**Abstract.** The prediction of debris flows is relevant because this type of natural hazard can pose a threat to humans and infrastructure. Debris-flow (and landslide) early warning systems often rely on rainfall intensity-duration (ID) thresholds. Multiple competing methods exist for the determination of such ID thresholds but have not been objectively and thoroughly compared at multiple scales, and a validation and uncertainty assessment is often missing in their formulation. As a consequence, updating, 5 interpreting, generalizing and comparing rainfall thresholds is challenging. Using a 17-year record of rainfall and 67 debris flows in a Swiss Alpine catchment (Illgraben), we determined ID thresholds and associated uncertainties as a function of record duration. Furthermore, we compared two methods for rainfall definition based on linear regression and/or true skill statistic maximization. The main difference between these approaches and the well-known frequentist method is that non-triggering rainfall events were also considered for obtaining ID-threshold parameters. Depending on the method applied, the ID-threshold 10 parameters and their uncertainties differed significantly. We found that 25 debris flows are sufficient to constrain uncertainties in ID-threshold parameters to  $\pm 30\%$  for our study site. We further demonstrated the change in predictive performance of the two methods if a regional landslide data set with a regional rainfall product was used instead of a local one with local rainfall measurements. Hence, an important finding is that the ideal method for ID threshold determination depends on the available 15 landslide and rainfall data sets. Furthermore, for the local data set we tested if the ID-threshold performance can be increased by considering other rainfall properties (e.g. antecedent rainfall, maximum intensity) in a multivariate statistical learning algorithm based on decision trees (random forest). The highest predictive power was reached when the peak 30-min rainfall intensity was added to the ID variables, while no improvement was achieved by considering antecedent rainfall for debris-flow predictions in Illgraben. Although the increase in predictive performance with the random forest model over the classical ID threshold was small, such a framework could be valuable for future studies if more predictors are available from measured or 20 modelled data.

## 1 Introduction

Debris flows are a common geomorphic process and hazardous phenomenon in mountain regions. They move rapidly as a surging flow of saturated debris. In contrast to other mass movements, such as shallow landslides, debris flows follow an established flow path, along which they often entrain substantial amounts of sediment and water stored in the channel (Hungr et al., 2014; de Haas et al., 2020). In Switzerland, where this study is conducted, landslides and debris flows caused 74 fatal accidents between 1946 and 2015 (Badoux et al., 2016). Globally, debris flows cause about 165 fatalities per year on average, with most of them occurring in mountainous regions of developing countries (Dowling and Santi, 2014). Furthermore, debris flows have the potential to damage property, infrastructure, managed forests and agricultural land (Hilker et al., 2009).

Therefore, the development of early warning systems (EWS) for debris flows and other rapid gravitational mass movements, involving novel measurement techniques and models, is a priority in many countries (Stähli et al., 2015). EWS often rely on rainfall thresholds (Guzzetti et al., 2020). The most common rainfall thresholds are drawn in the rainfall duration ( $D$ ) and mean rainfall intensity ( $I$ , or cumulative rainfall) space, taking the form  $I = \alpha D^{-\beta}$ , which is a linear curve in logarithmic space (Caine, 1980).

In alpine settings, debris flows mostly develop following a shallow hillslope landslide caused by increased pore water pressure (e.g. Iverson, 1997). Another cause can be runoff, where sediment deposits in the channel are mobilized as a mass movement (Takahashi, 1978, 1981) or sediments are progressively bulked up (Fryxwell and Horberg, 1943; Johnson and Rodine, 1984; Tognacca, 1999; Gregoretti, 2000). Physically-based models considering these mechanisms can be used to infer ID thresholds leading to debris-flow initiation (e.g. Berti and Simoni, 2005; Berti et al., 2020; Tang et al., 2019). However, because such models require a great deal of input data of high quality, empirically determined ID thresholds are still more common and are determined at the local, regional or global scale (e.g. Caine, 1980; Guzzetti et al., 2007; Coe et al., 2008; Badoux et al., 2009; Staley et al., 2013; Abancó et al., 2016; Bel et al., 2017).

A challenge in the use of ID thresholds is that there are multiple competing methods for their determination, which have not been objectively and thoroughly compared at multiple scales. Furthermore, ID-thresholds are rarely validated (Segoni et al., 2018). Consequently, generalizing and updating ID thresholds is challenging, as is comparing between them to hypothesize about the possible site-related differences in geomorphology, lithology, terrain and soil properties that lead to a different response to rainfall forcing (Segoni et al., 2018). The sensitivities of ID thresholds have to be better understood and studied for such comparisons to be meaningful. Major uncertainties arise from various issues related to the quality of the rainfall record used. ID thresholds often rely on rainfall data from rain gauges, which can be located on the valley floor or in a neighbouring valley rather than in the immediate vicinity of the debris-flow initiation area. Studies in the Italian Alps have shown that in orographically complex areas, especially for short convective rainstorms, precipitation intensities can decay significantly (30–60%) within short distances (5–10 km) from the centre of the rainfall cell (Marra et al., 2016). This may lead to underestimations of  $\alpha$  by up to 70%, and is one reason for the high false alarm rate of ID thresholds (Nikolopoulos et al., 2014). Another factor causing ID-threshold underestimation is the coarse temporal resolution of the rainfall data. Landslide and debris-flow data sets going far back in time, or relying on satellite-based estimates of rainfall, can be strongly affected by

a coarse temporal resolution. Especially if events are triggered by short-duration storms (minutes to hours), the event mean rainfall intensity is considerably underestimated when daily rainfall records are used. In a study with synthetic data, Marra (2018) showed that using daily data results in significant threshold underestimation. Gariano et al. (2020) confirmed this effect for a real case study in Italy. However, the accuracy of ID thresholds based on rainfall data with a sub-daily resolution can 60 also be limited, for example if the exact timing of the debris flows or landslides is unknown (Leonarduzzi and Molnar, 2020). This is often the case, unless the area is closely monitored or damage was caused and immediately recognized. Therefore, in studies where the landslide timing is only imprecisely known and sub-daily rainfall data are used, the entire rainfall event or the rainfall until the highest intensity was reached is considered to be the triggering rainfall. This uncertainty in event timing has been shown to lead to inflated triggering rainfall amounts and subsequently to overestimated ID thresholds (Staley et al., 65 2013; Leonarduzzi and Molnar, 2020; Bel et al., 2017). Additional uncertainties stem from the discretization of the rainfall time series into rainfall events. Rainfall events are usually separated by a minimum inter-event time (MIT), a period that is intended to mark separate, independent rainfall periods (Dunkerley, 2008). For studies in debris-flow torrents, the MIT can range from 10 min (e.g. Coe et al., 2008) to 6 h (e.g. Deganutti et al., 2000) and is often chosen subjectively without a sensitivity analysis. Bel et al. (2017) combined different MIT values with uncertainty in the timing of debris-flow detection in a French torrent. The 70 obtained uncertainty bounds in ID thresholds encompassed almost all ID thresholds previously published from other torrents. Despite their importance, uncertainties in ID curves are seldom used in prediction.

The inaccuracies in rainfall data used to establish ID thresholds are one source of uncertainty leading to the high false alarm rate. ID thresholds are also criticized for ignoring other information contained in the rainfall time series, such as peak intensities and antecedent rainfall. For debris flows, peak intensities at high temporal resolution ( $\leq 10$  min) have been shown 75 to have an especially high predictive power (e.g. Abancó et al., 2016; Bel et al., 2017). Multivariate statistical methods, such as logistic regression, have been tested and applied to improve the prediction of post-wildfire debris flows in the US (Cannon et al., 2010; Staley et al., 2017), and for debris flows in a French Alpine torrent (Bel et al., 2017). More advanced machine learning techniques are also becoming an attractive tool in the geosciences as the availability of both measured and modelled data increases, and the careful investigation of all possible physical interactions between the variables exceeds our capacities 80 (Reichstein et al., 2019). For post-wildfire debris-flow prediction, machine learning algorithms have in fact been shown to outperform logistic regression models and ID thresholds in predictions (Kern et al., 2017; Nikolopoulos et al., 2018).

Here, we address two research questions. First, what is the uncertainty associated with estimation methods, debris-flow record duration, and with the hazard data set in ID-threshold parameters? By resampling the Illgraben debris-flow record using different time windows, we estimate the confidence bounds of the ID-threshold parameters. Furthermore, we compare the 85 uncertainties of two methods that have been used recently for determining ID-threshold parameters (e.g. Leonarduzzi et al., 2017; Leonarduzzi and Molnar, 2020; Nikolopoulos et al., 2018). These methods use linear regression and/or true skill statistic to determine the ID-threshold parameters  $\alpha$  and  $\beta$ . The differences of these methods are evaluated both for a local debris flow inventory with local rainfall measurements and a regional landslide/debris-flow inventory with gridded rainfall information. Second, how do traditional ID-threshold-curve methods compare with machine learning algorithms? We extend the analysis of 90 debris-flow prediction with additional rainfall event attributes in a random forest algorithm (Breiman, 2001), test the predictive

skill, and discuss the pros and cons of the multivariate approach for local debris-flow detection based on different rainfall event properties (e.g. peak rainfall intensity, number of lightning events) and other seasonal proxies, for example those related to sediment recharge.

