Abstract. Theoretical source models of underwater explosions are often applied in studying tsunami hazards associated with submarine volcanism; however, their use in numerical codes based on the shallow water equations can neglect the significant dispersion of the generated wavefield. A non-hydrostatic multilayer method is validated against a laboratory-scale experiment of wave generation from instantaneous disturbances and at field-scale submarine explosions at Mono Lake, California, utilising the relevant theoretical models. The numerical method accurately reproduces the range of observed wave characteristics for positive disturbances and suggests a previously unreported relationship of extended initial troughs for negative disturbances at low dispersivity and high nonlinearity parameters. Satisfactory amplitudes and phase velocities within the initial wave group are found using underwater explosion models at Mono Lake. The scheme is then applied to modelling tsunamis generated by volcanic explosions at Lake Taupō, New Zealand, for a magnitude range representing ejecta volumes between 0.04 – 0.4 km³. Waves reach all shores within 15 minutes with maximum incident crest amplitudes around 4 m at shores near the source. This work shows that the multilayer scheme used is computationally efficient and able to capture a wide range of wave characteristics, including dispersive effects, which is necessary when investigating submarine explosions. This research therefore provides the foundation for future studies involving a rigorous probabilistic hazard assessment to quantify the risks and relative significance of this tsunami source mechanism.

1 Introduction

Submarine eruptions are a poorly understood volcanic hazard that can generate tsunamis. When fully submerged, they can transfer some of the eruption's released energy into generating impulsive waves by the displacement of water, either by regular or periodic jetting, flank instability or explosion (Duffy, 1992; Egorov, 2007; Paris et al., 2014). These processes can expand the hazard footprint of an eruption far beyond the classical primary hazards, posing danger along the shores of caldera lakes and coastal areas near known explosive volcanism. In general, volcanoes are estimated to be responsible for just 5% of all noted tsunamis since 1600 AD, yet account for 20-25% of all recorded fatalities resulting from volcanic activity (Mastin and

Witter, 2000). However, tsunamis are often neglected from hazard maps of volcanos - recent events such as Anak Krakatau in late 2018 have underlined the need to consider them in any disaster risk response (Grilli et al., 2019; Williams et al., 2019; Ye et al., 2020). This is especially pertinent for communities that are not exposed to or are less familiar with seismogenic tsunamis and may not consider themselves at risk.

While experimental data and detailed field studies of these phenomena are rare, some reliable observations exist, for example, at Karymskoye Lake, 1996, where a Surtseyan-style eruption was partially witnessed from the air including six explosions followed by tsunamis and base surges. Later ground investigation revealed run-up along the lake ranging from 19 – 1.8 m at distances 0.5 – 3 km from the vent, debris flows down the Karymskaya River, and boulder transportation up to 60 m inland (Belousov et al., 2000; Torsvik et al., 2010; Ulvrova et al., 2014; Falvard et al., 2018). The Ritter Island volcano generated one of the largest known tsunamigenic flank collapses in 1888, leaving only a small remnant above the water surface, and has since experienced occasional submarine eruptive activity and small local tsunamis in 1972, 1974 and 2007 (Johnson, 1987; Dondin et al., 2012). In the Caribbean near Grenada, Kick'em Jenny volcano was discovered mid-eruption in 1939 and has been regularly active and progressively shoaling, with eruption columns breaching the surface in 1939 and 1965 generating minor tsunami waves (Smith and Shepherd, 1993, 1996). Many other candidate eruptions are historically documented with small amplitude waves such as Kavachi, Solomon Islands, or lack detailed proximal observations, which leaves uncertainty as to the source mechanism responsible, for example, the 1952 Myojin-Sho submarine eruption which destroyed a naval research vessel, or the 1883 eruption of Krakatau (Dietz and Sheehy, 1954; Nomanbhoy and Satake, 1995).

Explosive volcanic eruptions are characterised by a directional gas-driven escape from the source, exsolution of water vapour and, in submarine settings, potentially violent vaporisation of sea or lake water on interaction with hot magma. This phreatomagmatic eruption can lead to rapid expansion of the resultant water vapour at depth leading to disturbance of the water surface and propagation of waves. To investigate the potential hazard range, we need to understand the relationship between source parameters of the eruption and the nature of waves they generate is needed.

Underwater explosions are well documented (Cole, 1948; Mirchina and Pelinovsky, 1988; Le Méhauté, 1971; Kedrinskiy, 2006; Egorov, 2007) primarily owing to military reports and research in blast mitigation and structural response in, for example, ship hulls and other coastal or off-shore structures (Klaseboer et al., 2005; Aman et al., 2012; Liu et al., 2018). As a result, significant research efforts have usually been focused on non-linear fluid-structure interactions such as pressure loading from shock waves rather than any wave generation relationships. Still, some tests were conducted on this matter during the nuclear-testing age and led to the development of theoretical models describing explosion-surface interaction and dynamics of the resultant wave field (Le Méhauté and Wang, 1996). Physical experimentation since the end of nuclear testing has been rare due to cost, practicalities, environmental concerns and the challenges of scale experienced by previous tests. In their place, numerical investigations are now the predominant area of research and offer the most likely route to advance the understanding of these processes.

The current theoretical models summarised by Le Méhauté and Wang (1996) have been used in recent years to simulate the wavefield generated from events that produce analogous water surface cavitation such as submarine volcanic explosions (Torsvik et al., 2010; Ulvrova et al., 2014; Paris et al., 2019; Paris and Ulvrova, 2019) and asteroids impacting in ocean

basins (Ward and Asphaug, 2000). However, numerical solutions often either utilise the empirically derived relations without validating their use in a numerical scheme against a suitable explosive physical experiment or test a generation mechanism in the local spatial range only at the cost of neglecting investigation of the generated wave field. Often, models such as those based on non-linear shallow water equations are applied to these problems without considering how dispersive the resultant waves may be (Paris and Ulvrová, 2019).

This work uses a recently developed non-hydrostatic multilayer solver for free-surface flows to model the physical problem. Firstly, the method is validated against a laboratory-scale experiment of released columns of water to ascertain the numerical solution's robustness in resolving a simplified comparable wave generation mechanism. Secondly, data from one of the last military explosive test series focused on surface wave observations is compared with results produced by implementing the theoretical model's initial conditions in the numerical method. These tests are to establish fitness of the underlying models, which are then applied to hypothetical explosive submarine eruptions at Lake Taupō, New Zealand.

2 Methodology

2.1 Underwater eruption model

An explosive subaqueous volcanic eruption is a dynamic and complex event involving abrupt fragmentation, volume change and numerous high energy interactions between pressurised magma, volatiles and water. Their wave generation capability depends on numerous physical parameters, including eruptive energy, depth, duration, and vent geometry (Egorov, 2007; Paris, 2015). Scarce availability of field observations combined with practical limitations both in field and laboratory necessitates simplifications to be made for an explosive eruption model such as considering it as a point-source explosion, as proposed and utilised by Torsvik et al. (2010), Ulvrová et al. (2014), and Paris and Ulvrová (2019).

The models developed for submarine explosions and their waves are derived from experimental data and visual observations from chemical and nuclear explosive testing during the 20th century. As documented at the time, water disturbances are born from the generation and rapid expansion of a gas bubble that interacts with the free-surface by collapsing into a crater-like cavity, accompanied by central jets of water and the initial dissipative cylindrical bore, which radially expands outward. The resultant cavity rapidly fills under gravity to produce the second, larger jet which produces a further cylindrical bore, after which the disturbance oscillates until rest, precipitating waves of decreasing amplitude. This free-surface interaction is strongly linked with the depth of explosion relative to its energy; small-yield or deep detonations lead the explosive bubble to transfer a large portion of its energy to the surrounding water through rapid oscillations and significantly reduce wave-making efficiency. (Le Méhauté, 1971; Le Méhauté and Wang, 1996)

Bubble dynamics is a very active area of research in computational fluid dynamics (CFD), though, in the explosive realm, the focus is usually on pressure waves and solid interactions (Wang et al., 2018). These studies are usually short in temporal range and are very computationally expensive as modelling the full problem requires accounting for compressibility and multi-phase flow; thus, this has spawned specialist codes for their solution (Hallquist, 1994; Li et al., 2018). Only in recent years have studies appeared that directly simulate expanding explosive bubbles interacting with deformable beds and a free-surface

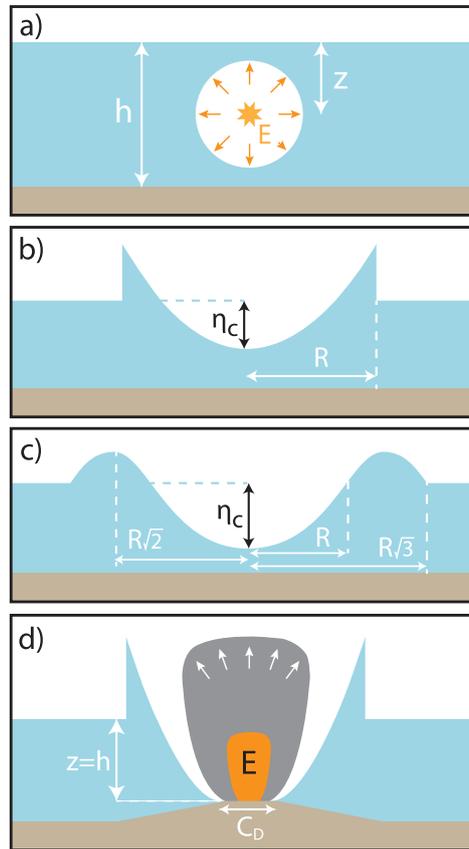

Figure 1. Illustrations of the submarine explosion problem. (a) An explosion of yield E at depth z in water of depth h . (b) The initial surface elevation profile is given by Eq. (1). (c) The initial surface elevation profile is given by Eq. (2). (d) Schematic of a volcanic scenario where such an explosion would occur at maximum depth where $z = h$, and crater diameter C_D can be measured or calculated using estimated ejecta volume V with Eqs. (9-10).

