component 20 experienced a similar
354 trend switch, where its overturning moment initially decreased for flow depths less than 14.0 m, but increased for 14.0 m or
355 more, changing from counter-clockwise to clockwise rotation beginning with the 16.0 m flow height case.

356

361 3.2 Structural analysis and damage assessment

362 The *OpenSees* model was developed using fiber-based line elements for the reinforced-concrete pier columns and preflex
 363 girders (a form of prestressed, concrete-encased steel beams). Nonlinear concrete (Concrete02) and steel (Steel02)
 364 constitutive models were employed to simulate uniaxial material response in the fibers. All concrete was assumed to have a
 365 compressive strength of 34.5 MPa. The steel reinforcement and encased structural steel was assumed to have yield stresses
 366 of 276 MPa and 379 MPa, respectively. The girders ends were connected to pier caps (modeled as rigid) via linear-elastic
 367 springs to represent bearings. The free spherical bearings were modeled as roller boundary conditions. The steel-laminated
 368 elastomeric bearing pads were modeled with lateral, vertical, rotational, and torsional stiffnesses based on linear theory of
 369 bearings as described by Stanton et al. (2008). The elastomeric bearing dimensions are shown in Figure 4; each had two, 13-
 370 mm-thick layers of elastomer reinforced with 3-mm steel plates. The elastomer was assumed to have a bulk modulus of 3100
 371 MPa and a shear modulus of 0.76 MPa; the bearing dimensions and material properties led to the stiffness parameters
 372 defined in Table 4. The bearing spring elements were connected to rigid links which simulated pier cap beams, providing a
 373 load path between the girders and pier columns. The bridge abutments were founded on rock on the north side and piles on
 374 the south side; both abutments were modeled as rigid. The piers were founded on rock and pier columns were modeled as
 375 fixed. It is noted that many bridge foundations are vulnerable to scour, especially under flood conditions; however, the piers
 376 and abutments of the considered bridge are founded on rock, thus scour is not a concern for this structure (and in general
 377 scour and soil-structure interaction effects are beyond the scope of the present work).

379 **Table 4. OpenSees elastomeric bearing spring stiffnesses**

Stiffness type	Direction	Value
Axial	—	142 kN/mm
Shear	—	1.69 kN/mm
Rotational	Deformation in short-axis direction	311 kN-m/rad
	Deformation in long-axis direction	2350 kN-m/rad
Torsional	—	17.9 kN-m/rad

380

381 To analyze the bridge, gravity loads were first applied based on the self-weight of the structural components; no live loads
 382 were considered. The lateral forces, vertical forces, and roll moments determined from *OpenFOAM* were then applied as
 383 distributed loads in *OpenSees* on each bridge girder (i.e., over all eight spans with 20 girders per span); this step is the key
 384 link between the CFD and structural models.

385 Under the range of loading investigated, yielding or cracking was not detected in the girders or columns, and the simulated
 386 hydraulic forces were not large enough to overcome the self-weight of the structure, which would result in uplift of the
 387 superstructure. However, the elastomeric bearing pads sustained large shear demands near the design limits specified by
 388 Section 14.7.5 of the AASHTO *LRFD Bridge Specification* (2017). Specifically, the elastomeric bearings were evaluated
 389 for:

- 390 i. loss of frictional resistance between the bearing and girder based on the ratio of shear and normal forces on the
 391 bearings,
- 392 ii. excessive shear deformation, and
- 393 iii. excessive shear strain due to combined axial load, rotation, and shear deformation.