## 2 The Illgraben study site

95 Illgraben is a north-facing catchment located in the Rhône valley in the Swiss canton of Valais (Fig. 1). It consists of two sub-catchments: the eastern Illbach ( $4.15 \text{ km}^2$ ) is hydrologically and geomorphologically disconnected, while the western Illgraben ( $4.83 \text{ km}^2$ ) produces on average  $\sim 5$  debris flows a year. The Illgraben sub-catchment has a maximum elevation of 2645 m a.s.l. at the summit of the Illhorn mountain. In this region, the main Rhône-Simplon fault line changes its orientation, resulting in numerous smaller faults in highly fractured bedrock and affecting the Illgraben catchment (McArdell and Sartori, 2021). The 100 main sediment source area is a highly active hillslope underlain by quartzite bedrock, ranging from 1250 to 2370 m a.s.l. and with slopes of up to  $80^\circ$ , where frequent landslides occur and deposit sediments in the trunk channel (Bennett et al., 2012; Berger et al., 2011). The main debris-flow channel starts just below this hillslope and is 5.2 km long. The first half is characterized by a mean slope of 16% until the fan apex at 886 m a.s.l. (Badoux et al., 2009). The second half is flatter (10%) and confined by check dams, before it joins the Rhône river at 605 m a.s.l.

105 In 1961 a large rock avalanche on the northern slope provided abundant sediment and increased the debris-flow frequency in the following years (Hürlimann et al., 2003). However, since then this part of the catchment has produced sediment at much lower rates than the main source area (Schlunegger et al., 2009). The rock avalanche prompted the construction of 30 concrete check dams to stabilize the channel, with the most upstream one being 48 m tall (Lichtenhahn, 1971). This upstream check dam was effective in stabilizing the toe of the rock avalanche deposit and reducing the number of debris-flow events in subsequent 110 years (Hürlimann et al., 2003).

115 Since 2000 the Swiss Federal Research Institute for Forest, Snow and Landscape (WSL) has been operating an observation network in the Illgraben catchment (Fig. 1), including rain gauges (added in 2001), geophones, depth sensors and a force plate (Rickenmann et al., 2001; Hürlimann et al., 2003; McArdell et al., 2007; McArdell, 2016). In this study, we used the data from rain gauge 1 and a debris-flow inventory including events up to the year 2017 (McArdell and Hirschberg, 2020). The other two rain gauges are not ideal for this study because rain gauge 2 has changed location during the study period and rain gauge 3 is sheltered by trees. Rain gauge 1 is suitable here because it is close to the debris-flow initiation area and has been measuring consistently.

120 Illgraben has an alarm system that operates independently from the debris-flow observation station. It serves the villages of Susten and the Pletschen-subdivision on the eastern side of the fan and protects the people visiting the Pfynwald nature park on the western side. Furthermore, hiking trails and sports fields close to the riparian zone make the fan a vulnerable area. Geophones mounted on check dams detect debris flows and activate alert lights and acoustic signals downstream in the riparian zone. After an initial phase of testing and optimization by WSL (see Badoux et al., 2009), the alarm system is now operated by the local municipality in cooperation with an engineering company.

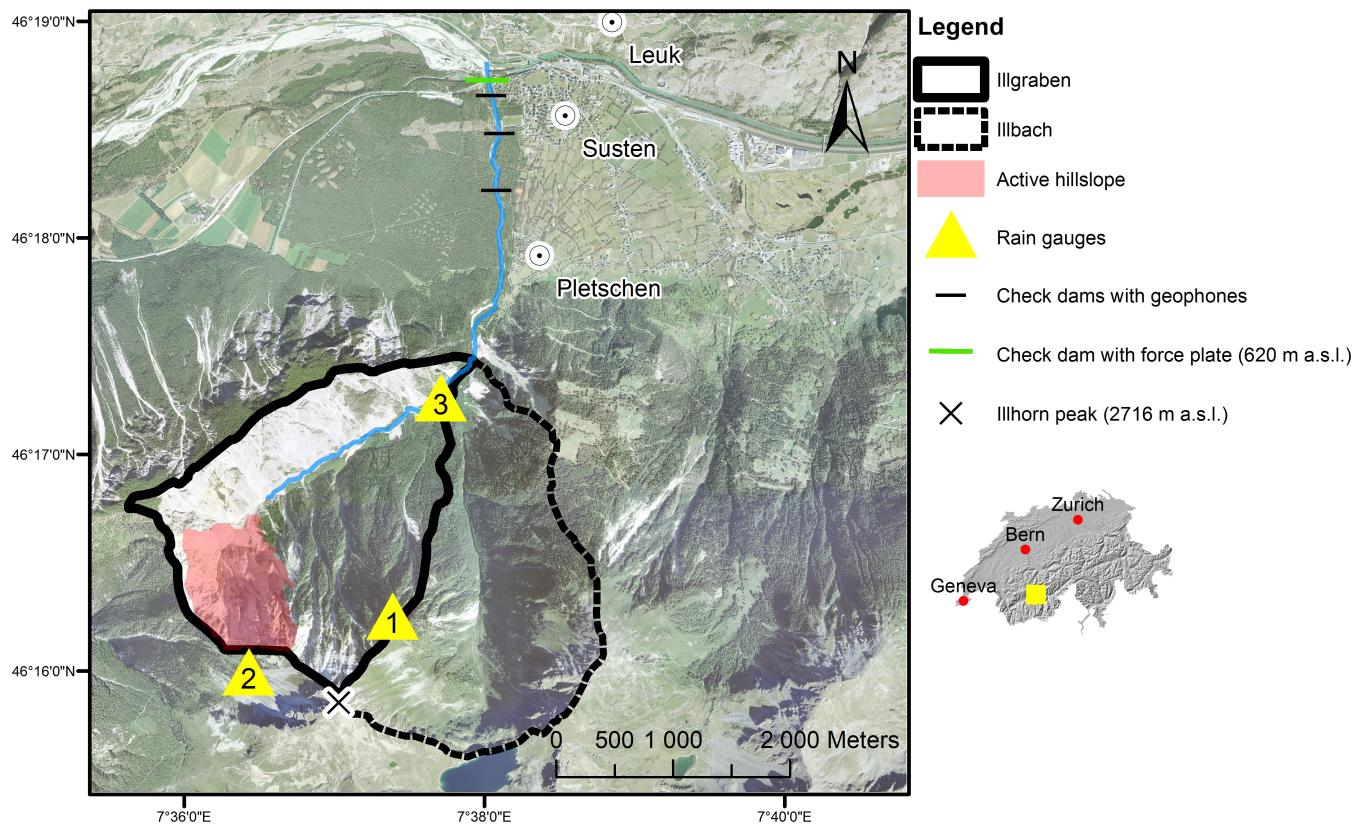

The mean annual precipitation at mean catchment elevation (1600 m a.s.l.) computed for the time period 1981–2010 was  
125 900 mm  $y^{-1}$  (HAD, 2015) and the mean annual temperature for the same period was 5.9°C (Hirschberg et al., 2021). Debris  
flows generally occur from May to October. Although climate change scenarios project longer debris-flow seasons in the future  
(Hirschberg et al., 2021), and recently debris flows have also been recorded in April (2020) and December (2018), most debris  
flows occur in response to convective rainstorms between June and August. Snowmelt can add considerable amounts of liquid  
water to the debris in other places (e.g. Mostbauer et al., 2018) but has never been observed to be the sole debris-flow trigger in  
130 Illgraben, although it likely affects the antecedent conditions in spring. Debris flows overflowing the banks are only expected  
in the case of the failure of a landslide-generated dam, levee failing or breaching, or if the channel conveyance capacity is  
reduced. Such a large debris flow was only observed after the failure of the dam formed by the 1961 landslide (Badoux et al.,  
2009).