90 (Petrov and Schmidt, 2015; Daramizadeh and Ansari, 2015; Xu et al., 2020). However, there is minimal focus on subsequent surface waves, let alone relations tested for their generation mechanisms or far-field propagation.

Following development of the physical theory of underwater explosions, mathematical models were developed by applying inverse methods to experimental time series and simplifying the result to a two-parameter model corresponding to initial conditions on the free-surface elevation (η_0) representing the maximum surface displacement from the explosive disturbance
 95 (Le Méhauté and Wang, 1996). η_c corresponds to the maximum depth of the disturbance below equilibrium and R to its radius extent. These parameters physically represent the size of the initial cavity and are functions of explosive yield E , water depth h , burst depth z and bed characteristics for which calibration is made with empirical data. The initial disturbance can therefore be

described analytically by one of a number of candidates for the general profile as Eq. (1-2). Note that Eq. (1) is discontinuous at its edge, while Eq. (2) returns back to zero. A schematic diagram illustrates the problem and initial profiles in Figure 1a-c.

$$100 \quad \eta_0(r) = \begin{cases} \eta_c \left[2 \left(\frac{r}{R} \right)^2 - 1 \right], & r \leq R \\ 0, & r > R \end{cases} \quad (1)$$

$$\eta_0(r) = \begin{cases} \eta_c \left[-\frac{1}{3} \left(\frac{r}{R} \right)^4 + \frac{4}{3} \left(\frac{r}{R} \right)^2 - 1 \right], & r \leq R\sqrt{3} \\ 0, & r > R\sqrt{3} \end{cases} \quad (2)$$

2.1.1 Depth classification

The relations between parameters η_c , R and explosive characteristics described here are derived empirically after many series of small and larger scale experimental observations and are well described and reviewed by Le Méhauté and Wang (1996).
 105 These relations depend on classifications of water depth h and charge depth below water surface z relative to explosive energy released E . In terms of a depth parameter $D = \frac{ch}{\sqrt[3]{E}}$, where an imperial unit conversion constant $c = 406.2$, three categories are specified when considering wave generation:

$$Classification = \begin{cases} Deep, & D > 14 \\ Intermediate, & 1 < D \leq 14 \\ Shallow, & D \leq 1 \end{cases} \quad (3)$$

For deep and intermediate cases, the cavity parameters are defined as:

$$110 \quad \eta_c = aE^{\frac{6}{25}}, \quad (4)$$

$$R = bE^{\frac{3}{10}}, \quad (5)$$

where constants a and b vary as;

$$a = \begin{cases} 0.02913, & 0 < \frac{z}{E^{\frac{3}{10}}} \leq 9.965 \times 10^{-4} \\ 0.01433, & 9.965 \times 10^{-4} < \frac{z}{E^{\frac{3}{10}}} \leq 2.9895 \times 10^{-2} \end{cases} \quad (6)$$

115

$$b = \begin{cases} 0.03803, & 0 < \frac{z}{E^{\frac{3}{10}}} \leq 9.965 \times 10^{-4} \\ 0.04293, & 9.965 \times 10^{-4} < \frac{z}{E^{\frac{3}{10}}} \leq 2.9895 \times 10^{-2} \end{cases} \quad (7)$$

For shallow cases, it is implicitly assumed that the explosion develops a cavity that extends through the entire water column and exposes the bed, and therefore its radius is larger than the water depth ($R > h$). In this instance, cavity radius is defined as:

$$120 \quad R = 0.03608 E^{\frac{1}{4}} . \quad (8)$$

The data calibrating these models include charges ranging from small (< 500 lb or $< 9.5 \times 10^8$ J) to a handful larger (< 9500 lb or $< 1.8 \times 10^{10}$ J) and further include a 23-KT nuclear test (Le Méhauté and Wang, 1996).

2.1.2 Volcanic context

For a volcanic case, illustrated in Fig. 1d, such explosions would occur on or near an edifice, meaning that the charge depth is
125 equivalent to the water depth at that point ($z = d$), therefore events that are capable of hazardous wave generation fit into the intermediate or shallow depth classes.

An approach first demonstrated by Torsvik et al. (2010) and expanded on by Ulvrová et al. (2014) and Paris and Ulvrová (2019) identifies use of the parabolic initial deformation (Eq. 1) and its compatibility with the shallow class radius definition (Eq. 8) when paired with the intermediate condition of Eqs. (4, 6). This is valid where the released explosion energy is estimated
130 from volcanic crater diameter C_D using the following empirical relationship by Sato and Taniguchi (1997):

$$E = 4.45 \times 10^6 C_D^{3.05} . \quad (9)$$

This method has recently been used for probabilistic hazard analysis of volcanogenic tsunamis at the Campi Flegrei caldera, Italy (Paris et al., 2019) and at Taal Lake, Philippines (Pakoksung et al., 2021). Some land studies suggest that the size of a volcanic crater cannot be assumed to directly reflect the size of the largest explosion causing it (Valentine and White, 2012),
135 so a further relation from Sato and Taniguchi (1997) relates the ejecta volume V with the released explosion energy:

$$E = 4.055 \times 10^6 V^{1.1} . \quad (10)$$

2.2 Numerical method

To compute simulations of the models described earlier, we use the open source CFD framework, Basilisk (Popinet, 2013). The software is widely used in studies involving multiphase problems from jet dynamics to viscoelastic and surface tension
140 investigations and includes several free-surface solvers with application to tsunamis, wavefield transformation and other hydrological areas (e.g. Lane et al., 2017; López-Herrera et al., 2019; Berny et al., 2020). The benefits of the Basilisk framework include OpenMP/MPI parallelism capability and an adaptive tree-based Cartesian grid with refinement algorithms that accept user-defined criteria. These allow appropriate resolution of areas of irregular shape or distant from one another within a domain with high scale separation while increasing the overall efficiency and speed of computation. (Popinet, 2011; van Hooff et al.,
145 2018)

2.2.1 Multilayer Scheme

The majority of the following work utilised the non-hydrostatic multilayer free-surface solver developed and described by Popinet (2020). A brief outline is given here. The scheme of n layers is a horizontally gridded and vertically discrete approximation of the incompressible Euler equations with a free-surface and gravity. It is described by the system:

$$150 \quad \partial_t h_k + \nabla \cdot (h\mathbf{u})_k = 0, \quad (11)$$

$$\partial_t (h\mathbf{u})_k + \nabla \cdot (h\mathbf{u}\mathbf{u})_k = -gh_k \nabla \eta - \nabla (h\phi)_k + [\phi \nabla z]_k, \quad (12)$$

$$\partial_t (hw)_k + \nabla \cdot (hw\mathbf{u})_k = -[\phi]_k, \quad (13)$$

155

$$\nabla \cdot (h\mathbf{u})_k + [w - \mathbf{u} \cdot \nabla z]_k = 0, \quad (14)$$

where, in the x - z reference frame, k is the layer index, h_k layer thickness, g gravitational acceleration, \mathbf{u}_k , w_k the horizontal and vertical velocity components, ϕ_k the non-hydrostatic pressure, η the free-surface height (sum of layer thicknesses and bathymetry height z_b), and

$$160 \quad z_{k+1/2} \equiv z_b + \sum_{l=0}^k h_l, \quad (15)$$

the height of layer interfaces.

Between them, the set expresses the evolution of layer thickness (Eq. 11), conservation of momentum (Eq. 12, 13), and conservation of volume/mass (Eq. 14). The framework allows the model to be built modularly, starting from the hydrostatic case where $\phi = 0$ and vertical momentum conservation (Eq. 13) is removed; these effectively become the generalised multilayer
 165 Saint-Venant (SV) or stacked shallow water equations. More components are added, for example, vertical remapping, adaptivity, non-hydrostatic and Keller box vertical projections, and a wave breaking method. The latter is implemented by introducing dissipation. This is handled by limiting the maximum vertical velocity by setting

$$w_k^{n+1} \leftarrow \text{sgn}(w_k^{n+1}) \min(|w_k^{n+1}|, b\sqrt{g|H|_\infty}) \quad (16)$$

where $\sqrt{g|H|_\infty}$ is the characteristic horizontal velocity scale of the wave and b is a specified breaking parameter smaller
 170 than one. *sgn* and *min* are sign and minimum functions respectively. Lastly, terrain is handled by looking up a pre-processed k -dimensional tree indexed database of heights and the model is able to discriminate and resolve areas of wetting and drying.