394 The solid lines in Figure 7 compare maximum shear forces, deformations, and strains in any of the elastomeric bearings for
 395 each of the loading scenarios investigated; Figures 7a, 7c, and 7e show these engineering demand parameters versus flow
 396 velocity and Figures 7b, 7d, and 7f show corresponding values with respect to flow height. The data suggest that peak
 397 steady-state demands on any of the elastomeric bearings in the bridge occur around a flow height 15 m, at which point the
 398 bridge has just reached full inundation. In addition, below a flow height of 15 m, demands consistently increase with
 399 velocity; such increases in demand after full inundation are not consistently observed, which suggests that the loading is
 400 primarily associated with hydrodynamic effects that are a function of the effective area of the cross-section, and may also be
 401 affected by the fact that the flow around the superstructure is less turbulent. To expand the data set, linear extrapolation to
 402 flow velocities of up to 6 m/s are shown in Figures 7a, 7c, and 7e as dotted lines with open markers. It is noted that the plots
 403 in Figure 7 show peak demands across all elastomeric bearings in the bridge, and the actual extent of damage depends on the
 404 progression of failure in multiple bearings.

405 The Commentary to the AASHTO *LRFD Bridge Specification* (2017) states a coefficient of friction of 0.2 between
 406 elastomeric bearings and concrete is appropriate for design, and this limit is used here to evaluate potential girder unseating
 407 due to loss of frictional resistance. For the purpose of this evaluation, dowel resistance is neglected, though this effect could
 408 prevent unseating in practice. Figures 7a and 7b plot the peak ratios of shear-to-normal forces across all bearings on the
 409 bridge, and it can be observed that the bearings are well below the limit suggested in the AASHTO Commentary (which is
 410 labeled as μ_{max} and shown as the grey line). However, it must be noted that the coefficient of friction may be lower than
 411 expected under wet conditions and that the lateral hydrodynamic loading can be significant, increasing vulnerability of
 412 unseating due to debris impact. To illustrate how the sequential fluid-structure modeling results may be applied, a highly
 413 conservative, reduced coefficient friction of 0.1 is considered. Using this threshold, the results indicate flow conditions for