### 3 Methods

#### 135 3.1 Data

The timing and volume of debris flows were derived from the local observation system and are reported in McArdell and  
Hirschberg (2020). The debris-flow data set contains 75 entries from the years 2000 to 2017, with 1–8 debris flows occurring  
every year and bulk volumes ranging from 2000 to over 100,000 m<sup>3</sup> (median 25,000 m<sup>3</sup>). The debris-flow mean bulk density  
was typically 1800–2200 kg m<sup>-3</sup> (Schlunegger et al., 2009). Because the local rain gauges (Fig. 1) were installed in June 2001,  
140 only 67 of these debris flows overlap with the rainfall record and were used in this study. The local rain gauge is a 0.2 mm  
resolution tipping bucket with a 10-min sampling rate. It is not heated and therefore only measurements in the period from  
May to October are considered, which coincides well with the debris-flow season. During this period, 480 mm of rainfall is  
measured annually on average, corresponding to about half of the total annual precipitation. The majority of debris flows are  
triggered by events with cumulative rainfall exceeding 5 mm. Although this amount is exceeded by about 30 storms each year,  
145 only 4.2 debris flows are triggered annually on average.

Temperature data was provided by the Swiss Meteorological Office (MeteoSwiss) from the Montana meteorological station,  
located about 11 km northwest of the study area. Although the local rain gauges measure temperature, the sensors are not prop-  
erly shielded and the measurements therefore unreliable. The measurements were interpolated using local lapse rates to account  
for the difference in elevation of about 200 m, as described in Hirschberg et al. (2021). The 10 min total of recorded lightning  
150 strikes at a distance of 3–30 km was also derived from the Montana station and used as a secondary variable for the convective  
character of storms (Gaál et al., 2014) in the machine learning algorithm. The local predictive power of debris flows in Illgraben  
was also compared with a regional prediction of slope failure using a regional data set on shallow landslides in Switzerland  
including associated rainfall events (Leonarduzzi et al., 2017). It is based on a gridded daily rainfall product (RhiresD) and  
the *Swiss flood and landslide damage database* (WSL). RhiresD consists of a 1km x 1km gridded product of daily precipita-  
155 tion sums obtained by interpolation of rain gauges (ca. 420), accounting for local climatology and precipitation-topography  
relationships (Frei and Schär, 1998). The regional data set consists of 2137 landslides which occurred in Switzerland between

**Figure 1.** Aerial view of the Illgraben study site (Federal Office of Topography) with the debris-flow observation system. Most sediments are generated on the active hillslope. Debris flows mostly initiate in the channel below this slope and are identified with geophones mounted to the check dams downstream. Volumes are calculated based on data collected at the location of the force plate. Data from rain gauge 1 were used in this study to characterize rainfall events.

1972 and 2018 and for which damage was reported. Only the data from 2001 to 2017 was used, to be consistent with the local data set.

### 3.2 Performance statistics for debris-flow prediction

160 Confusion matrix and receiver operating characteristic (ROC) curves were used to compare models and optimize thresholds for debris-flow triggering (Fawcett, 2006). A confusion matrix can be computed for any binary classifier by counting the True Positives (TP), False Negatives (FN), True Negatives (TN) and False Positives (FP). Various performance statistics can be calculated from the confusion matrix. The most common measures in debris-flow and landslide forecasting are the following

(e.g. Staley et al., 2013; Gariano et al., 2015; Leonarduzzi et al., 2017; Leonarduzzi and Molnar, 2020; Mirus et al., 2018):

165 Sensitivity (hit rate or true positive rate):  $SE = \frac{TP}{TP + FN}$  (1)

Specificity (complement of false positive rate):  $SP = 1 - \frac{FP}{FP + TN}$  (2)

True Skill Statistic:  $TSS = SE + SP - 1$  (3)

170

Threat Score (critical success index):  $TS = \frac{TP}{TP + FN + FP}$  (4)

In literature, TSS is also referred to as the Peirce Skill Score (Peirce, 1884), Youden's index (Youden, 1950) or the Hanssen and Kuipers discriminant (Hanssen and Kuipers, 1965). The benefit of using the specificity over the false positive rate (FPR =  $FP/(FP+TN)$ ) is that in a perfect model TSS, sensitivity and specificity all equal 1. As noted by others (e.g. Leonarduzzi et al., 2017; Postance et al., 2018; Mirus et al., 2018), optimizing TS leads to more conservative (higher) thresholds, while

175 optimizing TSS yields more balanced rainfall thresholds. The choice of score used in practice is therefore the user's decision. In this study, TSS was optimized to calibrate thresholds and to compare classifiers, mainly because it is less sensitive to data sets with unbalanced class prevalence. In particular, TSS was used in the following analyses:

1. In the determination of thresholds for single predictors (section 3.3)
- 180 2. In the determination of the ID-threshold parameters (section 3.4)
3. In the determination of probability thresholds from the random forest classifier (section 3.5)
4. In the comparison of these predictive models

Another metric for predictive model comparison is the Area Under the ROC Curve (AUC). To estimate the AUC, SE and 1-SP are calculated and plotted for all possible threshold values. AUC equals 1 if there is a threshold that can perfectly separate 185 triggering and non-triggering events. A model with an AUC of 0.5 has no predictive power.

### 3.3 Rainfall event definition and other properties

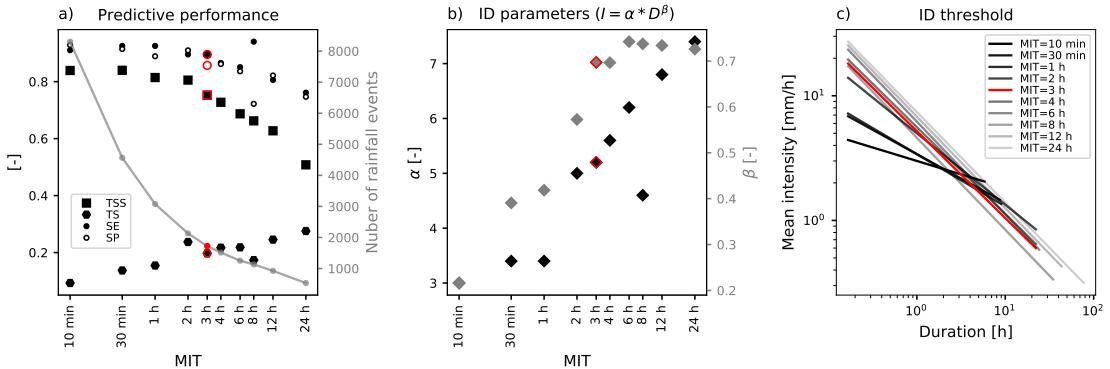

The precipitation time series was discretized into rainfall events, which were separated by a Minimum Inter-event Time (MIT). Rainfall events were considered independent if no rainfall was recorded during this time. For triggering events, the end of the rainfall event was set either to the day of the event (for the regional data set) or to the 10-min instance before the event was 190 recorded (for the local data set). This procedure avoids threshold overestimation (Staley et al., 2013; Leonarduzzi et al., 2017).

**Table 1.** List of models and single predictors evaluated on their predictive performance for debris-flow triggering. Data source “Illgraben” refers to the local rain gauge, “Montana” to the MeteoSwiss weather station located 11 km from the catchment, and “Debris flows” to the Illgraben debris flow data set.

Model name	Description	
ID LR&TSS	Intensity-duration threshold where the shape parameter was determined by linear regression on the triggering events, and the scale parameter was set to maximize TSS	
ID TSS&TSS	Intensity-duration threshold where both parameters were set to maximize TSS	
RF_ID	Random forest model with rainfall event duration and mean intensity as input	
RF_all	Random forest model with all single predictors as input	
RF_ID+X	RF_ID and one additional input (best single predictor, i.e. highest AUC)	
RF_ID+var	RF_ID with four additional inputs: best (highest AUC) I-Tm, best Ra-Td, best Ta and lightning strikes	
Single predictor name	Description	Data source
Duration	Rainfall event duration in hours	Illgraben
I-mean	Mean rainfall intensity in mm	Illgraben
Rtot	Total event rainfall in mm	Illgraben
I-Tm	Maximum rainfall intensity over T minutes within the event in mm/h ( $10 \leq T \leq 120$ )	Illgraben
Ra-Td	Antecedent rainfall within T days prior to the rainfall event in mm ( $1 \leq T \leq 90$ )	Illgraben
Ta_min, Ta_mean, Ta_max	Minimum, mean and maximum air temperature at the day of the rainfall event in °C	Montana
Ta_span	Ta_max - Ta_min	Montana
lightnings	Number of lightning strikes recorded within a radius of 3–30 km from the station	Montana
Freezing Days	The number of freezing days in the winter prior to the debris-flow season	Montana
time w/o DF	Elapsed time since the last debris flow in days	Debris flows
month, dayofyear	The month and the day of the year of the rainfall event	Debris flows

For the regional data set we defined MIT = 1 d as in Leonarduzzi and Molnar (2020). This definition of events overestimates event duration and underestimates mean intensity compared to hourly data, but compensates for this by longer and more dense records (see Leonarduzzi and Molnar, 2020). For rainfall records with sub-daily resolution, MIT is often chosen subjectively and varies between 10 min at Chalk Cliffs (USA) to 6 h at Moscardo (Italy) for local debris-flow analyses (Coe et al., 2008;