The scheme has been tested against numerous benchmark cases, including standing waves, sinusoidal wave propagation over a bar, the Tohoku tsunami of 2011 and its dispersive features, viscous hydraulic jumps, and breaking Stokes waves

(<http://basilisk.fr/src/layered/nh.h#usage>). Able to provide accurate solutions for surface gravity waves across a wide range
175 of scales, the multilayer scheme is ideal for resolving the evolution of an explosive source initial condition, resulting wave
propagation and shore run-up. (Popinet, 2020)

2.2.2 Other Schemes

Accompanying models used for validation and comparative purposes include a Volume-of-Fluid method (N-S/VOF) in the
same framework which solves the two-phase Navier-Stokes equations for interfacial flows, including variable density and
180 surface tension (Popinet, 2009, 2018), a solver for the shallow water or Saint Venant equations (SV), and finally another
for the Serre-Green-Naghdi equations (SGN), a Boussinesq higher order approximation for non-linear and weakly dispersive
flows (Popinet, 2015). Their inclusion is to support and inform evaluation of the multilayer scheme against well known and
commonly used methods.

In this work's context, the main discriminations between the schemes used are both the hydrostatic assumptions involved
185 and their resolution of vertical gradients such as the velocity profile: in the hydrostatic SV solver, a constant velocity profile
is assumed; the non-hydrostatic SGN equations represent a Boussinesq-type analytical approximation of the vertical structure;
the multilayer method resolves the vertical to n layers with capability to include non-hydrostatic terms; the N-S/VOF scheme
fully resolves the vertical as an additional dimension. The addition of having to fully solve a 2D slice through the vertical
versus 1D means the N-S/VOF has a larger domain to compute for the same region when considering water waves.

190 3 Laboratory-scale validation

To determine suitability of the numerical method for use in modelling a submarine disturbance, validation against a suitable
case study is required. Prins (1958) conducted a flume experiment investigating surface waves produced from an instanta-
neously raised or depressed column of water. This case is replicated using the multilayer scheme and, additionally, the N-
S/VOF, Saint-Venant and SGN schemes for full numerical comparison. Unless otherwise specified, all length units in this
195 section only are in imperial standard for consistency and ease of comparison with the Prins (1958) dataset.

The experimental set up involved a column of water at rest of extent L , height from equilibrium Q and in a one-foot wide
flume of water depth h ; these parameters were varied by steps: $L = 2, 1, 1/3$ ft; $Q = \pm 0.1, \pm 0.2, \pm 0.3$ ft; $h = 2.3, 0.5, 0.35, 0.2$ ft.
Figure 2a illustrates a schematic diagram of the setup. The height-adjusted column was held by a difference in air pressure and
released by means of a sliding door opened by hand in under 0.03 s. The resulting waves are measured at five gauges positioned
200 every 10 ft starting at 5 ft. A sloped 'wave absorber' dampened reflections from the flume end.

The numerical models to replicate this are relatively simple. For the multilayer, SGN and SV schemes, a 1D domain of
length 100 ft is initialised with the origin translated by L , the positive part of the domain with initial water depth $\eta_0 = h$,
and the negative with $\eta_0 = h + Q$. The displaced column is released instantaneously. While a reflective boundary condition
is applied to both ends, extending the positive domain far beyond the experimental case to prevent reflections has negligible
205 computational cost. In the multilayer simulations, 20 regularly spaced layers were used and the breaking parameter is set to

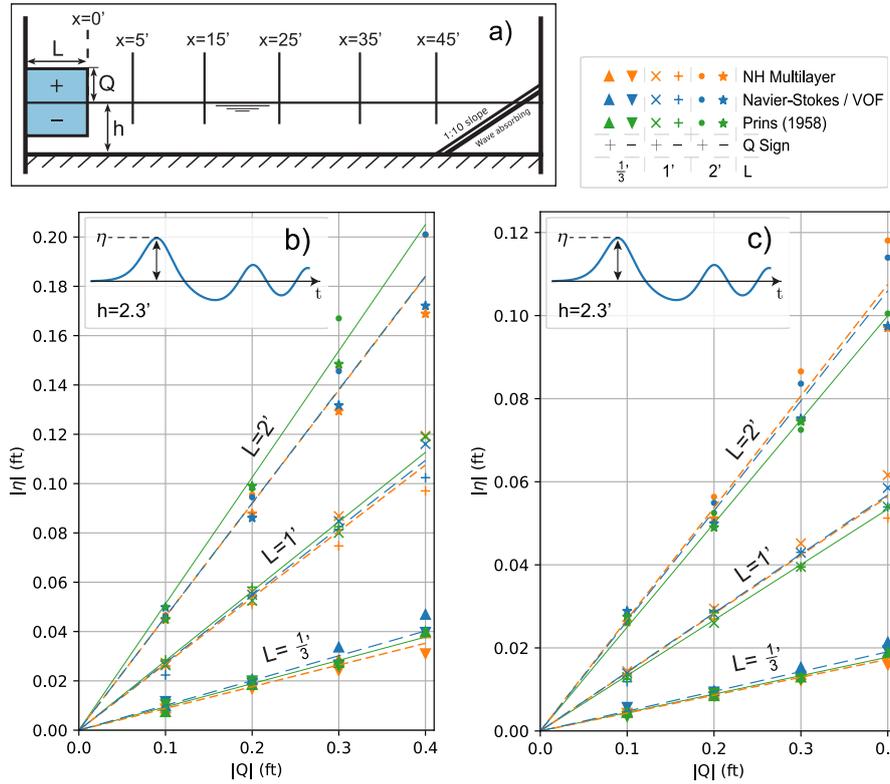

Figure 2. (a) Schematic diagram of Prins (1958) experimental set up, with gauge locations and the initial disturbance. (b) η - Q relation for first arrival crest or trough amplitude at $x = 5$ feet. (c) η - Q relation for first arrival crest or trough amplitude at $x = 25$ feet. Regression lines through origin are plotted for each L -model combination.

$b = 0.38$. The N-S/VOF scheme's geometry is built similarly but in two-dimensional vertical (2DV), such that the origin is translated by $(-L, -h)$. Material properties (i.e. density, dynamic viscosity, surface tension coefficient) of the two phases are also specified, as is gravitational acceleration. For all presented cases, unless otherwise specified, the maximum level in the grid is 14, which, for a domain of length 100 ft, gives a maximum horizontal mesh resolution of 6.1×10^{-3} ft.

210 3.1 Model comparison

Figures 2b-c and 3 present direct comparisons between the numerical models and the published experimental data. The N-S/VOF and multilayer approaches each conform well when varying L and Q at $h = 2.3$ ft and generally confirm the experimental findings for initial wave amplitude throughout the flume range. Some experimental data points at high Q are missing; however, the model output highlights a slight divergence in first arrival amplitudes between +ve (higher) and -ve (lower) disturbances at larger Q .

215

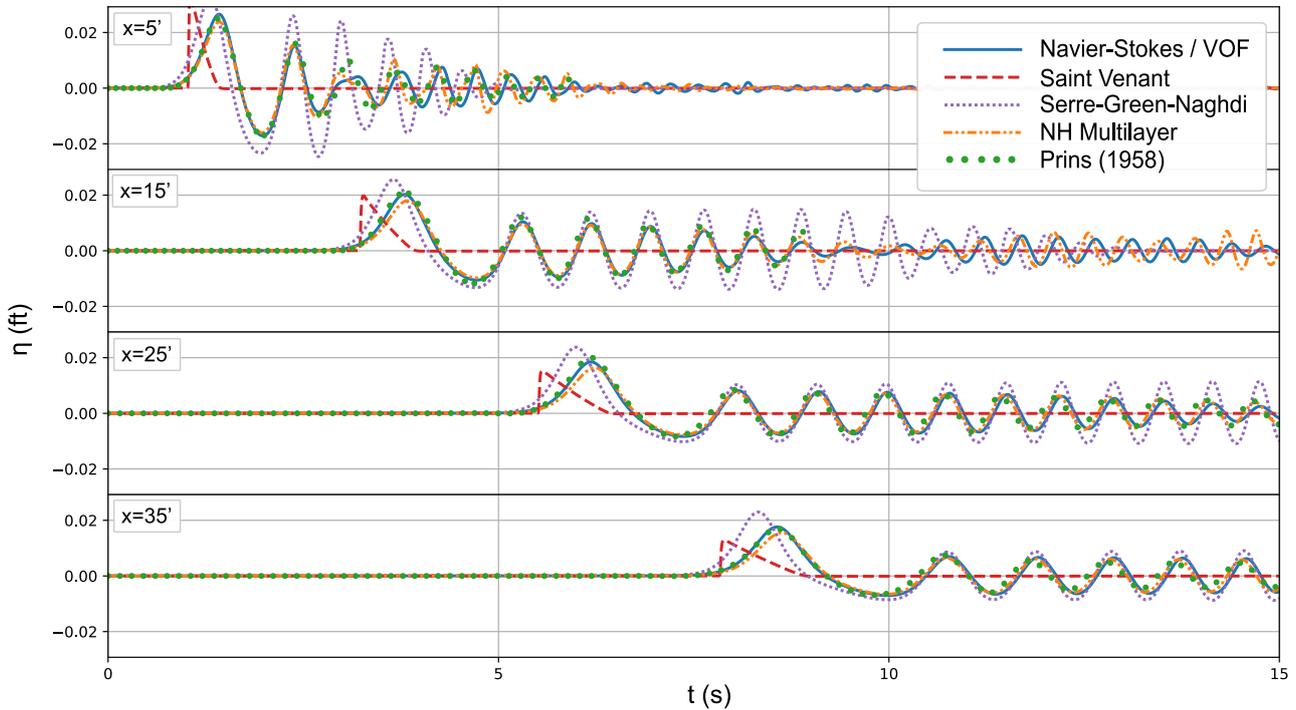

Figure 3. Model comparison of time series of waves produced by a disturbance of $Q = 0.3$, $L = \frac{1}{3}$ when $h = 0.5$.

