**Abstract.** The Delft3D hydrodynamic and wave model is used to hindcast the storm surge and waves that impacted La Rochelle, France and the surrounding area (Aytré, Châtelailleur-Plage, Yves, Fouras and Ille du Re) during Storm Xynthia. These models are validated against tide and wave measurements. The models then estimate the footprint of flow depth, speed, unit discharge, flow momentum flux, significant wave height, wave energy flux, total water depth (flow depth plus 15 wave height), and total (flow plus wave) force at the locations of damaged buildings for which insurance claims data are available. Correlation of the hydrodynamic and wave results with the claims data generates building damage functions. These damage functions are shown to be sensitive to the topography data used in the simulation, as well as the hydrodynamic or wave forcing parameter chosen for the correlation. The most robust damage functions result from highly accurate topographic data, and are correlated with water depth or total (flow plus wave) force.

## 20 1 Introduction

In the end of February of 2010 the Xynthia extratropical storm caused damage and casualties along the Atlantic coast of Spain and France (Slomp et al., 2010, Chauveau et al. 2011). The highstrong winds-fields, and low atmospheric pressure both together with the landfall of the storm at high spring tide, createsgenerated an unprecedented water levels at La 25 Rochelle and surroundings (Bertin et al., 2014.) The present paper develops damage curves for buildings in the area where the storm surge and waves of from the Xynthia storm caused the most damage. We drawon methods used to quantify damage due to hurricanes and tsunamis in the USA and Japan (Suppasri 2013, Hatzikyriakou et al., 2018, Tomiczek et al., 2017), but for the first time apply these to modern masonry structures in Europe affected by storm surge and waves from an 30 extratropical cyclone. Therefore, the main objective of the present study is to develop damage curves from damage ratio claims supported by hydrodynamic modelling, but not to present a new hydrodynamic model for this event which has been

Comment [MDL1]: Comment number 1 reviewer 2

already extensively and properly researched. A total of 423 reported claims in the area of study were used (Figure 1). The damage ratio (DR) is defined as the ratio of damages claimed by each property, to the total insured value of that property. More than 9% of the structures had a damage ratio (DR) higher than 0.5 (considerable damages), 30% had DR higher than 0.2 (medium damages) and 49% had low damages, this is a typical behaviour for damage data like the one reported in Fuchs, S. et al., 2019.

Comment [H2]: Comment editor

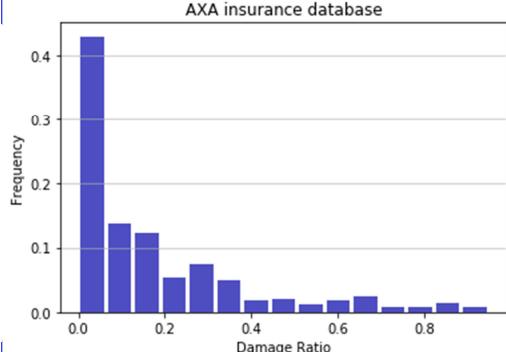

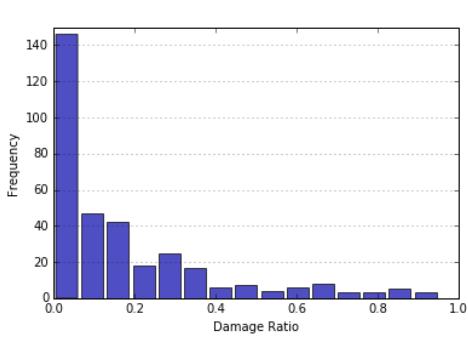

Figure 1: Damage ratio histogram for insurance claims data in the region.