195 Deganutti et al., 2000). In Switzerland, a MIT of 2–3 h has been shown to be appropriate for the separation of thunderstorms (Gaál et al., 2014) and storms initiating bedload transport in an Alpine watershed (Badoux et al., 2012). However, as the subjectivity in the rainfall event definition complicates the comparison of rainfall thresholds, we followed the suggestion of Bel et al. (2017) to choose MIT for the local data set as the duration where the number of rainfall events stabilizes, which indicates its independence from MIT duration. In this process, the sensitivity of rainfall threshold performance scores to the

**Figure 2.** ID thresholds and their predictive performance statistics as a function of rainfall event definition (minimum inter-event time, MIT). (a) Analysis of true skill statistic (TSS), threat score (TS), sensitivity (SE), and specificity (SP) as a function of MIT. The number of rainfall events also varies with MIT and is shown in grey. (b) Analysis of ID-threshold parameters as a function of MIT. (c) Visualization of ID thresholds for different values of MIT. MIT = 3 h (red) was chosen for this study (see text).

choice of MIT was also evaluated (Fig. 2a). The measures SE, SP and TSS from fitting ID curves were found to decrease with increasing MIT as the number of events drops. However, in absolute terms, the number of false alarms is higher at a short MIT because of the large total number of rainfall events, and this also reflects in the TS statistic. At MIT = 3 h, the number of rainfall events stabilizes. This is seen in the stable TS, meaning that there are no additional false alarms. The shape parameter of the ID threshold ( $\beta$ ) reduces its increasing trend at the same MIT (Fig. 2b). The scale parameter ( $\alpha$ ) increases because the rainfall events become longer with increasing MIT and therefore the rainfall amounts increase. Consequently, MIT = 3 h was used throughout this study and it was confirmed that in the Alps a MIT of 2–3 h is an appropriate time period for separating rainfall into independent events for various applications, as found in independent studies by Badoux et al. (2012), Gaál et al. (2014) and Bel et al. (2017). Nevertheless, a suitable MIT should be objectively tested for each study site if possible.

Once MIT was defined, other rainfall-event properties were extracted in addition to the duration and mean intensity (Table 1, single predictors). Multiple maximum rainfall intensities were computed over periods of 10 min to 2 h. Antecedent rainfall was defined as cumulative rainfall prior to the rainfall event and computed for a range of periods from 1 to 90 days prior to the rainfall event. These event properties can be computed from any rainfall time series and are important for the soil moisture saturation and the likelihood of runoff formation in response to rainfall.

Furthermore, event properties related to air temperature were added. The daily mean, minimum and maximum temperature was computed for the day of each rainfall event. If an event spanned several days, the day the event started was considered. In the case of low temperatures, it could be snowing in the higher parts of the catchment, reducing the amount of liquid water contributing subsequent runoff. In this case, the rain gauge can possibly not be trusted because it is not heated. However, most debris flows occur in summer, when solid precipitation is rare even in the higher parts of the basin. As an indicator of convective rainfall, the daily temperature span and the number of lightning strikes were added. To account for seasonality effects, the day-

220 of-year and the month of each event were included. As proxies for sediment availability, the time elapsed since the last debris flow was added and the number of freezing days of the current hydrological year (November–October) was computed from the temperature time series. The aim of the latter was to account for sediment recharge related to frost-weathering processes (Hirschberg et al., 2021).

### 3.4 Rainfall intensity-duration (ID) thresholds

225 ID thresholds are defined as  $I = \alpha D^{-\beta}$  (Caine, 1980). In the log-log space this relation becomes linear where the scale parameter  $\alpha$  defines the intercept of the threshold line and the shape parameter  $\beta$  its slope. The best way to determine the scale ( $\alpha$ ) and shape ( $\beta$ ) parameters of rainfall ID curves and their uncertainties is an ongoing discussion. Brunetti et al. (2010) presented a statistical approach (frequentist method) involving estimating  $\beta$  with a linear regression (in logarithmic space) fitted to all triggering rainfall events and decreasing  $\alpha$  by an amount which is equal to the distance of the median residual 230 to a chosen lower percentile. While this method is objective and, when applied as an EWS, makes it possible to control the hit rate, it neglects the information from the non-triggering rainfall events and thus does not consider the false positive rate. Lately, confusion matrix and ROC methods (see section 3.2) have been used as objective measures to assess the predictive performance of ID thresholds and also as an alternative way to determine the  $\alpha$  and  $\beta$ .

235 For the ID thresholds computed here, sensitivity (Eq. 1) and specificity (Eq. 2) were calculated. The threshold performance was then evaluated in terms of TSS (Eq. 3). Two approaches were applied to optimize the ID-threshold parameters. In the first approach, as in the frequentist method, the  $\beta$  is determined in the log-log space with a linear least-squares approximation of the debris-flow triggering ID pairs. In a next step,  $\alpha$  is tuned to maximize TSS. This method is called LR&TSS hereafter. In the second approach, the scale parameter  $\alpha$  and the shape parameter  $\beta$  are simultaneously tuned to maximize TSS. This approach is hereafter referred to as TSS&TSS (Table 1, models). The fundamental difference of these two approaches is that LR&TSS 240 only relies on triggering rainfall events to define  $\beta$  while TSS&TSS considers both triggering and non-triggering rainfall events. Hence, different values and sensitivities for  $\beta$  can be expected for these two approaches depending on e.g. the number of triggering rainfall events and the ratio of triggering to non-triggering rainfall events.

245 To test the uncertainty of these two methods associated with the record duration, resampled (bootstrapped, James et al., 2013a) time series of rainfall and debris-flow/landslide events from 1 to 30 years were produced. Thus, only entire years were resampled, to avoid breaking up any natural intra-annual patterns. One sampled year consisted of all debris-flow/landslide triggering and non-triggering rainfall events. For example, for a record duration of 5 years, a sample consists of 5 years of measurement. Each year of measurement was drawn from the full 17-year observation period with replacement. This means that a specific year could occur multiple times in one 5-year sample. The multiple occurrence of the same year in a sample is fundamental to the uncertainty assessment and is of course more likely for longer than for shorter record durations. For each 250 record duration, 100 samples were obtained by following this procedure, e.g. 100 samples with a record duration of 5 years. Finally, the bias in ID-threshold parameters was estimated for each sample. The bias was defined as the relative deviation of estimates of  $\alpha$  and  $\beta$  from the corresponding reference values, i.e. the ones calculated from the original complete (17-year) record using LR&TSS and TSS&TSS.

### 3.5 Random forests for debris-flow prediction

255 Much of the information contained in the rainfall time series, such as antecedent rainfall and peak intensity, is lost when  
discretized into events and characterized only by mean rainfall intensity and duration. As an alternative, Random Forests (RF,  
Breiman, 2001) were used to include more rainfall event properties (Table 1) for the classification of rainfall events into debris-  
flow triggering and non-triggering. Random forests are based on a statistical learning algorithm that uses multiple decision  
trees. Each of these trees is trained with a subset of the predictor variables in the training data set. This procedure (also called  
260 bagging) is fundamental to the algorithm because it decreases the correlation among the trees and makes random forests suitable  
for capturing complex interactions and structures in the data. For detailed information, the reader is referred to Breiman (2001)  
and James et al. (2013b). The Scikit-learn module in Python was used to develop a RF classifier (Pedregosa et al., 2011).

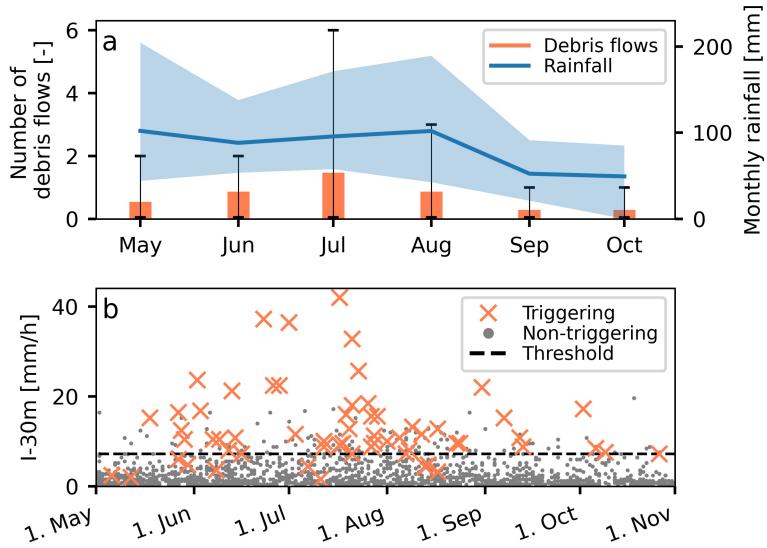

265 For the prediction of debris flows, logistic regression models have been used extensively in regional post-fire debris-flow  
studies to account for rainfall threshold variability due to spatial differences in slope and burned area (e.g. Cannon et al., 2010;  
Staley et al., 2017). Moreover, Bel et al. (2017) showed, for a French debris-flow torrent, that when ID thresholds were used  
270 in conjunction with a logistic regression model including variables for peak rainfall intensity, antecedent rainfall conditions  
and the number of days since winter, the number of false alarms could be reduced. RF were used instead in the present study  
because of their ability to consider multiple predictor variables with non-linear relationships and correlating predictors. To our  
knowledge, the predictive power of RF have not yet been tested for local debris-flow or landslide predictions. Nikolopoulos  
et al. (2018) used RF for regional post-fire debris-flow predictions in the western United States and showed that RF improved  
debris-flow predictions when a variable representing the location was added.