Figure 3 plots the full time series for a mid-range parameter run and includes solutions from the non-linear shallow water (SV) and Boussinesq-type (SGN) schemes. While the SV solution exhibits a good approximation of the phase velocity of the initial wave (4.39 ft s^{-1}), it is, unsurprisingly, unable to resolve any of the trailing wave field. The SGN scheme resolves this element at far-field well; however, it often overestimates initial wave amplitude and the overall dispersivity. The multilayer scheme is shown to be very accurate compared to the N-S/VOF result and the experimental trace and reinforces the good fit found in Fig. 2. This suggests that the scheme faithfully replicates the process of a collapsing water column or infilling of a uniform depth and the associated wave generation, along with reflections from behind the initial disturbance.

The generation process is shown in Figure 4 which illustrates how the four models resolve an initial disturbance and reveals significant variations in handling the vertically critical jump in the first half-second. The SV source quickly develops into the classic steep-fronted crest often seen in dam-break problems where the amplitude is proportional to the initial disturbance height. The higher-order SGN scheme is able to resolve frequency dispersion and therefore handles the source development better; however, there are clear exaggerations such as at 0.05 s near $x = -L$ where, intriguingly, the water height temporarily increases above Q . Qualitative comparison between the development of both the N-S and multilayer solutions show a high consistency across all stages involving the collapse of initial disturbance and breaking of the generated wave. Notable variation includes the varying maximum amplitude of the resultant wave's intermediate stage and any bubbles/droplets produced, demonstrating the restriction of a single value for function on the 1D multilayer scheme not present on a 2D multiphase VOF

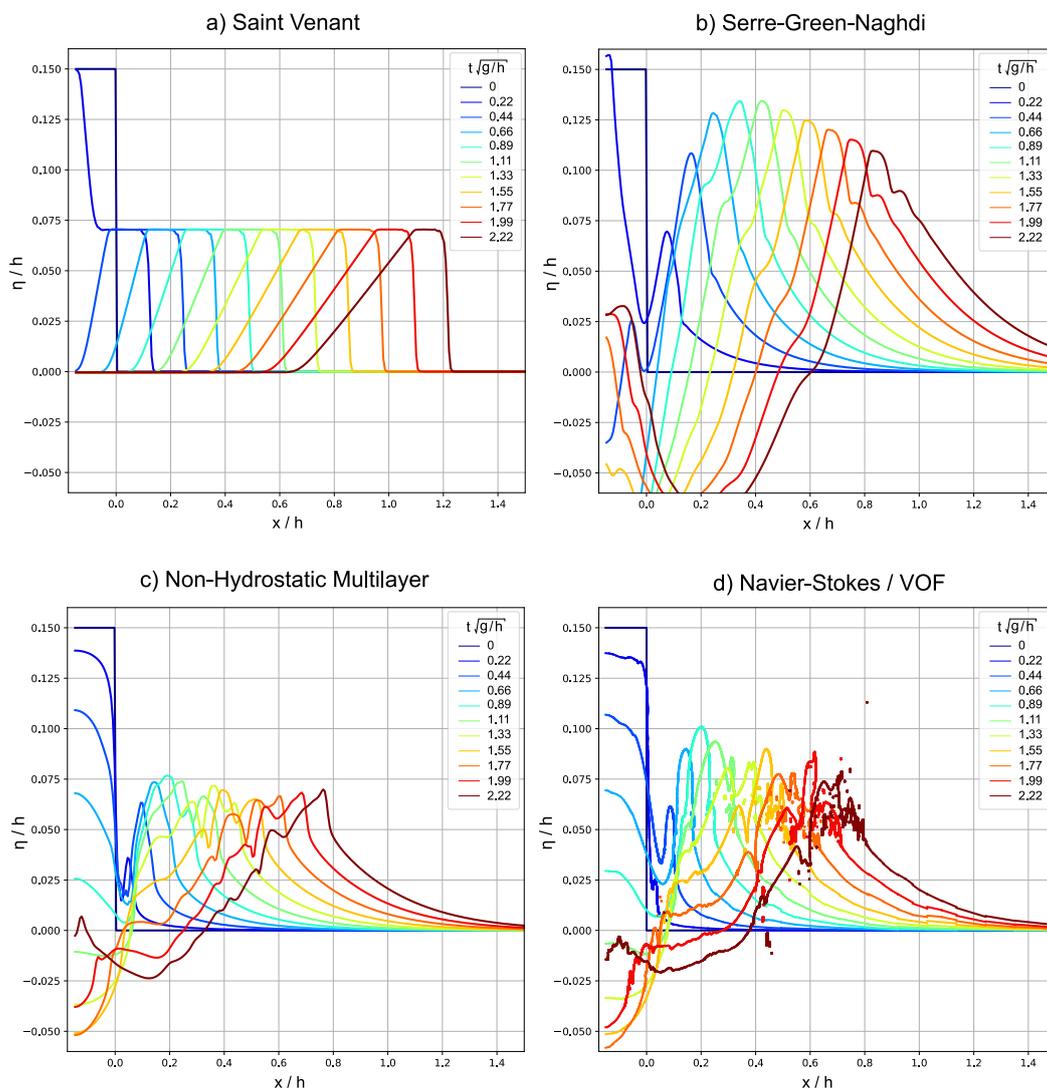

Figure 4. Comparison of numerical solutions for the disturbance collapse from initialisation to $t = 0.5$ seconds. Distances are normalised with water depth h and are vertically exaggerated.

235 solver. Also, note graphical artefacts on free-surface height at the leading gradient in the N-S solution which occur at coarser regions of the adaptive grid. Despite these minor variations, it is clear that the multilayer model has greater validity in application to this case than either of the single layer models and is remarkably consistent with the physical experiment as well as the directly simulated approach.

Finally, Table 1 presents performance metrics for the numerical schemes across three maximum refinement levels for an example run case. All were performed with OpenMP parallelism on eight CPU cores. The multilayer scheme fits between the SV and SGN methods in terms of wall time processing and offers a vast improvement in computational efficiency compared

Table 1. Table of numerical model performance for run $h = 2.3'$, $L = 0.2'$, $Q = 0.3'$. Runtime in seconds and speed in $points \times timesteps \times layers / sec / cores$.

Scheme	Level	Runtime	# Timesteps	Speed
Saint Venant	13	93	44049	477513
	14	231	88167	478551
	15	1022	176414	496146
Serre-Green-Naghdi	13	215	44077	209928
	14	825	88779	220389
	15	2444	179392	300650
Multilayer (10 layers)	13	125	4407	358552
	14	477	7017	301021
	15	1763	11392	264652
Multilayer (20 layers)	13	379	5183	279903
	14	957	11874	507919
	15	2935	16123	450039
Navier-Stokes / VOF	13	4174	4276	15834
	14	22751	12686	14840
	15	126279	27859	13705

with the N-S/VOF solver considering result similarity. It also demonstrates superior speed than the dispersive SGN method, primarily due to the computation time required to solve the higher order approximation.

3.2 Wavefield classification

All simulated cases are plotted in Figure 5 by the size of initial disturbance relative to water depth using a nonlinearity parameter $\frac{|Q|}{h}$ against a dispersivity parameter k^*h where $k^* = \frac{2\pi}{2L}$. Six additional simulations were run outside of the original experimental parameter space to expand the model dataset reach. As done by Prins (1958), the $+Q$ runs are categorised into groups with similar wavefield characteristics starting with strong oscillatory properties (blue) where $k^*h > 10\frac{|Q|}{h}$, tending through increasingly solitary wave properties (purple and green) once $k^*h \leq 10\frac{|Q|}{h}$ until a succession of diminishing amplitude solitary waves result where $k^*h < \frac{|Q|}{h}$ (orange). Beyond this region, the initially generated bore survives far enough down the numerical flume before it would likely separate (black). For the $-Q$ domain, all resultant wave fields were similar except for the length of initial trough relative to the following periodic wave group. This ratio initially remains approximately unity in the same region as the $+Q$ oscillatory character group and grows larger towards higher $\frac{|Q|}{h}$ and lower k^*h .