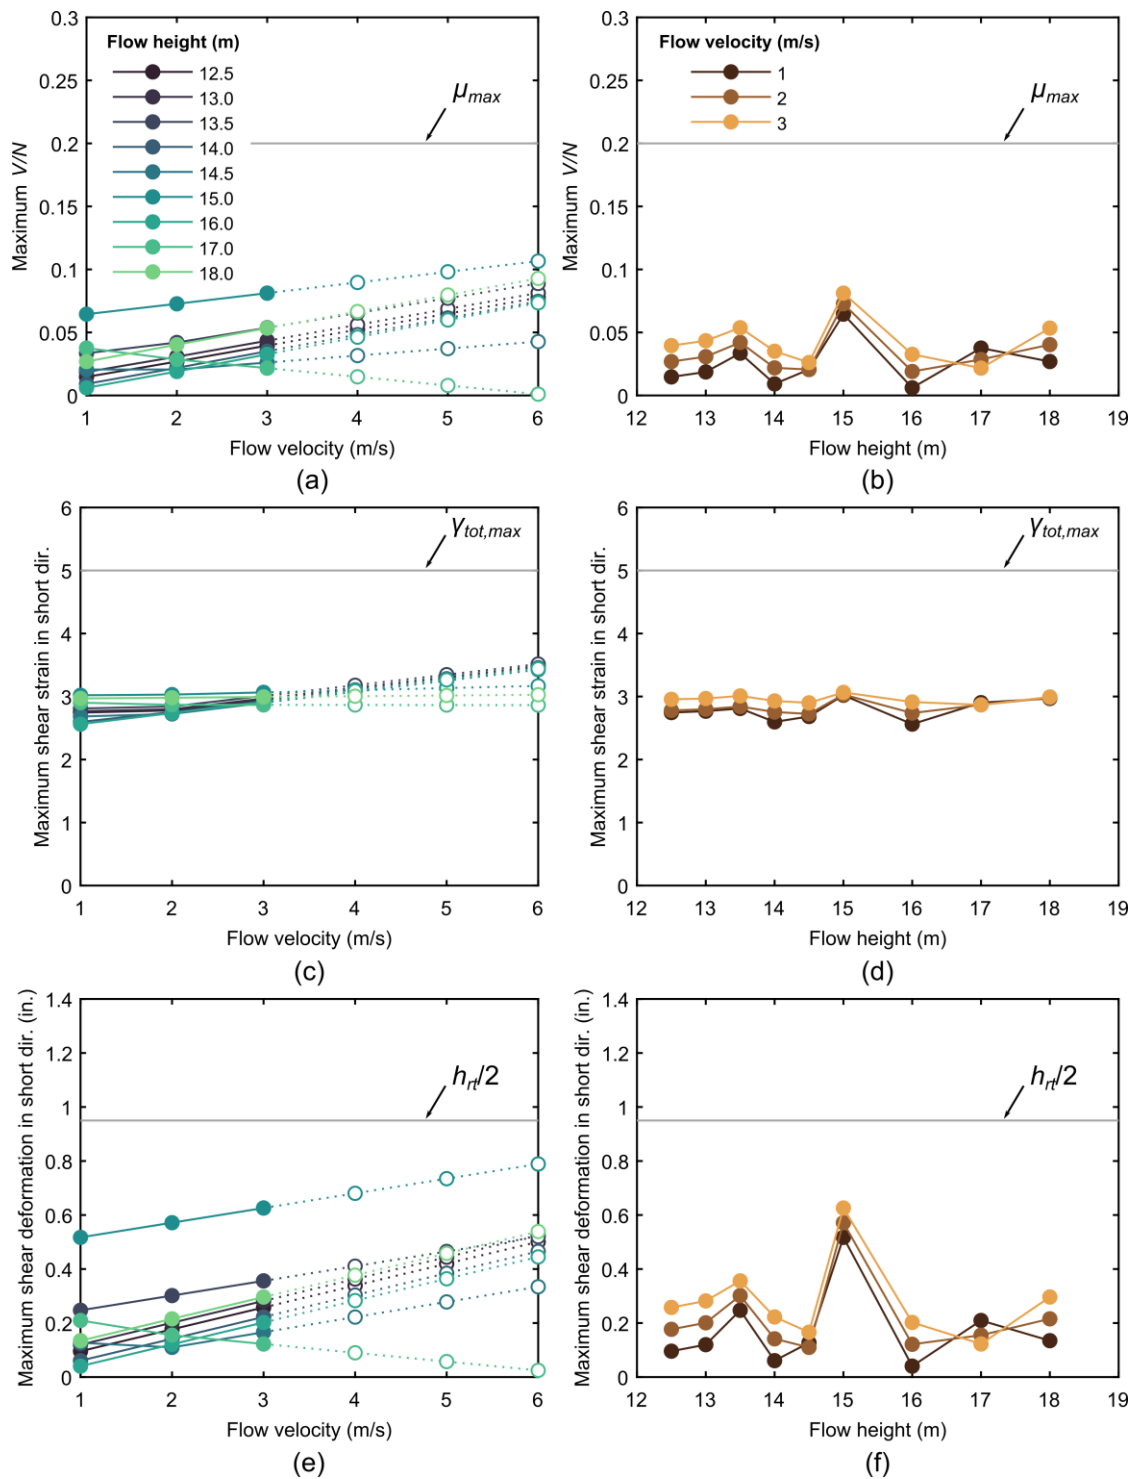

414 which the given frictional resistance is approached or exceeded: 13.5-m flow depth with velocity of at least 6 m/s, 15-m flow
 415 depth with velocity of at least 5 m/s, 18-m flow depth with velocity of at least 6 m/s.
 416 Figures 7c and 7d show peak shear strains due to loading perpendicular to the short edge of the bearing pad (see Figure 4b)
 417 due to combined axial load (γ_a), rotation (γ_r), and shear (γ_s). The shear strains are computed based on Eqs. 4-6 based on the
 418 AASHTO *LRFD Bridge Specification* (2017).