The damage curve is an important tool in risk assessment science related to the vulnerability of structures (Pistrikas et al., 2010; Englhardt et al., 2019). From the structural point of view, damage curves depend on the construction materials that buildings are made of (Huizinga, et al., 2017; Postacchini et al., 2019; Masoomi et al., 2019). Damage curves also depend on construction methods, codes, and building layout, including the distance between buildings (Suppasri et al., 2013; Jansen et al., 2020; Masoomi et al., 2019). The current paper focuses on 1-2 story masonry buildings under the effect of storm surge and wave forces produced by an extratropical storm in northwest France. The Xynthia storm provided a rare dataset of empirical measured damage from coastal flooding in a European country. In the same direction, inclusion Similar analysis of damage from other storms, with different return periods happened in the same region would have had help to reduce uncertainty scatter the extremes uncertainty (Breilh et al. 2014 and Bulteau et al. 2015), but for now but unfortunately no other claims data were available.

Comment [MDL4]: Reviewer 2 Line 30 comment

In flood risk assessment, the relation between the damage and the hazard is displayed by means of the quantified by fragility curves and the depth damage curves. The differences between these two is that the fragility curves express the probability that a structure is damaged into a certain proportion specified structural state (Tsubaki R. et al., 2016), and while the depth damage curves instead is focused to assess the percentage cost of economic damage that incurred by flooding of a flood event can lead given structure (Englhardt J. et al., 2019 and Huizinga, J., et al., 2017). For both cases it is important to highlight the fact that these curves are usually build relating the hydraulic depth with the percentage of damage.

Comment [MDL5]: Comment xavier

55 flood depth alone to quantify the hazard (Pregnolato M. et al., 2015), and while there are fewer studies that attempt to relate other variables to the hazard by other variables like the flow velocity, significant wave height or wave energy force (Kreibich H. et al., 2009 and De Risi R. et al., 2017). For instance, in Tomiczek T. et al. (2017), an analysis respects related the flow velocity and to the structure damages state (DS) in New Jersey for hurricane Sandy was executed. In the present study we relate eight different hydrodynamic variables to the damage ratio coming from real insurance claims following extratropical storm Xynthia. |

Comment [MDL6]: Comment reviewer 2 line 38

Comment [MDL7]: Comment 1 reviewer 1

60 Damage curves are commonly developed by the correlation of field or laboratory measurements of damage, with numerical simulations of hazard level. Tsubaki et al. (2016) measured railway embankment and ballast scour in the field, and correlated this damage with flood overflow surcharge calculated by a hydrodynamic flood simulation. Englhardt et al. (2019) and Huizinga et al. (2017) used big-data analytics to correlate tabulated damages with estimated flood levels over a large scale. 65 Pregnolato et al. (2015) showed that most damage functions are based on flood depth alone, though a few also consider flow speed (De Risi et al., 2017; Jansen et al., 2020) or flood duration. The water depth is an important variable since it accounts for the static forces that act over a structure. Nevertheless, in storm events, structures close to the coast at a foreshore/backshore can be subjected to dynamical forces like the action of flow and waves (Kreibich et al., 2009; Tomiczek et al., 2017). For this reason, in order to consider other possible forces the following hydrodynamic parameters are analysed: 70 water depth ( $h$ ), flow speed ( $v$ ), unit discharge ( $hv$ ), flow momentum flux ( $\rho hv^2$ ), significant wave height ( $H_{sig}$ ), total water depth ( $h + H_{sig}$ ), wave energy flux ( $E_f$ ), and total force ( $\frac{E_f}{C_g} + \rho hv^2$ ). The wave energy flux is defined via Eq. (1) as in Bricker et al. (2017).

$$E_f = \frac{1}{16} \rho g H_{sig}^2 C_g, \quad (1)$$

75 where  $H_{sig}$  (m) is the significant wave height,  $C_g$  (m/s) is the wave group velocity,  $\rho$  (kg/m<sup>3</sup>) is the water density and  $g$  (m/s<sup>2</sup>) is the acceleration due to gravity, and  $C_g = \sqrt{gh}$  over land where waves impact buildings. |

## 2 Methods

80 Formatted: Heading 1

Damage curves were developed by hindcasting the hazard with a meteorological model, followed by a hydrodynamic (tides and storm surge) and wave model, and then correlating the resulting flood conditions with claimed damages (Figure 2).