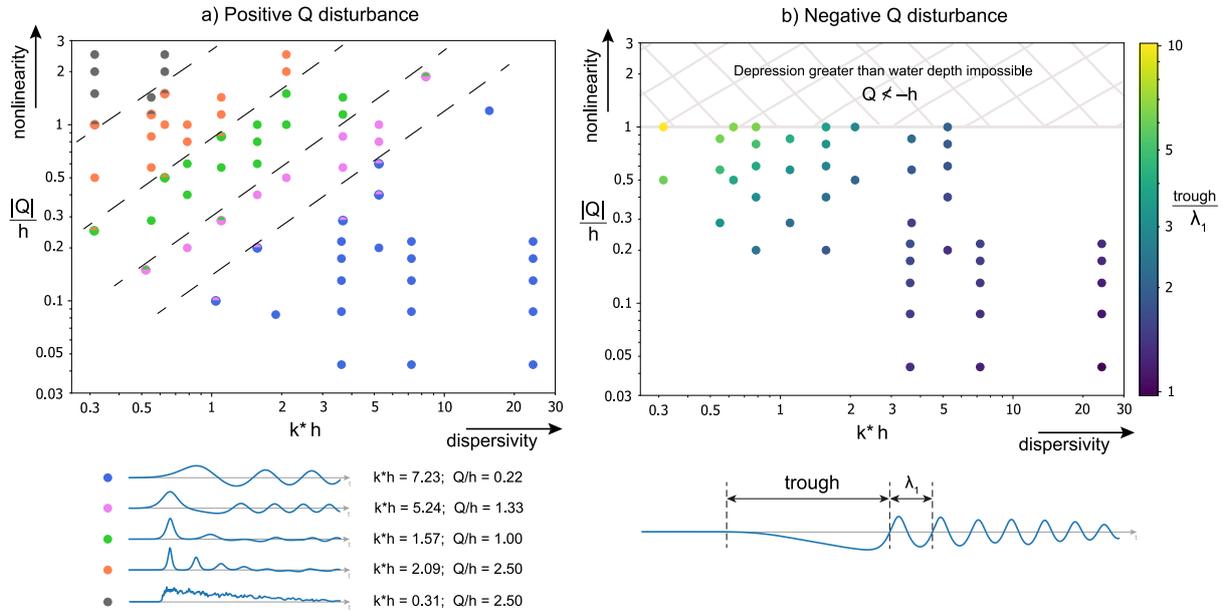

Figure 5. Plots of numerical runs by dispersivity parameter against nonlinearity parameter. All data from time series at $x = 35$ feet. (a) Classification of $+Q$ disturbances by their generated wave field. Legend underneath is illustrated by plots of example runs. (b) $-Q$ disturbances coloured by the ratio of initial trough length divided by the following wavelength.

Results of the $+Q$ disturbance (Fig. 5a) corroborate the experimental wave field descriptions of Prins (1958), including the transition of an oscillatory field through to solitary initial waves. Bore formations in the first stages were also observed during the experiment, those of which last a considerable length of the flume match model results. Accounting for tolerance in qualitative descriptions, groups match closely and the additional results beyond experimental scope further confirm these definitions in the studied range. Such an analysis of the $-Q$ part was not attempted in the original research; however, effort in this area can be made with the numerical results (Fig. 5b). The length ratio of initial trough to the following oscillatory waves increases with higher Q/h and lower k^*h . This matches the trend towards solitary characteristics with $+Q$. Intriguingly, this pattern holds regardless of the length ratio that defines the initial disturbance (i.e. Q/L).

In suitable replication of the experimental findings, the present numerical scheme is seen to be fit for generating accurate waves from initialised disturbances and modelling their near-field propagation across a significant regime range where non-linear and dispersive effects may be prevalent. The method also demonstrates suitability for further investigations either beyond or in complement, such as to widen parameter spaces with relatively low computational expense.

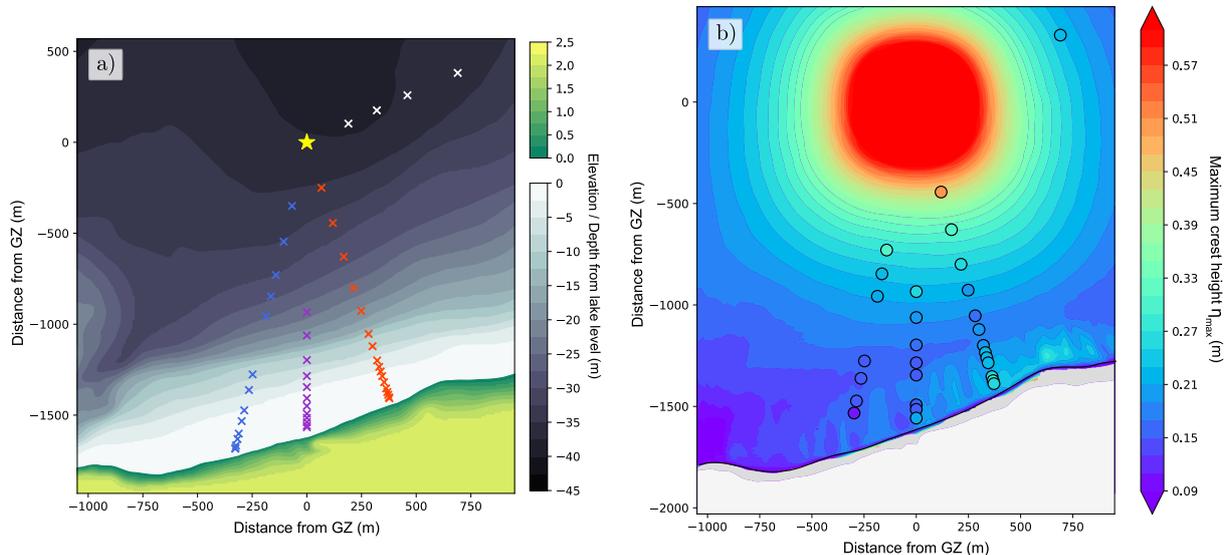

Figure 6. (a) Setting of test series on the south of Mono lake with bathymetry and near shore terrain elevation. Yellow star marks ground zero (GZ), crosses mark gauge locations. Gauge radials are coloured by; red (one), purple (two), blue (three), white (four). (b) Numerical results of maximum crest amplitude for Shot 3 overlaid by observed maximum crest amplitudes at gauge locations.

4 Field-scale validation

The next stage is to assess use of the underwater explosion models of Sect. 2.1 within the numerical scheme. To do this, we
265 utilise datasets from the Mono Lake test series in 1965, conducted by the Waterways Experiment Station, and documented by
Walter (1966); Wallace and Baird (1968); Whalin et al. (1970); Pinkston et al. (1970). This was one of the largest chemical
explosive test series designed to investigate subsequent water wave generation and shore effects. A series of ten approximately
9,250 lb (~4,196 kg) spherical TNT charges were detonated off the south shore of Mono Lake, California. The test area is
illustrated in Figure 6a, and this also shows the location of wave gauges arranged in four radials directed away from ground
270 zero (GZ), along with contoured terrain. GZ was located at a site of approximate water depth $h = 39$ m.

The numerical model was built with the multilayer scheme, including a digital elevation model of the Mono Lake bathymetry
by Raumann et al. (2002), where the lake water level was set at 1945.7 m which left approximately 2 m of shore topography
surrounding. Numerical gauges were defined at distances from GZ described in the experiment.

Data from shots 3 and 9 are chosen to test the numerical method against, as these experiments resulted in the highest quality
275 data and were detonated at different depths, $z_3 = 0.427$ m and $z_9 = 6.401$ m. The initialised disturbance takes the form of
Eq. (2) and, for these charges, $D = 6.1$ therefore the depth is classified as intermediate. The resultant values using Eqs. (4-7)
are given in Table 2. Considering doubts regarding the charges raised in the report of Walter (1966), additional lower yield
simulations were added.

Table 2. Numerical values used in Mono Lake models.

Shot	Energy E ($\times 10^{10}$ J)	Depth z (m)	$\frac{z}{E^{1/3}}$	a	b	η_c (m)	R (m)
3	1.755	0.427	3.61×10^{-4}	0.02913	0.03803	8.36	44.90
(75% Yield) 3	1.317	0.427	3.93×10^{-4}	0.02913	0.03803	7.67	41.18
9	1.739	6.401	5.42×10^{-3}	0.01433	0.04293	4.12	50.83
(75% Yield) 9	1.304	6.401	5.91×10^{-3}	0.01433	0.04293	3.85	46.62