$$\gamma_a = D_a \frac{\sigma_s}{G S_i} \quad \text{Eq. 4}$$

$$\gamma_r = D_r \left(\frac{L}{h_{ri}} \right)^2 \frac{\theta_s}{n} \quad \text{Eq. 5}$$

$$\gamma_s = \frac{\Delta_s}{h_{rt}} \quad \text{Eq. 6}$$

419 In the above equations, D_a and D_r are empirical coefficients, σ_s is the average compressive stress, G is the shear modulus, S_i
 420 is the shape factor of the i^{th} internal layer, L is the bearing length perpendicular to the axis of rotation, h_{ri} is the thickness of
 421 the i^{th} internal elastomeric layer, h_{rt} is the total thickness of the elastomer, θ_s is the rotation demand, n is the number of
 422 interior elastomeric layers, and Δ_s is the shear deformation. Note that σ_s , θ_s , and Δ_s are outputs from the structural analysis;
 423 the rotation demand, θ_s , includes 0.005 rad of rotation due to misalignment. For design per the AASHTO *LRFD Bridge*
 424 *Specification* (2017), the combined shear strain due to these actions should not exceed 5.0, and this criterion is satisfied in
 425 the analyses (all values, including extrapolated values, are below the grey line in Figures 7c and 7d).
 426 The shear deformation demand on the bearing Δ_s is shown to be more critical than the combined shear strains: Figures 7e
 427 and 7f show these data with the annotated shear strain limit of $h_{rt}/2$ in grey; this limit is also based on the AASHTO
 428 *Specification* (2017). The demand is clearly largest for a flow height of 15 m, and it increases linearly with the flow velocity.

429

430 **Figure 7. Maximum simulated demand on elastomeric bearings in M6 bridge, including (a)/(b) shear force, (c)/(d) total shear**
 431 **strain due to combined axial, moment, and shear demands, and (e)/(f) shear deformation; plots on left show demand versus flow**
 432 **velocity and plots on right show demand versus flow height.**

433 3.3 Network impact and consequence assessment

434 The results of the loosely coupled CFD and structural analyses described in Sec. 3.2 suggest a potential for either girder
 435 unseating due to loss of frictional resistance or excessive shear deformation, which may lead to debonding and delamination
 436 for this particular bridge. In addition, damage associated with these limit states is most expected at a flow height of 15 m and
 437 flow velocity of at least 5 m/s. The impact of damage in this flood scenario is therefore considered in this section. Based on
 438 Table 1, the damage state is estimated as moderate because: (i) the bearings approach but do not exceed limit states, (ii)
 439 scour is assumed to be insignificant compared to damage to the superstructure and bearings, and (iii) water overtops the
 440 bridge deck. A moderate damage state implies the bridge closure for 5-12 days (see Table 1). In the case of the M6 bridge,

441 its closure causes disruptions to all southbound and northbound users that are travelling along the M6 (Figure 8). Compared
 442 to the baseline journey, results show that private cars are delayed by 12 minutes and have additional ca. 9 km due to
 443 rerouting. HGVs cannot travel via the historic Eden Bridge (city center) and are subjected to a longer rerouting, which leads
 444 to 19 minutes and ca. 20 km of delay and additional travelling respectively.

445
 446 **Figure 8. Routes for crossing the river Eden along the highway in baseline and disrupted conditions; private and heavy vehicles**
 447 **are rerouted on different journeys when the M6 bridge is disrupted.**

448 The cost of the impact due to the M6 bridge disruption is computed in terms of direct and indirect consequences using Eq. 1;
 449 output and input values are specified in Table 5.