275 Here, four RF models – with the number of predictor variables ranging from 2 to 26 – were tested, with the first being the  
equivalent of the traditional ID threshold (RF\_ID, Table 1). The model output included the probability of being debris-flow  
triggering for every rainfall event. The probability threshold for classification had to be tuned because the threshold-optimizing  
TSS is likely not 50% but rather somewhat smaller (Nikolopoulos et al., 2018). The predictive performance was then compared  
280 with ID threshold obtained as described in section 3.4, and with all single predictors (Table 1).

## 4 Results & Discussion

### 4.1 Debris-flow ID thresholds and their seasonality

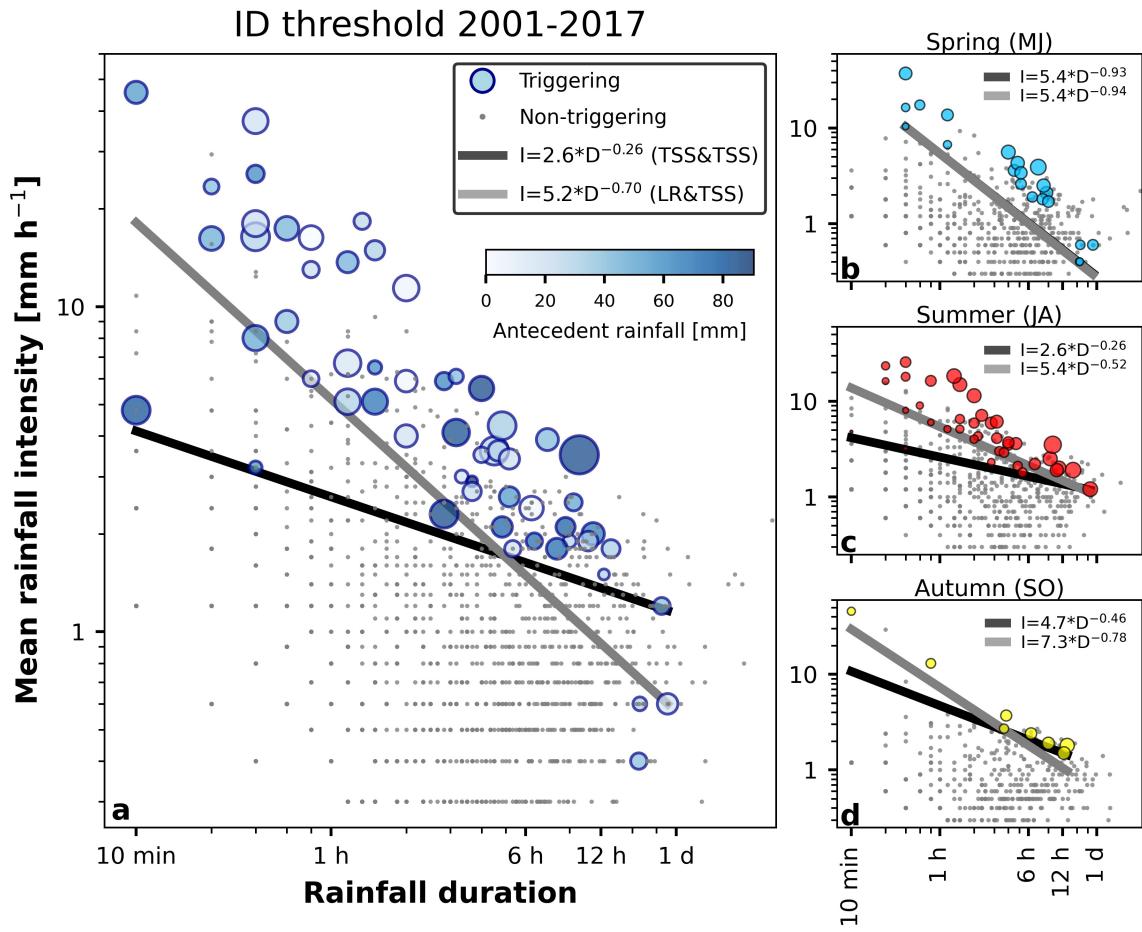

280 In the study period from 2001 to 2017, 21 debris flows were triggered in spring and early summer (May and June, with the  
local influence of snowmelt), 38 in summer (July and August) and 8 in autumn (September and October) (Fig. 3). The monthly  
inter-annual variability was especially high in July, when between 0 and 6 debris flows occurred. This was also the month with  
the most extreme 30-min rainfall due to convective storms. The debris-flow activity dropped considerably in autumn, when  
285 the monthly rainfall also reduced by about 50%. Such seasonality is typical for Alpine debris-flow torrents (e.g. Schneuwly-  
Böllschweiler and Stoffel, 2012; Bel et al., 2017). In spring, snowmelt generates additional runoff and saturates the debris,  
which may lower the rainfall threshold for debris-flow initiation. This likely played a role in the events which were triggered

**Figure 3.** (a) Mean number of debris flows per month (orange bars) and mean monthly rainfall (blue line) in the Illgraben catchment. The thin error bars (black) and the shaded area (blue) show the inter-annual variability, i.e. the observed minimum and maximum in each month between 2001 and 2017. (b) Peak 30-min rainfall intensity in debris-flow triggering and non-triggering rainfall events. The threshold ( $7.2 \text{ mm h}^{-1}$ ) was determined by optimizing the TSS (0.75).

at low rainfall amounts (30-min duration) before mid-June. There were also some lower-intensity events in July and August which still triggered debris flows. However, at this time of the year, inaccurate rainfall measurements and high spatial variability during convective storms are a more likely explanation. The rainfall event with the highest peak 30-min rainfall intensity that did not trigger a debris flow was in October, possibly indicating sediment supply-limited conditions.

290 Debris-flow triggering threshold curves in Illgraben showed the typical negative power-law relationship between mean intensity and duration (Fig. 4). Debris flows occurred mostly during high rainfall intensities. However, triggering and non-triggering events could not be separated perfectly. There were a few outliers at very short ( $<1 \text{ h}$ ) and very long rainfall durations ( $>16 \text{ h}$ ), which were triggered by comparably little rainfall. ID thresholds were computed with two methods (TSS&TSS and LR&TSS) for the entire data set and for individual seasons (Fig. 4). The scale parameter  $\alpha$  had values between 2.6 and 7.3, with lower 295 values for TSS&TSS (2.6–5.4) and higher values for LR&TSS (5.2–7.3). The shape parameter  $\beta$  was consistently smaller for TSS&TSS (0.26–0.93) than for LR&TSS (0.52–0.94) and varied considerably between the seasons. These parameter ranges largely comprise values reported for other debris-flow torrents (Bel et al., 2017). Only in spring, the thresholds were practically identical (Fig. 4b). For the entire data set, this resulted in the median TSS&TSS threshold being lower for short durations ( $\leq 4.5 \text{ h}$ ) and higher for long durations. The LR&TSS threshold was very similar to a curve defined earlier for Illgraben, with  $\alpha = 5.4$  300 and  $\beta = 0.79$  (McArdell and Badoux, 2007), although there  $\alpha$  was set to detect all triggering events. If the same procedure had been used for the data set used here, the ID threshold would also be lower.

**Figure 4.** ID thresholds for the Illgraben catchment computed with two methods. (a) ID thresholds for the entire data set. For the 67 triggering events, the 14-day antecedent rainfall (blue colour) and the (relative) bulk volume (marker size) of the debris flows are also shown. (b)–(d) ID thresholds for each season, where the lines are the thresholds computed using TSS&TSS (black) and LR&TSS (grey). The marker size indicate the total rainfall volume.

The seasonal ID thresholds differed, but direct comparison is difficult because of differences in the number of events (Fig. 4b–c). In autumn, it is clearer than in other seasons that only high-intensity rainfall events triggered debris flows. This may be due to (a) rainfall measurements being more representative and accurate for the initiation area than in summer when more convective events take place; (b) sediment availability being exhausted at the end of the debris-flow season (Berger et al., 2011; Bennett et al., 2014); or (c) grain size coarsening throughout the wet season, increasing the hydraulic conductivity in the channel bed and therefore also the rainfall threshold that must be exceeded to generate runoff (Domènech et al., 2019). As a consequence, the false alarm rate was lower in autumn than in other seasons.