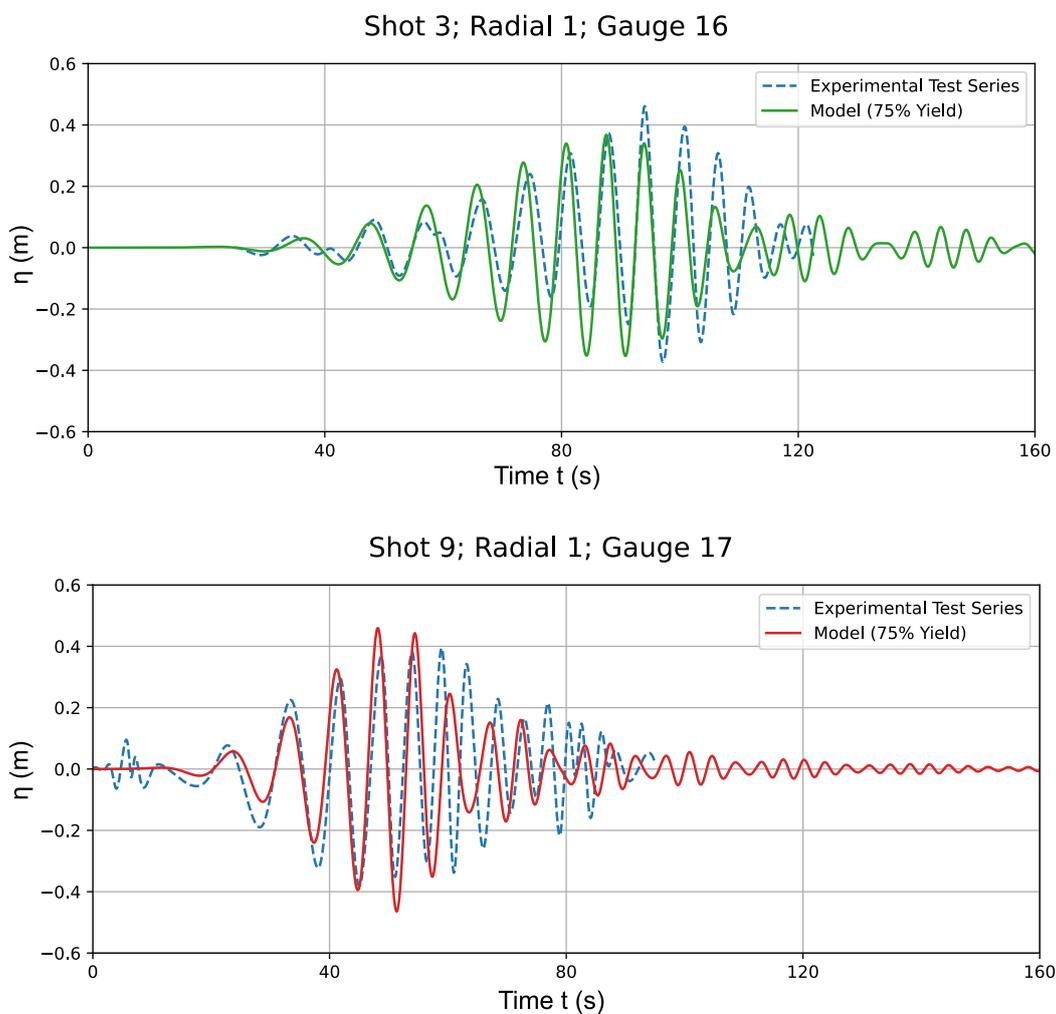

Figure 7. Maximum crest amplitudes at gauge locations for full yield model, fitted model, and experimental tests.

4.1 Generated wavefield

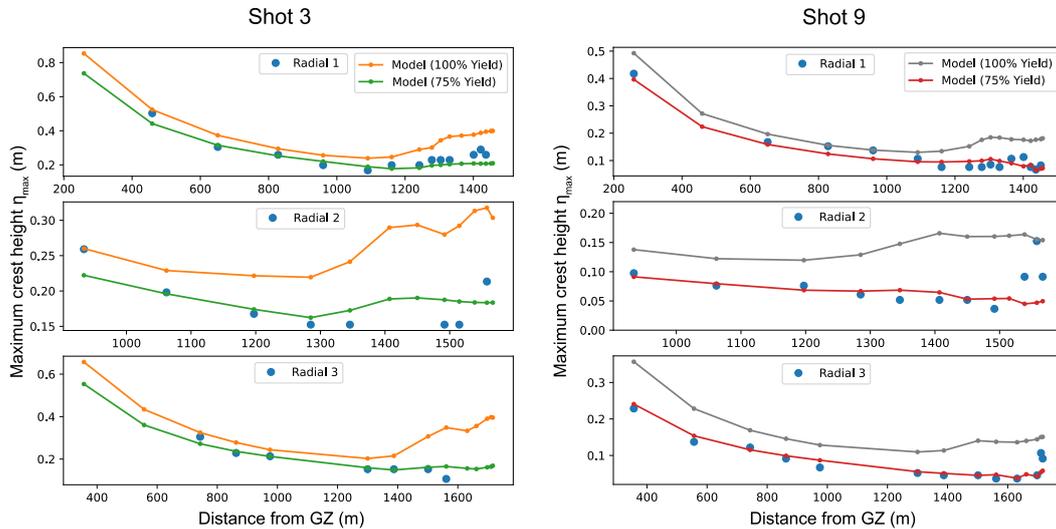

Figure 8. Time series comparison at closest gauge to GZ for both considered shots.

280 Figure 6b illustrates the generated field of maximum crest amplitudes from the numerical simulation paired with data transcribed from the experimental gauge records for Shot 3. This, and all other included simulations, are presented quantitatively in Figure 7 to show maximum crest amplitudes for all gauges. The maximum amplitude of the initial envelope decreases with radial distance from GZ as expected, matching experimental observations. Shoaling is most pronounced at the closest incident shoreline, in the region 500 m east of Radial 1, and becomes far less significant with distance as seen on the western shore of the region. Maximum crest amplitudes at gauge locations follow similar patterns in all runs; however, the higher energy yield simulations produce greater amplitudes (additional 0.11–0.05 m) throughout and experience more significant shoaling in all shallow areas. The lower yield simulations are a closer match to experimental observations for both shots, especially in shallow zones; however, the experimental data has noticeably greater variation at shore.

290 The experimental gauge time series at locations closest to GZ are plotted alongside the lower yield model traces in Figure 8 and are useful to compare the phase arrival times and the initial development of the wave train. For both simulations, the first arriving phases match the experimental record very well, with the exception of minor noise immediately following detonation in Shot 9 which is likely to be shock or debris related. The time of maximum envelope amplitude also conforms well, where the differences are 9 and 7 seconds for Shots 3 and 9 respectively. The latter part of the initial wave group maintains higher amplitudes in the experimental trace for both records, whereas the envelope decay is sooner in the numerical model. Shot 3 295 also seems to exhibit a positive amplitude shift in the early part of the experimental envelope.

4.2 Model implications

While the models used fit the experimental results and trends well overall, it is significant that the lower yield data is a much better fit. In reports following the test series (e.g. Whalin et al. (1970)) it is noted that, except for two charges, all shots delivered

below average expected maximum crest amplitudes as predicted by earlier experimentation, particularly the deep water shots. A
300 further similar deep test at Mono Lake in the following year delivered much greater amplitude waves in line with expectations,
leading to the suggestion by Wallace and Baird (1968) that, beyond scaling effects or measurement issues, the charges used in
the series may have been faulty and delivered a lower yield. This is supported by the numerical data as, when energy is reduced,
the maximum crest amplitudes can be accurately predicted in addition to the resultant early wave group and individual phases.

Many data from the experimental series were unreported or discarded following the series due to various problems, including
305 excess noise generated from the explosion itself or wind-driven waves and are thus missing from comparisons in this work.
Instrumental issues meant gauges near the shore were often unable to be acceptably calibrated for amplitude. Many experienced
+ve noise due to wave breaking and bores, responsible for some spikes in measurements; however, these were kept for reliable
arrival times and periods. (Wallace and Baird, 1968)

Despite the experimental challenges, the multilayer scheme is shown to be excellent at resolving the initialised disturbance
310 into a wave field very consistent with that generated by an intermediate depth submarine explosion. With the capability to
accurately propagate such a source in the relatively deep near-field through to the shore, it demonstrates suitability to model
such events at these scales. However, this test did not contain any shallow depth underwater explosion tests, for which there
are no case examples at this scale.

5 Taupō Scenario

315 Lake Taupō is New Zealand's largest freshwater lake of area approximately 616 km². It lies in the southern section of the Taupō
Volcanic Zone and conceals most vent sites and features of Taupō volcano; the lake itself is the result of caldera collapse after
the c. 25.5 ka Oruanui supereruption, with modifications in following events. The lake has experienced numerous volcanic
episodes post-Oruanui, with some 21 events occurring from 7.05-1.8 ka, including the ~ 232 CE Taupō eruption which is
globally one of the most powerful eruptions in the Holocene. (Barker et al., 2020)

320 Figure 9 illustrates the lake bathymetry and surrounding terrain accompanied by geological features and settlement locations.
The lake is fed by multiple rivers and notably from Tongariro hydroelectric power station via the Tokaanu Tailrace Canal. The
sole outflow is the Waikato River, controlled by gates at the largest settlement on the lake, Taupō, which leads to numerous
further hydroelectric dams downstream. Surrounded by abundant geothermal resources, strong trout fishing and agricultural
industries, the area also boasts plentiful tourism opportunities, hosting over one million tourists each year, and is of great
325 cultural significance accompanied by the surrounding land.

In building a model representing an example tsunamigenic explosive eruption in Lake Taupō, it was required to build a
terrain dataset by combining a bathymetric model of the lake (Rowe et al., 2002) with an elevation model generated using
LiDAR datasets from the Waikato Regional Council which cover the entire foreshore. The limiting resolution of the resultant
digital terrain model is that of the bathymetric model (10 m), therefore the simulations were performed at a grid refinement
330 level of 11 resulting in a horizontal resolution of 16 m.