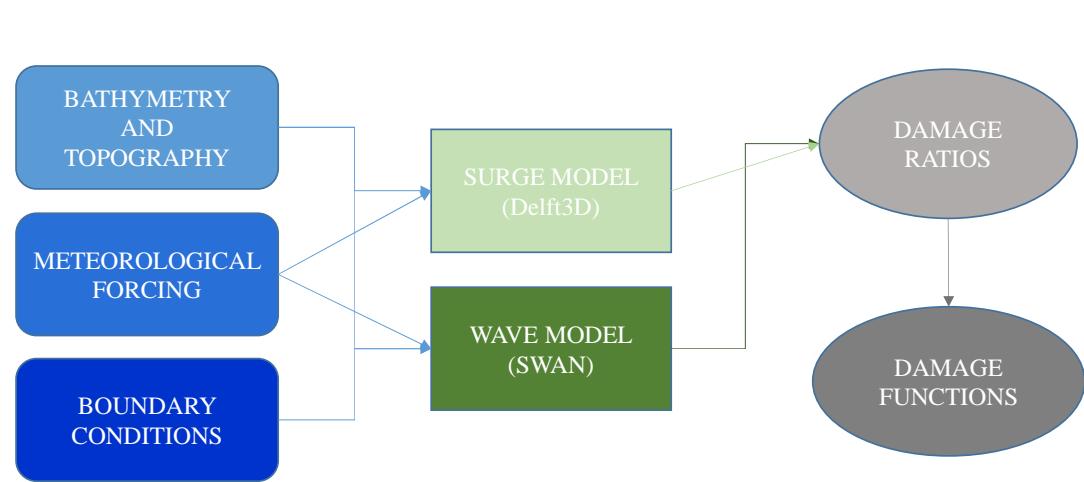

Figure 2: Flow chart of the framework used in development of damage curves.

← → Formatted: Caption

### 2.1.2 Meteorological model setup

To generate pressure and wind fields to drive the storm surge model, dynamically downscaled surface meteorological data were generated for the French Atlantic study region (Figure 3). This contains zonal and meridional winds 10 m above ground ( $u_{10}$ ,  $v_{10}$ ) and surface pressures over sea and land, with 3.5 km spatial resolution and 3hrs temporal resolution. The dynamical downscaling was performed with the regional climate model WRF (Skamarock et al., 2008), based on NCEP CFSR reanalysis data (Saha et al., 2010). The regional non-hydrostatic WRF model (version 3.4) simulated 15 February 2010 until 05 March 2010. The initial and lateral boundary conditions are taken from the CFSR reanalysis at 0.5° resolution, updated every 6 h. The horizontal resolution is 7 km; we use a vertical resolution of 35 sigma levels with a top-of-atmosphere at 50hPa. The simulation domain was chosen to be wide enough in latitude and longitude for WRF to fully simulate the large-scale atmospheric features of the Xynthia extratropical cyclone. A spin-up time of 5 days was considered in the study to remove spurious effects of the top layer soil moisture adjustment even though most of the analyses here are performed over the ocean. Land surface processes are resolved by using the Noah Land Surface Model scheme with four soil layers. Numerical schemes used in the Xynthia downscaling WRF simulation are the Multi-Scale Kain-Fritsch scheme for convection, the Yonsei University scheme for the planetary boundary layer, the WRF Single-Moment 6-class scheme for microphysics, and the RRTMG scheme for shortwave and longwave radiation. WRF outputs are generated every 3 hours. As shown schematically in Figure 2, Delft3D FLOW calculates non steady flow phenomena that result from tidal and meteorological forcing on a rectilinear or a curvilinear grid (Deltares, 2021). At the same time, and coupled with Delft3D, a numerical wave model (SWAN) calculates significant wave height and period fields. Delft3D FLOW and SWAN were used to hindcast the physical forcing at the locations of all claims in the database. Afterwards, a probability standardized normal

105

distribution function proposed by Suppasri et al., 2013 was used to develop damage curves by correlating claimed damage with a variety of hydrodynamic forcing variables.