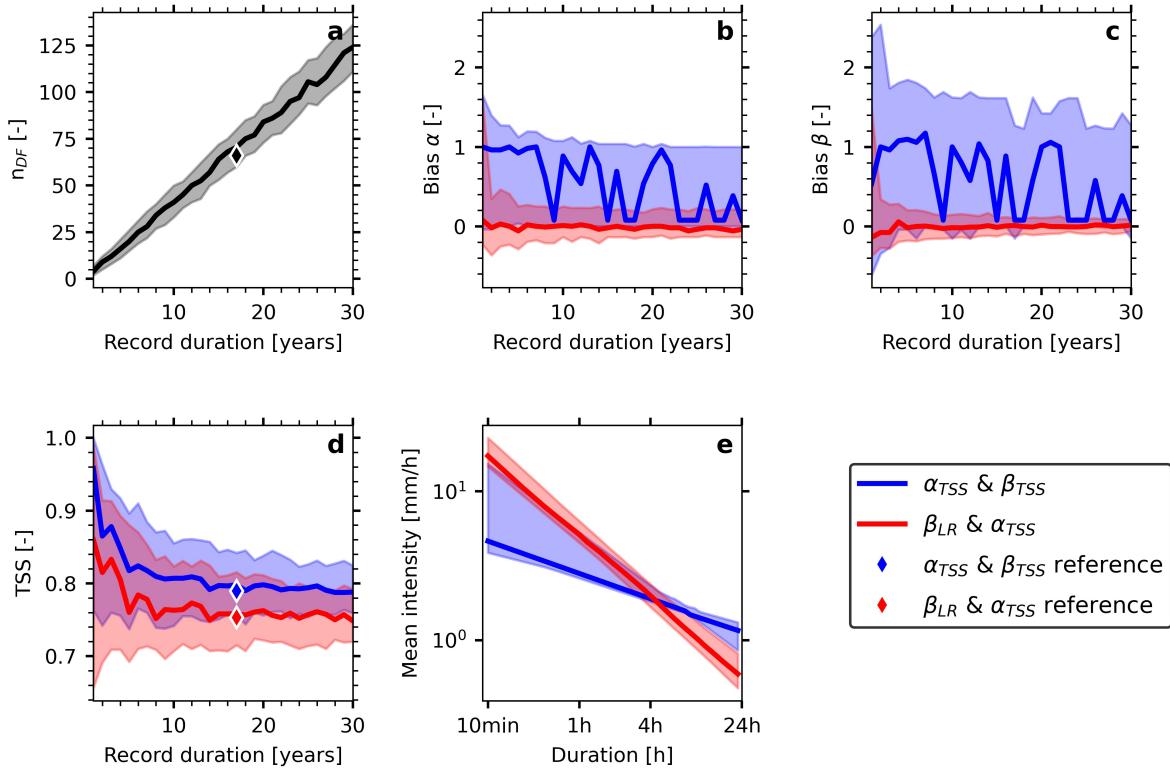

For longer durations, larger rainfall amounts are required for debris-flow triggering (Fig. 4b-d), and this reflects the balance 310 of infiltration, storage and drainage of water. However, for short and long rainfall durations ID pairs fail to plausibly describe the hydrological processes leading to landslide initiation (Bogaard and Greco, 2018). However, here it was not clear if this was also the reason for the outliers triggered by lower mean rainfall intensities. There were two debris flows in summer at rainfall 315 durations of 10 and 30 min which were triggered by significantly lower mean rainfall intensities than the other debris-flow events associated with these durations. One possible reason is that rain gauges, although close to the initiation area ( $\sim 1$  km), are prone to not capturing peak intensities, especially of convective storms, even at short distances (Nikolopoulos et al., 2014; Marra et al., 2016). These two events were, however, also characterized by high antecedent rainfall, which could have lowered the triggering threshold. In spring, three events were triggered at low mean rainfall intensities ( $<1$  mm h $^{-1}$ ) and after more than 320 16 h. It could be that the MIT parameter does not separate rainfall events accurately in these cases, that the rainfall threshold was lower due to snowmelt, that there were errors in the rainfall data, or simply that these debris flows were triggered by other mechanisms than rainfall excess, such as the breaching of a small landslide dam.

Debris flows occur at a wide range of 14-day antecedent rainfall conditions, with many events occurring with very low 325 values for this variable (Fig. 4a). Antecedent rainfall does not appear to be a significant precondition for debris-flow triggering in the Illgraben catchment. This has also been observed at other alpine locations (e.g. Abancó et al., 2016). Here, the debris-flow magnitudes were not affected by the intensity of the triggering rainfall consistent with other studies (Hirschberg et al., 330 2019; Pastorello et al., 2018). However, the magnitudes were affected by the amount of antecedent rainfall. Higher antecedent rainfall amounts lead to a higher degree of pore saturation along the entire channel bed. Although, antecedent rainfall may also contribute to lateral flow on the hillslopes (e.g. Papa et al., 2013), the steep hillslopes in Illgraben and the time scale of 14 days gives us confidence that this antecedent rainfall mainly affects the channel bed. In this case, sediment entrainment experiences a positive feedback from increased pore water pressure as the debris-flow surge passes by, increasing the debris-flow volume (Iverson et al., 2011; McCoy et al., 2012; Hirschberg et al., 2019).

## 4.2 Sensitivity of ID thresholds to record duration and identification method

Illgraben ID thresholds where the ID-threshold parameters are jointly tuned to optimize TSS (TSS&TSS) have slightly larger 335 TSS values compared with ID thresholds with parameters estimated by first fitting  $\beta$  to the triggering events and then tuning  $\alpha$  to optimize TSS (LR&TSS) (Fig. 5b-d). However, this increase in TSS is accompanied by higher uncertainties, measured as the 10<sup>th</sup> to 90<sup>th</sup> percentile range, in both  $\alpha$  and  $\beta$  biases. TSS&TSS thresholds are significantly lower than LR&TSS thresholds for short durations ( $<4.5$  h) and higher for long durations (Fig. 5e).

TSS&TSS parameter estimates are overestimated by  $>100\%$  even after 30 years of observations and the medians do not 340 converge (Fig. 5b,c). The fluctuations in the median suggest that there are 2–3 parameter sets with TSS values which are all close to the optimum. Therefore, there are no unique ID-threshold parameters for Illgraben when estimated with TSS&TSS. The uncertainty range is not located around zero but biased towards positive values because the reference values (see Fig. 4a, solid threshold line) are at the lower end of possible solutions. The medians and the uncertainty bounds from parameters estimated with LR&TSS still converge after the reference record duration of 17 years, with biases of  $\pm 20\%$  for both  $\alpha$  and  $\beta$

**Figure 5.** ID threshold sensitivity for the Illgraben catchment, assessed by resampling (bootstrapping) 100 times for each record duration (1–30 years) from the 17-year data set of debris-flow triggering and non-triggering rainfall events. (a) number of debris flows; (b) bias in the scale parameter  $\alpha$ ; (c) bias in the shape parameter  $\beta$ ; (d) true skill statistic (TSS); (e) ID thresholds with variability from the observed record duration of 17 years. Solid lines are the medians and shaded areas comprise the 10<sup>th</sup> to 90<sup>th</sup> percentiles of the resampled data. The diamonds (reference) refer to the values obtained when the full 17-year data set was used.

(Fig. 5b,c). However, the biases decrease to  $\pm 30\%$  already after 6 years or  $\sim 25$  triggering events. Furthermore, the TSS score, which is overestimated for short records because it seems to be easier to fit an ID curve to only a few points, decreases and 345 stabilizes after 6 years. Because the Illgraben record is a local data set, it is not affected by climatic, topographic, lithologic or land-use differences between sites as present in most large-scale regional data sets. Therefore, the uncertainties can be associated with the respective method with high confidence and the Illgraben data set is well-suited to study such ID-threshold sensitivities.

Important advantages of using TSS for ID-threshold parameter estimation are that information from both triggering and 350 non-triggering events is considered with equal weight and that the measure is prevalence independent. However, although the

355 narrow uncertainty range for long record duration (Fig. 5d) additionally indicates the robustness of the TSS score, it does not imply robustness in the parameter estimates that are based on TSS (Fig. 5b,c). In our case, with 67 debris flows, the ID-threshold parameters computed with TSS&TSS seem to be highly sensitive to a few triggering events, which may be outliers but exist in any data set and are difficult to single out with certainty. Consequently, for local ID thresholds we advise against simultaneously optimizing  $\alpha$  and  $\beta$  against the TSS score (TSS&TSS). Local data sets are often comparatively small (<100 triggering events), and therefore this method can be sensitive to outliers.