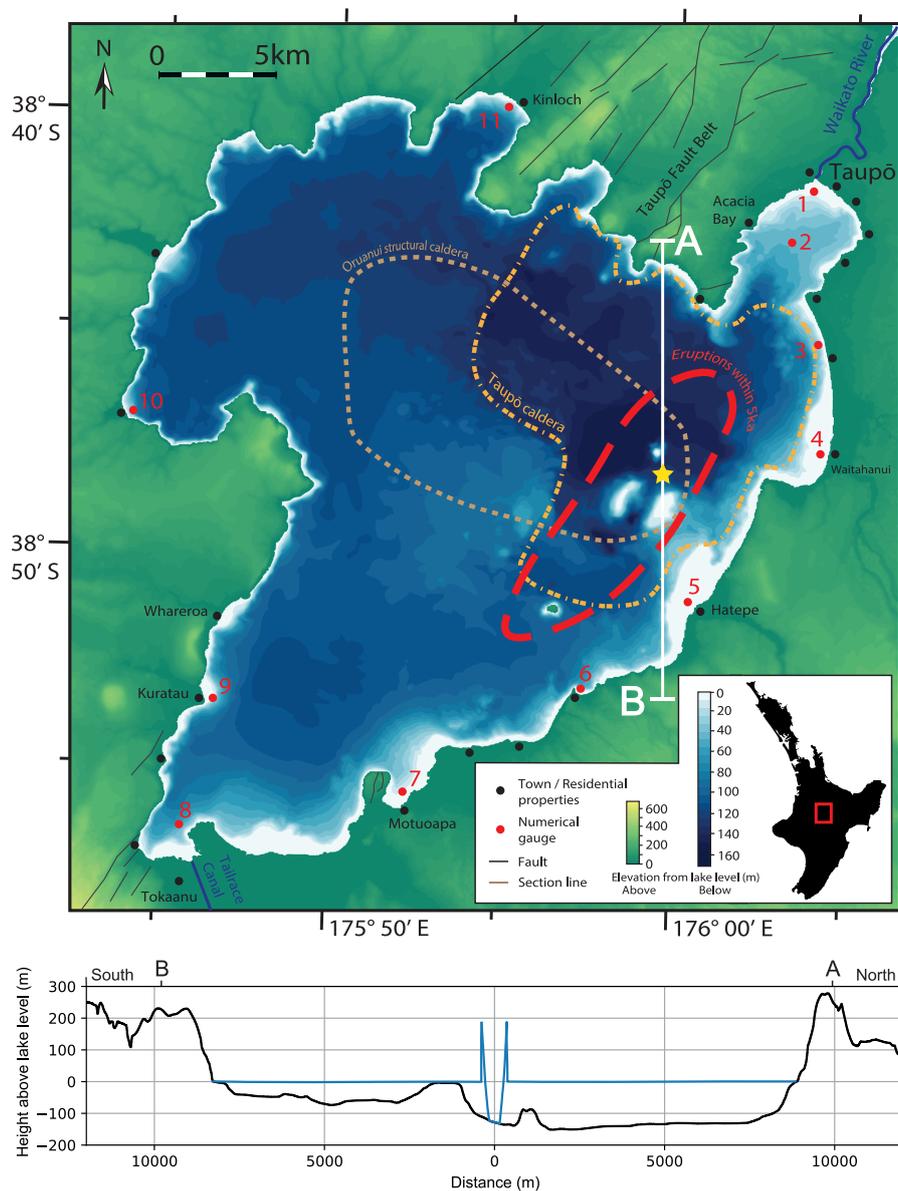

Figure 9. Lake Taupō setting with lake bathymetry, surrounding terrain, marked fault zones and building areas. Also highlighted are the caldera zones of the Hatepe / Taupō eruption and the Oruanui supereruption. The red dashed area encloses area of activity within 5 ka. The star indicates simulated eruption location at -38.804° S 175.990° E. Below is a cross-sectional profile of high run initial condition with terrain elevation in a N-S direction in line with source location.

The eruption site chosen is within the region where most Holocene vents are located (Barker et al., 2020) and, for this example, two simulations are run corresponding to the range of most eruptions occurring during this period, excepting three larger episodes. The estimated ejecta volume V is between $0.04 - 0.4 \text{ km}^3$ (Wilson, 1993) and, using Eqs. (9-10), the equivalent

Table 3. Numerical values used in Lake Taupō models.

Run	Ejecta volume V (km^3)	Energy E (J)	Depth z (m)	η_c (m)	R (m)
High	0.4	1.13×10^{16}	128	207.5	372.0
Low	0.04	9.02×10^{14}	128	113.1	198.7

explosive energy can be obtained. At this depth ($h = 128$), all events of $V > 0.0074 \text{ km}^3$ yield $D < 1$, falling into the shallow
335 depth class. Following the rest of the method in Sect. 2.1.2, model parameters for both models are detailed in Table 3. The
resulting models were run for 1000 seconds of simulated time. A further simulation of the scenario was performed with the
Saint Venant scheme with identical terrain and model geometry for comparison.

5.1 Generated wavefield and shoreline impacts

Figure 10 describes the travel times and maximum crest amplitudes for the larger simulation. As demonstrated earlier, a
340 succession of waves radially propagate outwards from the centre of the explosion. The initial phase velocity typically starts
from $40 - 45 \text{ ms}^{-1}$ until they heavily interact with the nearby Horomatangi Reefs. Due to the limited area of the lake, all of
the shoreline experiences wave phenomena from these sources within 15 minutes, with only a slight increase of arrival times
for the weaker run, due to a slightly shorter period group generated by the smaller source. Long wavelength oscillations (up to
seiche) linger throughout the lake beyond simulation length (17 min).

345 The initial wave at all locations is a crest, reflecting the positive amplitude lip of the initial condition. Earliest arrivals at
shore occur about the closest point east of the source at 3 min, after which arrival time generally scales with radial distance
excepting for areas with extended shallow zones. The highest wave heights incident to the shore are, unsurprisingly, located
nearest the event on neighbouring eastern and northern shores where crest amplitudes reach over 4 m. The lowest are found in
the further area of the south-west besides Gauge 8 (Tokaanu) and in sheltered parts away from direct paths such as by Gauges
350 10 and 11 (Kinlock). Taupō township is relatively sheltered compared to the surrounding shoreline due to shielding from the
lake morphology.

Figure 11 presents numerical gauge time series for both runs. Throughout the domain, the high ejecta volume run returns
significantly higher maximum crest amplitudes than the low run. Wave periods vary from $\sim 65 \text{ s}$ early in group to $\sim 15 \text{ s}$
towards its end, 10 min later. The first arrival is generally the longest period wave but rarely the greatest amplitude at the gauge
355 locations. Gauge 4 and 5, positioned in shallow zones near the eruption, initially record bores of amplitude 1.6 m and 3.5 m
respectively in the high run. While phase velocities are very similar between runs, the generated group velocity is slower for
the low run. This is best seen in Gauges 2, 3 and 6 which are positioned with relatively unobstructed direct paths from the
source.

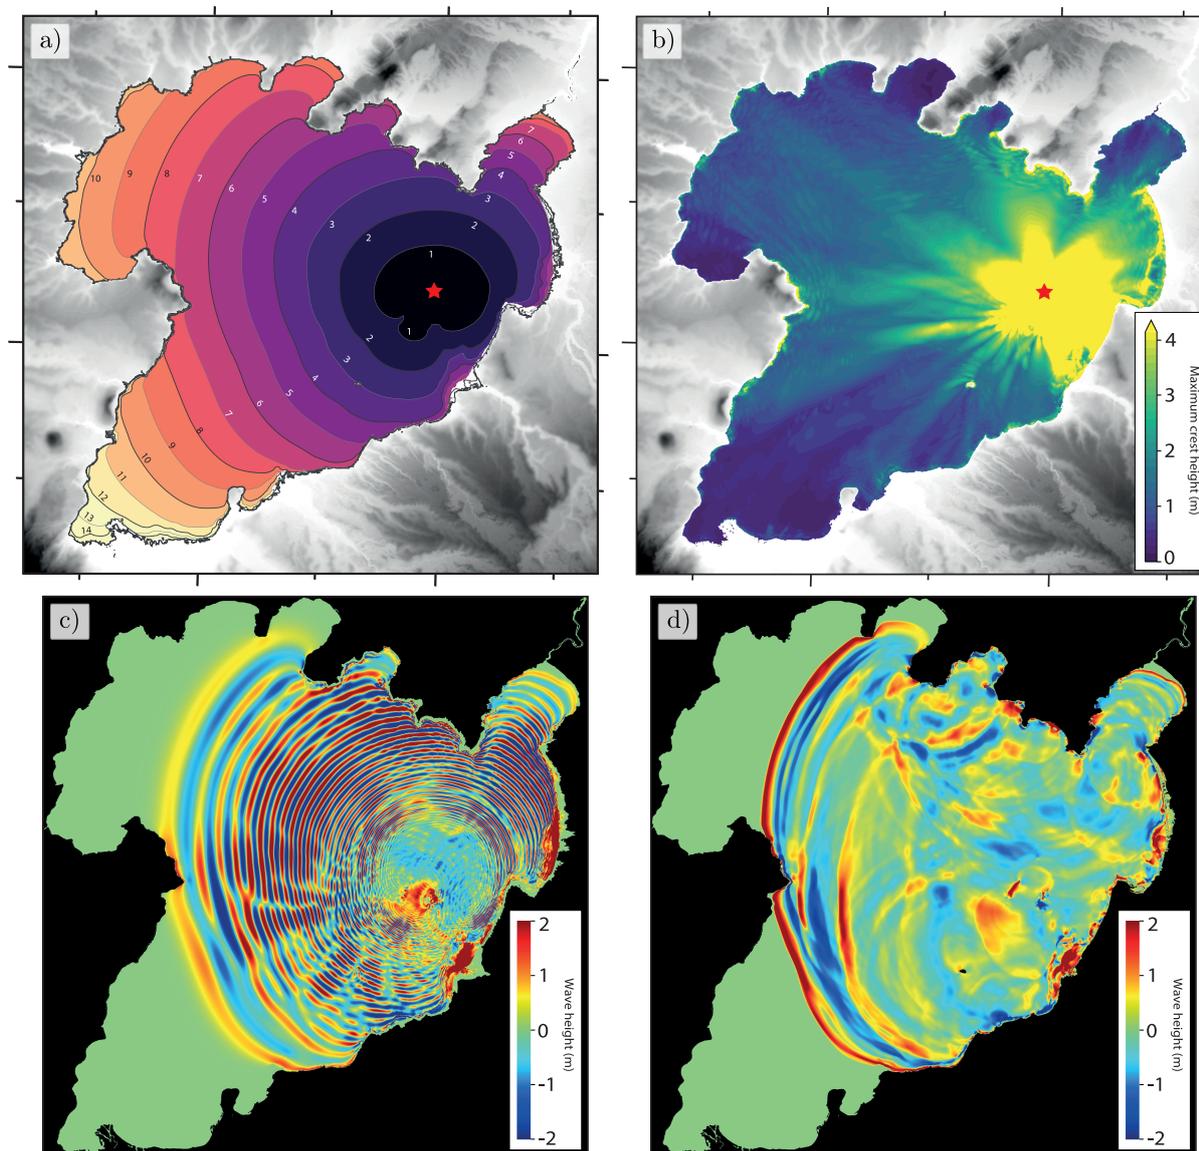

Figure 10. Multilayer simulation of potential volcanic explosion in Lake Taupō. (a) First arrival travel times in minutes. (b) Field of maximum crest amplitudes. (c) Snapshot of wave amplitudes at $t = 8$ minutes. (d) Equivalent of (c) but using the Saint Venant scheme.