450 **Table 5. Output and input data for the impact cost calculation considering disruption due to an extreme flood event on the M6**
 451 **bridge in Carlisle. Acronyms: VTT – Value of Travel Time; HGV - Heavy Good Vehicle; VOC – Vehicle Operating Cost; ADT -**
 452 **Average Daily Traffic.**

	VARIABLE	DATA	SOURCE

	C_{clean}	£29,476.00	Panici et al. (2020)

	C_{detour}	£30,878.65/day	computed
	C_{delay}	£44,818.47/day	computed
TOTAL		£566,663.81	

453

454 The values of Value of Travel Time (VTT) of HGVs (Heavy Good Vehicles, working condition) and average private cars
455 (unspecified conditions) can be found in the UK Department for Transport (DfT) appraisal methods, illustrated in the Cost
456 Benefit Analysis (COBA) manual (DfT, 2009). Data regarding the additional travel time for rerouting has been computing
457 via transport model (Sec. 2.5) and verified with Google Maps (Figure 8); for the UK, topological road network links are
458 freely available nationwide. Data regarding Average Daily Traffic (ADT) flow are freely available
459 (<http://webtris.highwaysengland.co.uk/>) and were obtained by considering the annual northbound and southbound flows for
460 the relevant sites (36,670 veh/day: Site 9538/2 on link M6 southbound and Site 9540/2 on link M6 northbound; 2019 data),
461 considering the traffic composition at 78% for private cars and 5% for HGVs (DfT, 2019).

462 The repair cost (C_{repair}) was computed using Table 1 and assuming 7 days (average) of bridge closure; the cost of debris
463 removal was obtained by looking at the highest cost for a single event in the UK (Panici et al., 2020), since the simulated
464 flooding is an extreme and rare event. The additional vehicle operating due to the detour per day (C_{detour}) was calculated
465 using Eq. 2; the cost associated with trip delays (C_{delay}) was calculated using Eq. 3.

466 For the case study undertaken (Carlisle, UK; 1-in-a-500-ys event), the total cost of the flood impact to the bridge is
467 £566,663.81, considering seven days of bridge closure. The largest proportion (93.5%) of this cost is due to the indirect cost
468 of rerouting traffic (£75,697.12 per day of closure, i.e. £529,879.81); the 6.5% of the total cost is due to direct damages only
469 (£36,784.00).

470 4 DISCUSSION AND FUTURE RESEARCH

471 This study developed an integrated method that uses a multiphysics, multilevel approach for assessing the effect of flooding
472 hazards on a local transportation network. For the city of Carlisle (UK), a 1-in-500-years flooding event was simulated and
473 the resulting hydrodynamic forces on the highway bridge (M6) modelled. While simulated hydrodynamic forces and Finite
474 Element (FE) analysis did not show uplift failure, overtopping of the bridge is shown to occur at inundation heights of 14 m
475 and above. Given the potential for flood-related disruption of traffic, overtopping should be considered temporary network
476 failure in its own right. The elastomeric bearings supporting the bridge girders approached shear deformations near design
477 limits at a flow height of 15 m, and a potential loss of frictional resistance between the elastomer and concrete is also
478 observed. While these limit states were not exceeded for flow velocities up to 3 m/s, extrapolation to faster flow rates
479 suggests higher potential for damage. Under this hypothesis, the bridge would lose immediate functionality at a flow height
480 of between 13.5 and 14.0 m due to inundation of the deck even if the structure sustains no damage. The impact analysis
481 showed that indirect damages covered the 93.5% of the total cost of damages to the bridge, proving that limiting the
482 assessment to repairs and debris cleaning would greatly underestimate the impact of flooding to bridges.

483 The produced outputs are conceptual results and thus approximate and indicative for multiple reasons. First, there is a dearth
484 of UK-specific data regarding bridge repairs, duration time of repair, etc.; research or survey to solicit post-flood data are
485 highly recommended to improve impact estimates. For example, a bridge could be partially closed during repairs (according
486 to its damage state) and allow traffic in one direction. Second, the modeling approach presented herein used several
487 intentional simplifications for demonstration purposes, including reducing the CFD domain, neglecting soil-foundation
488 effects and scour modeling, and assumed rigidity of the structural system among others. In scenarios where these issues (or
489 others) may be of more concern for a particular bridge, the fidelity of the modeling approach could be improved.
490 Additionally, the failure states presented here may not translate broadly to the general bridge inventory, but additional or