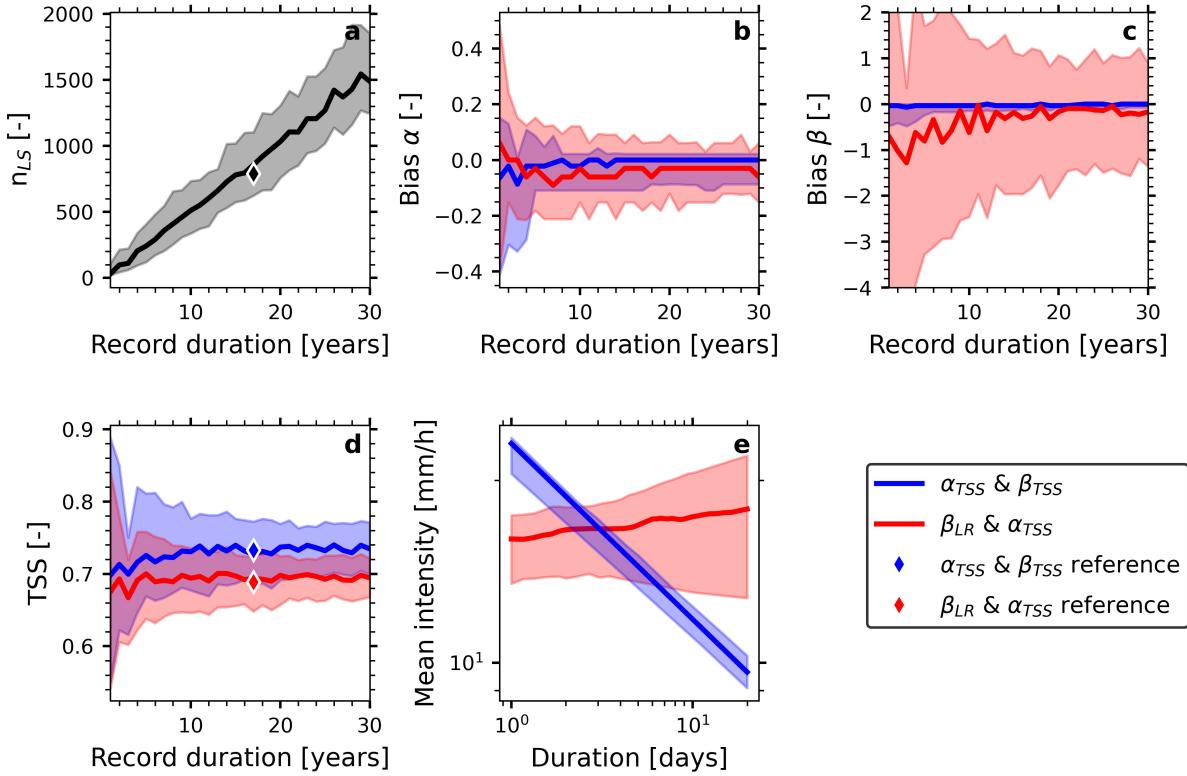

360 Conducting the same sensitivity analysis on the regional data set showed the opposite result than for the local data set. For the regional data set, TSS values could be slightly enhanced when using the TSS&TSS instead of the LR&TSS method (Fig. 6d), as in the local data set. In contrast to the local data set, this enhancement in TSS is not accompanied by larger uncertainties in ID-threshold parameters (Fig. 6b,c). LR&TSS thresholds are practically flat (Fig. 6e) and parameter ranges are still converging after the reference record duration of 17 years. Using LR&TSS even makes the duration redundant because  $\beta$  estimated with LR&TSS converges to 0. Note that the large range in  $\beta$  bias for LR&TSS (Fig. 6c) is also because  $\beta$  is close to 0, and absolute values are small (see section 3.4). TSS&TSS threshold parameters converge after  $\sim$ 8 years, corresponding to  $\sim$ 400 landslides. These are more events than reported for data sets in Italy, where  $\sim$ 200 were enough both on the regional and on the national 365 scale (Peruccacci et al., 2012, 2017).

370 The regional data set is inherently subject to much larger uncertainties, which can be disregarded in the local data set. These uncertainties are mainly related to climatic, topographic and lithologic differences among the landslide locations. Furthermore, the rainfall uncertainties are higher in the regional data set because the regional analyses rely on interpolated, daily precipitation. As a result, the slope of the ID curve, when fitted with linear regression, may lose the typical power-law relationship of extreme rainfall. TSS&TSS instead profits more from the information in the non-triggering rainfall, by setting a threshold high enough to be above the many non-triggering rainfall events with low intensity and short duration, and steep enough to detect triggering events as a response to long-lasting rainfall (Fig. 6e).

375 The main differences between the methods used here and the well-known frequentist method (Brunetti et al., 2010) are that non-triggering rainfall events are considered either in the determination of the scale parameter  $\alpha$  (LR&TSS) or in both  $\alpha$  and the shape parameter  $\beta$  (TSS&TSS). Parameters estimated by LR&TSS for the local data set have lower uncertainties than when estimated by TSS&TSS. For the regional data set the TSS&TSS method yields both better predictions and lower parameter uncertainty. Hence, this comparison of a local and a regional data set suggests that the range of climatic, topographic, lithologic or land-use differences within a data set should be considered when deciding which method to apply for ID-curve estimation.

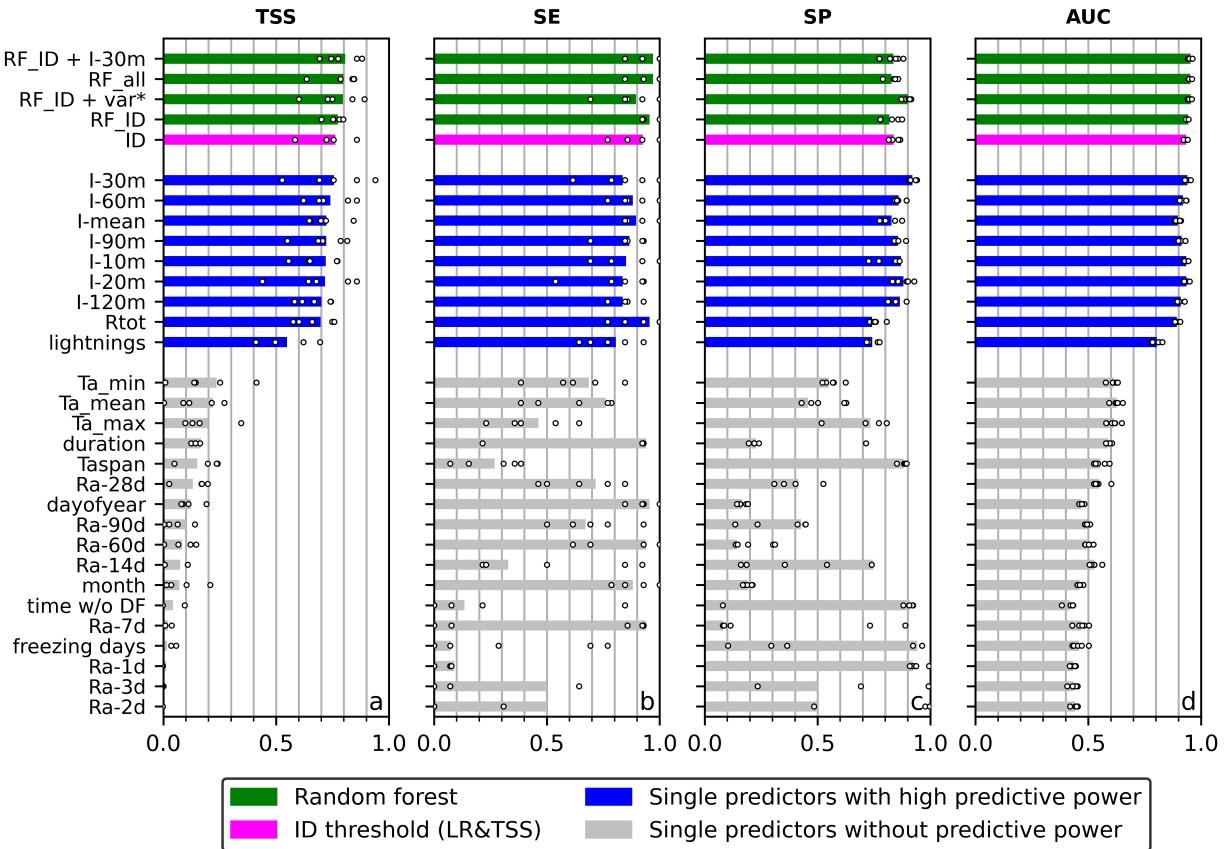

#### 4.3 Predictive power of uni- and multivariate models

380 We compared debris-flow triggering proxies related to maximum rainfall intensity, antecedent rainfall and temperature, among others (Table 1, lower part). Each proxy was evaluated as a single predictor in terms of TSS. These were also compared with five multivariate models: the LR&TSS-ID threshold and four RF classifiers with different single predictors as input (Table 1, upper part). The TSS&TSS-ID threshold was excluded here due to the large uncertainties in estimated parameters. The models were validated with five-fold cross-validation (CV).