## 125 2.1 Hydrodynamic model of the Xynthia Storm

In order to capture the hydrodynamic storm characteristics, a regional model domain over the Atlantic Spanish and French coasts was built. As shown schematically in Figure 2, Delft3D calculates non-steady flow phenomena that result from tidal and meteorological forcing on a rectilinear or a curvilinear grid (Deltares, 2021). At the same time, and coupled with Delft3D, a spectral wave model (SWAN) calculates significant wave height and period fields. Delft3D and SWAN were used to hindcast the physical forcing at the locations of all claims in the database. Afterwards, a probability standardized normal distribution function as proposed by Suppasri et al. (2013) was used to develop damage curves by correlating claimed damage with a variety of hydrodynamic forcing variables. To conserve computational resources and reduce computation time, domain decomposition (2-way hydrodynamic nesting) was implemented with grids of resolution of ~2km over the open ocean, ~400m close to the study area and ~80m over the area of claims data (Figure 3Figure 23). Additionally, a survey of the flood walls height was performed during August of 2020 in order to include them as thin weirs inside the Delft3D model, and in this way overcome the fact that inside the high resolution 5m topography, this structures are not represented as suggested by Bertin et al., 2014.

**Comment [JB15]:** no temporal evolution if you don't have the track. Delete the title then.

Figure 3: Domain decomposition of three nested grids running in parallel. The Xynthia storm track-center is shown as a triangle with at the time of minimum atmospheric pressure of 966 hPa at 2010-02-27 21:00:00 (Extreme Wind Storm Catalogue). Topographic map inset covers the smallest domain shown on the large map. Satellite image by OpenLayers – QGIS.

### 2.1.1 Topography and Bathymetry

145 We use two types of topography datasets: a global dataset for the bathymetry/topography (GEBCO 2019, which is based on SRTM 15+ v2 over land), and a higher resolution bathymetry (MNT – HOMONIM project) and topography (IGN institute). Additionally, a survey of the flood walls height was performed during August of 2020 in order to include them as thin weirs inside the Delft3D model, and in this way overcome the fact that inside the high resolution 5m topography, these structures are not represented, as suggested by Bertin et al. (2014).

150 Luppichini et al. (2019) and Ettritcha et al. (2018) found that the quality of bathymetry and topography data has a large effect on estimation of the hazard, and Brussee et al. (2021) similarly found topography data quality affects resulting damage estimates. In order to investigate the effect of the quality of topographic and bathymetric data on the resulting damage functions, three scenarios are considered in our work (Table 1).

155 **Table 1: Case studies for investigating sensitivity of model result to DEM resolution.**

Item	Low resolution (a)	High resolution (b)	High resolution + structures (c)
Topography	GEBCO (500m)	IGN (5m)	IGN (5m) + flood walls surveyed by the authors with an RTK-GPS
Bathymetry	GEBCO (500m)	GEBCO (500m) in deep water + MNT (100m) nearshore	GEBCO (500m) in deep water + MNT (100m) nearshore

### 2.1.2 Meteorological setup

To generate pressure and wind fields to drive the storm surge model, dynamically downscaled surface meteorological data were generated for the French Atlantic study region (Figure 3). It contains zonal and meridional winds 10 m above ground ( $u10, v10$ ) and surface pressures over sea and land, with 3.5 km spatial resolution and temporal every 3 hrs temporal resolution. The dynamical downscaling was performed with the regional climate model WRF (Skamarock et al., 2008), based on NCEP CFSR reanalysis data (Saha et al., 2010). The regional non-hydrostatic WRF model (version 3.4) simulated 15 February 2010 until 05 March 2010. The initial and lateral boundary conditions are taken from the CFSR reanalysis at  $0.5^\circ$  resolution, updated every 6 h. The horizontal resolution is 7 km; we use a vertical resolution of 35 sigma levels with a top of atmosphere at 50hPa. The simulation domain was chosen to be wide enough in latitude and longitude for WRF to fully simulate the large scale atmospheric features of the Xynthia extratropical cyclone. A spin up time of 5 days was considered in the study to remove spurious effects of the top layer soil moisture adjustment even though most of the analyses here are performed over the ocean. Land surface processes are resolved by using the Noah Land Surface Model scheme with four soil layers. Numerical schemes used in the Xynthia downscaling WRF simulation are the Multi-Scale Kain-Fritsch scheme for convection, the Yonsei University scheme for the planetary boundary layer, the WRF Single-Moment 6-class scheme for microphysics, and the RRTMG scheme for shortwave and longwave radiation. WRF outputs are generated every 3 hours.