491 alternative structural/functional failure states could be applied. Third, the impact analysis was limited to private cars and
492 HGVs for demonstration purposes; however, advanced transport appraisal could better capture users' choices and the
493 engineering response of lifelines by including a wider range of vehicles categories and traffic scenarios. In terms of impact,
494 the presence of floodwater on the roads is not simulated for limiting the focus of this work on riverine flooding and the
495 bridge impact consequences; for properly analyzing the flooding impact to road networks, simulation of surface water
496 flooding should be undertaken; this analysis would be a study on its own, and currently out of the scope of this piece of
497 research. Flood impact on other parts of the network would limit the capacity of the alternative routes, causing additional
498 delays to the traffic; thus, obtained results represent an underestimation of the overall systemic cost. Nevertheless, the
499 proposed approach of impact analysis can give modelers and analysts a comprehensive method for assessing susceptibility to
500 flooding and relative consequences at systemic level and the case study presented here represents an archetype for this
501 approach.

502 Thus, the importance of this study consists in the proof of concept of a new holistic methodology which uses a multilevel
503 approach to improve the fidelity of network failure predictions, taking advantage of seemingly disparate physical models.
504 The computed hydrodynamic forces were applied directly into a traditional FE model to predict the global structural
505 response to identify critical structural components and damage states. Notably, the hydrodynamic forces induced large
506 demands on bearings that are often not considered in design. Because of the critical nature of bridges to a transportation
507 network, the impact analysis revealed that indirect cost cover almost all the total cost due to flooding; this consideration is
508 fundamental for infrastructure owners and managers when managing assets and budgets.

509 Next steps of this study will analyze the impact of the closure for a second bridge (e.g. the masonry arch Eden Bridge), in
510 isolation first and then in combination with the M6 bridge. Future work should investigate the impacts of other limit states
511 which could result in total or partial bridge closure; a wider range of bridge types should be investigated too. Such analyses
512 would benefit from 3D CFD and FE models to help refining demands on the structure and reducing uncertainty in the
513 predicted bridge performance. Ultimately, this approach can be applied to any coastal or riverine structure where large-scale
514 water inundation is expected.

515 **5 CONCLUSION**

516 This study focused on riverine bridges prone to failures during flood events. This study established rigorous practices of
517 Computational Fluid Dynamics (CFD) for modelling hydrodynamic forces on inundated bridges, and understanding the
518 consequences of such impact on the surrounding network. The hydrodynamic forces were modelled as demand on the bridge
519 structure and inputted into a vulnerability analysis of the structure; the performance evaluation s showed a moderate damage
520 state of the bridge which was used to approximate the overall direct and indirect consequences. For the city of Carlisle (UK)
521 and a 1-in-500-years flooding, results showed that the flood impact to the M6 bridge (highway bridge) caused more than
522 £500k of damages of which 93.5% indirect damages (rerouting and delays). The relevance of this work resides in the
523 integrated method that couple practices of CFD with performance and network analysis, which allows to estimate the cost
524 due to flooding impact to a bridge considering the surrounding transport system. Infrastructure owners and managers, as well
525 as modelers and researchers, should build on this work to better predict local fluid pressures that may lead to bridge
526 structural failure and related network-wide consequences.

527 **DATA AVAILABILITY STATEMENT**

528 All relevant and publicly available data will be shared via the DataBris repository of the University of Bristol if the paper
529 will be accepted for publication; data sources are clearly specified throughout the paper.

530 **ACKNOWLEDGEMENTS**

531 MP was supported by the Engineering and Physical Sciences Research Council (EPSRC) LWEC (Living With
532 Environmental Change) Fellowship (EP/R00742X/1 and 2). The authors also grateful acknowledge: Mark Pooley at
533 Highways England; John L. Kelsall at Phoenix Architecture & Planning; Mohammad Fereshtehpour at Ferdowsi University
534 of Mashhad.