**Figure 6.** ID-threshold sensitivity for the regional data set, assessed by resampling (bootstrapping) 100 times for each record duration (1–30 years) from the 17-year data set of landslide triggering and non-triggering rainfall events. (a) number of landslides; (b) bias in the scale parameter  $\alpha$ ; (c) bias in the shape parameter  $\beta$ ; (d) true skill statistic (TSS); (e) ID thresholds with variability from the observed record duration of 17 years. Solid lines are the medians and shaded areas comprise the 10<sup>th</sup> to 90<sup>th</sup> percentiles of the resampled data. The diamonds (reference) refer to the values obtained when the full regional data set is used.

385 We found that the RF classifier's TSS values (0.77–0.81) are only slightly higher than the classical ID threshold's TSS (0.76) (Fig. 7a). This improvement is due to a generally higher sensitivity score (Fig. 7b). However, as seen in the distribution of the 390 points from the CV (with dots in Fig. 7), RF can reduce uncertainties. The best improvement in TSS is seen when only one additional predictor (peak 30-min rainfall intensity) is added to the intensity and duration of rainfall events. If all available data are used by an RF classifier (RF\_all), the performance even decreases compared with RF\_ID+I-30m. This is likely due to overfitting and can happen when many of the input variables have poor predictive power. In this case, the RF classifier is fitted to the noise from the poor predictors while the predictive information from other variables gets lost. Hence, CV avoids the overfitting of a model set-up, and further improvements may be achieved by testing different combinations of variables.

\* RF\_ID + var = RF\_ID + I-30m + Ra-28d + lightnings + freezing days

**Figure 7.** Model comparison (see Table 1) for the prediction of debris flows in the Illgraben catchment, with reference to (a) true skill statistic (TSS), (b) sensitivity (SE), (c) specificity (SP) and (d) area under the curve (AUC). The threshold for single predictors with predictive powers was set at  $AUC = 0.65$ . The bars refer to models using the full data set for training. The dots represent results from the five-fold cross-validation. The models are sorted top-down with decreasing TSS.

This analysis demonstrated that the best single predictor in terms of TSS is the peak 30-min rainfall intensity (TSS=0.76), and its specificity is also the highest overall (0.92) (Fig. 7c). In general, the predictors relating to maximum rainfall intensities of different time scales have relevant predictive power, while predictors related to antecedent rainfall do not. Of all debris flows, 96% can be identified with a threshold (5 mm) for total event rainfall (Fig. 7b). Furthermore, peak 30-min rainfall intensity and mean rainfall intensity on their own perform similarly to the ID threshold. These rainfall properties are simple to calculate with a moving window from any rainfall time series, even without adding uncertainty by rainfall event separation. Surprisingly, lightning strikes also have some predictive power, even though they were recorded within an area which is almost 600 times larger than the catchment size ( $\sim 2800 \text{ km}^2$ ). This indicates that debris flows are favourably triggered when thunderstorm

clusters occur. The single predictors listed below lightning strikes in Fig. 7 have (almost) no predictive power because their AUC values are  $\sim 0.5$ , which is close to a random guess.

Although ID thresholds are widely used in applications, a common problem is the number of false alarms they cause. For Illgraben, although 92% of the debris flows are detected with the ID threshold estimated with LR&TSS, only 20% of the rainfall events exceeding the threshold are expected to produce a debris flow. This performance is usually even smaller if the threshold is defined for larger spatial scales. For example, for the regional data set used here, only 0.38% of threshold-exceeding events are expected to be landslides. This highlights the difficulties in capturing complex interactions leading to hazardous events and justifies the need to explore more data-rich approaches. Here, we systematically analyzed the predictive power of single predictors and multivariate models based on the RF algorithm. Although the RF classifier only marginally improved the TSS score, the potential of overcoming some of the well-known limitations of ID thresholds is evident. For example, rainfall properties could be combined with measured, remotely sensed or modelled variables, such as discharge or soil moisture products (Wicki et al., 2020). Recently, random forests have been used to detect mass movements from seismic signals (Wenner et al., 2021; Chmiel et al., 2021) and could be coupled with rainfall measurements or forecasts to potentially increase the accuracy. It would also be interesting to study the spatio-temporal rainfall structure from radar-based rainfall estimates and their influence on debris-flow triggering (Marra et al., 2016). Of course, random forests are only one alternative to ID thresholds, and there are other algorithms to be tested (see Kern et al., 2017, for a review on post-wildfire debris flows). A drawback of such empirical thresholds is that long-term observations are required to establish them. Where such data are available, additional predictors can easily be implemented in a RF classifier, as presented here, and tested regarding their predictive power.

## 420 5 Conclusions

In this study we used a 17-year record of precipitation and debris-flow timing and magnitude to complete a systematic analysis of rainfall conditions leading to debris-flow triggering in a Swiss catchment, Illgraben. Based on 67 debris-flow triggering and 1657 non-triggering rainfall events (prevalence of 3.8%) we defined a rainfall intensity-duration threshold  $I = 5.2 \cdot D^{-0.70}$  with the most suitable fitting method applied in this work. Given the high debris-flow frequency in Illgraben, it can be considered as a lower threshold for rainfall-induced debris flows in the Swiss Rhône valley.

425 Debris-flow activity is greatest in summer, coinciding with peaks in total monthly rainfall accumulations and peak 30-min rainfall intensity. Although we find differences in seasonal ID thresholds, they are partly based on the occurrence of only a few triggering events (e.g. in autumn). It remains challenging to determine if the reason for this seasonality is due to seasonal differences in rainfall, in sediment availability or related to processes such as snowmelt or grain size coarsening.

430 Our systematic analysis of the uncertainties associated with ID thresholds shows that, for a catchment with rainfall-induced debris flows, 25 debris-flow observations are sufficient to constrain the ID-threshold parameters  $\alpha$  and  $\beta$  with uncertainties of  $\leq 30\%$ . However, our findings demonstrate that this uncertainty strongly depends on the data set and the method used to determine ID-threshold parameters. When comparing the Illgraben (local) data set with a Swiss landslide (regional) data set,

more triggering events (400) were needed for threshold parameters to converge in the regional data set, due to the higher spatial  
435 variability in the data set. More importantly, the best method to minimize uncertainties changed from LR&TSS for the local to TSS&TSS for the regional data set. This underlines the need for standardized methodologies for rainfall threshold identification and validation, and proper reporting of the methods used (see Segoni et al., 2018).

Finally, we aimed to lower the false alarm rate often associated with ID thresholds. Using a random forest model including the predictors rainfall event duration, mean rainfall intensity and the peak 30-min rainfall intensity increased the TSS (true skill  
440 statistic) by 0.04 (i.e.  $\sim 3$  more hits or  $\sim 70$  fewer false alarms). Adding more input variables to the random forest model, including antecedent rainfall, did not improve the performance. Although the expectation of significantly decreasing the false alarms was not fulfilled, we present a flexible framework where additional input variables can easily be tested. The aim of future work should be to include variables such as modelled or measured soil moisture or information on spatio-temporal rainfall structure from radar-based rainfall estimates. Machine learning algorithms can be helpful for maximizing information exploitation from  
445 available data and for increasing the accuracy of (debris-flow) early warning systems, and we have highlighted this potential.

*Data availability.* The debris-flow volumes are available from the Environmental Data Portal EnviDat (McArdell & Hirschberg, 2020, <http://dx.doi.org/10.16904/envidat.173>). Climate data are available for research purposes from the agencies mentioned in section 3.1.

*Author contributions.* JH conducted the analysis, produced the figures and wrote the original article draft. JH, BMA, AB and PM designed the study. EL provided the metadata of the regional data set and guided the analysis. All authors contributed to the interpretation of the results  
450 and to the revision of the article.

*Competing interests.* The authors declare that they have no conflict of interest.

*Acknowledgements.* This study was partly funded by the WSL research program CCAMM (Climate Change Impacts on Alpine Mass Movements). PM acknowledges funding from the Swiss National Science Foundation (grant no. 165979). We thank MeteoSwiss for providing climate data and the municipality of Leuk for providing rainfall data. We thank Melissa Dawes for improving the use of English in an earlier  
455 version of this manuscript. Finally, we thank Ben Mirus and Clàudia Abancó for their constructive reviews, which helped to improve the manuscript.