The resultant waveforms produced from this source are similar to those in Sect. 3 and indicate that the multilayer scheme is suitable for modelling their propagation. The combinations and transformations between highly dispersive, non-linear and shallow waves across the whole domain require treatment that would likely lack validity if only modelled using the shallow water equations. A snapshot of this comparison is illustrated in Fig. 10c-d, and clearly shows the heavy dispersion modelled in the multilayer scheme which is missing in the Saint Venant method. The benefit of non-hydrostatic pressure terms and

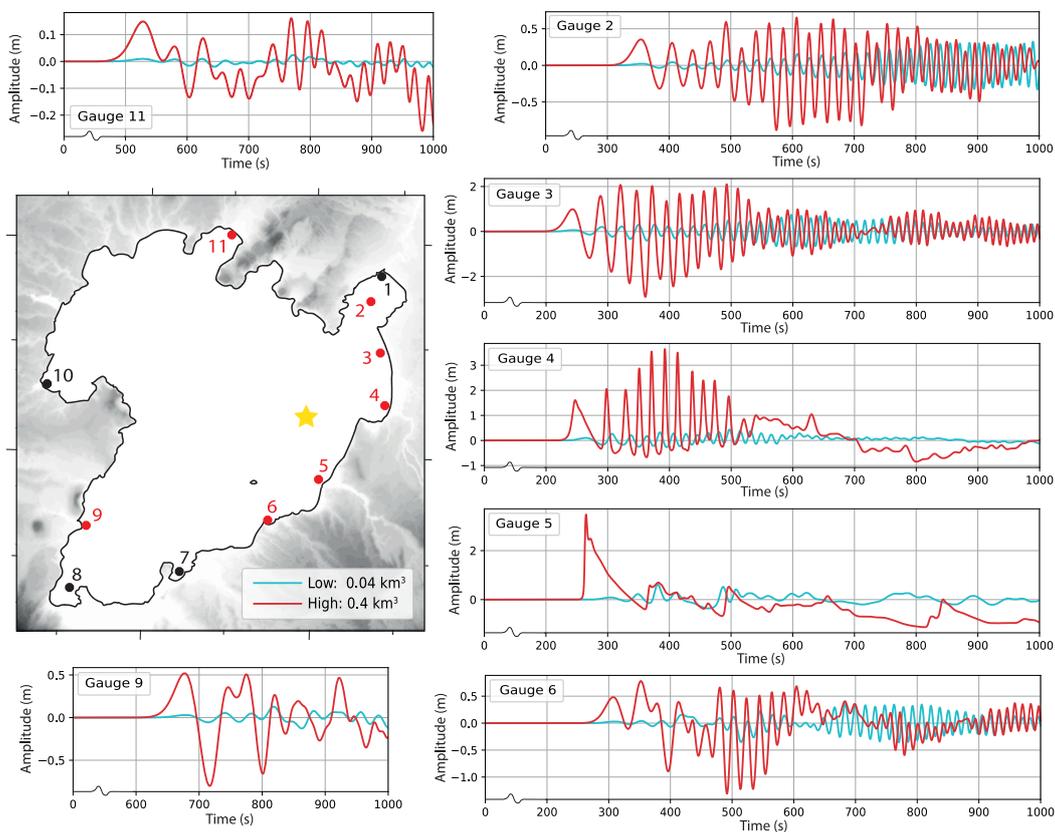

Figure 11. Time series for numerical gauges with gauge locations highlighted in red on inset map including ground zero signified by the star. The high volume (0.4 km^3) run is in red, and low volume (0.04 km^3) run in light blue. Time series have varying y-axis scales and truncated x-axes.

numerical wave breaking therefore adds robustness to the near-shore solution for this type of source. Notably, the explosion
365 model prescribes an initial condition that intersects the bathymetry in the present high ejecta volume case, resulting in additional
mass added via the volume of lip surrounding the cavity. It would be expected that a higher energy explosion in similarly
shallow water depth would transmit less energy into the water and towards wave-making. To rectify mass imbalance, the lip
height could be lowered to better match the excavated volume; however, no alteration to the explosion model is made in present
work.

370 5.2 Hazard implications

These preliminary results suggest many potential implications for wave hazard from explosive subaqueous eruptions. If an
eruption of sufficient magnitude at Lake Taupō produces an initial explosion there is clearly a threat posed to nearby shores.
As with most lacustrine tsunami hazards, there is minimal time from source to shore impact; no possible warning system

would ever be able to respond to an eruption with sufficient speed. Instead, resilience should come from preparation for events
375 including disaster management and exclusion zone planning by local authorities, with ongoing monitoring of the volcanic
system such as seismicity, ground deformation, changes to the geothermal system, and geophysical imaging.

The underlying caldera has frequently experienced minor unrest (Potter et al., 2015), and current thought suggests eruption
probabilities in the near-term are not negligible; for instance, an event of magnitude at least in the upper range considered
here (0.2 km^3) is estimated to have 5% probability within 100 years (Bebbington, 2020). Taupō volcano can produce far
380 greater magnitude events than considered here, including the aforementioned CE 232 Taupō eruption (24 km^3) and the c. 25.5
ka Oruanui supereruption ($> 1100 \text{ km}^3$). Events of such magnitude undoubtedly carry wide ranging hazards well beyond the
lake's proximity, and even those towards the lower end of the scale could produce numerous volcanic dangers, including ashfall
and pyroclastic density currents. Therefore, an additional complexity of modelling the suite of hazards posed by submarine
volcanism will be to determine the relative weight each source component possesses with events of varying location and
385 magnitude.

Only a brief effort is made at present on modelling this hazard as an example application of the multilayer numerical scheme
and its benefits on resolving the resultant wavefield and significant outputs. Further work should incorporate this or similar
numerical methods into conditional probabilistic hazard models for assessing the relative significance of this tsunami source
mechanism, using wide parameter space comprising all likely sublacustrine eruption locations and magnitudes. Such a model
390 would be able to take advantage of this scheme's broad wave regime validity and computational efficiency, potentially able to
investigate inundation in detail at various points onshore with, for instance, building data or similar additional model layers.

6 Conclusions

The non-hydrostatic multilayer scheme used in this paper has been shown to accurately replicate the collapse of various initial
disturbances into a resultant wavefield that exhibits varying degrees of non-linear properties and frequency dispersion. By
395 capturing some depth aspects of the model without fully resolving the vertical, it is superior in accuracy to shallow water
equation based schemes while being far more computationally efficient than direct numerical methods. The method was used
to verify experimental results of positive amplitude disturbance wave generation and probe their validity at a wider parameter
range while also further investigating negative amplitude disturbances, revealing extension of the leading trough relative to
trailing oscillations for larger size disturbances and smaller water depths.

400 Initialisations of wave generation via underwater explosion were tested for use with the multilayer scheme by simulating
detonations of explosives as done in a US Army test series at Mono Lake. Including consideration of uncertainty with experi-
mental data, the combination of empirically derived underwater explosion model and the numerical scheme was able to capture
the significant elements of the generated waves as measured experimentally and help validate use of the underlying empirical
relations.

405 These were then used to simulate a volcanic explosion under Lake Taupō based on estimated eruptive energy by ejecta
volume. Implications for tsunami hazard under lakes are suggested for small to medium magnitude phreatomagmatic eruptions,

with data revealing areas of varying exposure to hazardous waves, of above 4 m near source to 0.3 m in the most sheltered areas, and waves reaching throughout the lake within 15 minutes. A probabilistic investigation is required to assess the full range of possible scenarios at this location, including eruption geometry and size, while potentially considering further complexity, such as any syneruptive variation in initial conditions. This will help resolve the significance of this hazard source compared to alternative tsunamigenic sources and volcanic hazards across varying magnitudes of eruption. Further work could include numerical investigation of non-detonation eruptions involving sustained jetting.

Video supplement. Animation of the free-surface elevation of the high volume Lake Taupō multilayer run is available from the TIB AV-Portal at <https://doi.org/10.5446/52050> and for high quality on request.