### 2.2 Hydrodynamic and Wave Model setup

Delft3d was coupled together with SWAN in a domain decomposition mode in order to hindcast storm tide and waves. Model boundary conditions consisted of astronomical tidal water elevations from the Global Tide and Surge Model (GTSM) of Muis et al. (2016) for the period from 20 February until 1 March 2010. The hydrodynamic model was run with a computational time step of 30 sec and a uniform Manning's  $n$  of 0.025. The air-sea drag coefficient of Smith and Banke (1975) was used. Other model parameters retained their default settings.

## 180 2.3 Hydrodynamic and wave model validation

## 2.3.1 Storm tide validation

The hydrodynamic model was run from 20 February until 1 March 2010, the duration of the meteorological forcing data, with GTSM astronomical tide boundary conditions.

To better understand how the modelled tide follows the observed tide which of the variables fit (and also to compare the damage functions development best). For validation, three accuracy indicators are assessed: root mean square error (RMSE, Equation 3), relative root square error (RRSE, Equation 4), and the Pearson correlation coefficient ( $\rho$ , Equation 5).

$$RMSE = \sqrt{\frac{\sum_1^T (y' - y)^2}{T}}, \quad (3)$$

$$RRSE = \sqrt{\frac{\sum_1^T (y' - y)^2}{\sum_1^T (y - \bar{y})^2}}, \quad \bar{y} = \frac{\sum_1^T y}{T} \quad (4)$$

$$\rho_{y,y'} = \frac{cov(y, y')}{\sigma_y \sigma_{y'}}, \quad (5)$$

190 where  $y'$  is the predicted value,  $y$  is the actual value and  $\bar{y}$  is the average of the actual values to predict.  $T$  is the number of values, and  $\sigma$  indicates the standard deviation

195 After 2 days of model spin-up (the time required for the model to correct the assigned initial condition), the comparison between the observed water levels from SHOM-Coriolis tide gauges (<http://www.coriolis.eu.org/>), and modelled water levels from Delft3dD, during the whole simulation is goodacceptable (Figure 4) according to the results for the goodness of fit indices in table 2. If we compare these values with typical values in the literature like in such as Matte et al. (P. et al., 2014) or Tranchant Y. et al. (2021) we observe the current modelled water levels fit the observations goodwell. Note that the Les Sables gauge failed at the peak of the storm (on 2010-02-28 03:00:00) so a data point is missing in the observations at that time. At La Rochelle the difference between the observed and modelled water level is only 36cm at peak storm tide.

Comment [MDL17]: Comment reviewer 2 line 136

Comment [MDL18]: Comment reviewer 2 line 142

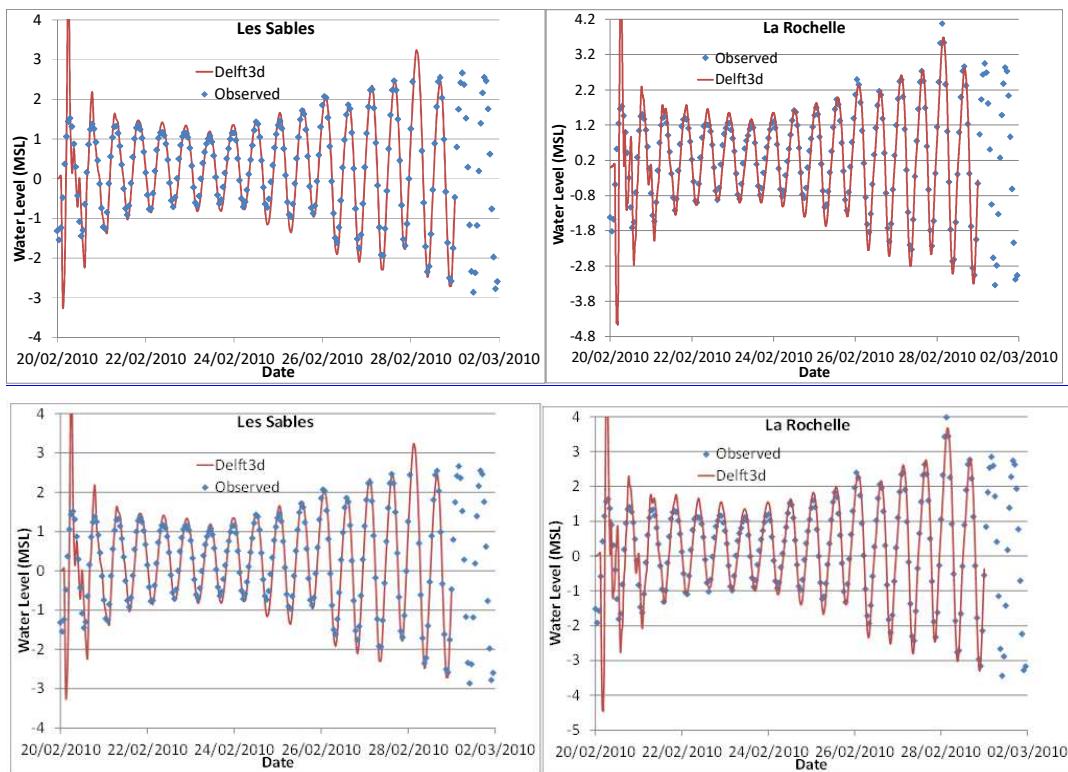

Figure 4: Observed and modelled tide at La Rochelle and Les Sables. Note that during the peak of the storm tide at Les Sables, the tide measuring gauge was out of operation, resulting in a missing data point in that data series.

#### 205 2.3.2 Wave model validation

The wave model was validated against data from the [SHOM-CORIOLIS](http://www.coriolis.eu.org/About-Coriolis) operational oceanography center (<http://www.coriolis.eu.org/About-Coriolis>) in Figure 5. Important to mention is that the data available at the buoys stations do not include the significant wave height, therefore the swell height were was extracted to compare the results from Delft3D-SWAN. The uncertainty produced by the meteorological downscaling by means of the WRF model in the hindcast 210 of the winds can add errors in the results. Unfortunately, no more meteorological information is available. If we again compare the indices from table 2 to those found in the literature like such as Baron-Hyppolite et al. (, C., 2019), we find comparable goodness of fit between modelled and measured waves see that the big difference is probably due to the comparison of two different variables.

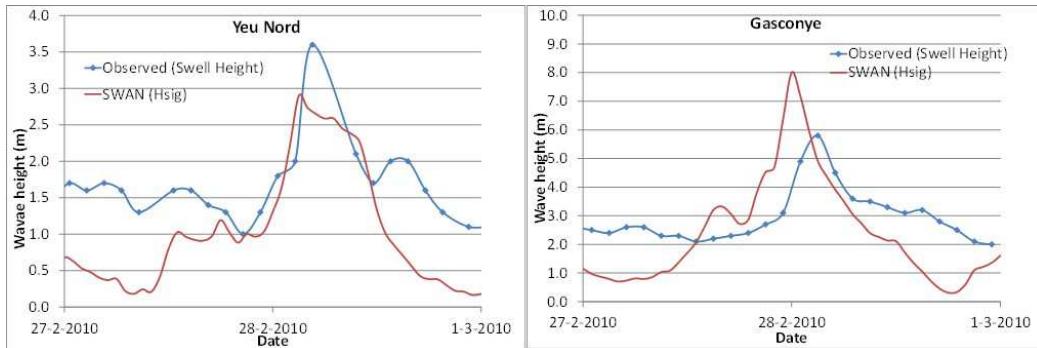

Figure 5: Deep water buoys of Yeu Nord (left) and Gasconye (right). In the first case the buoy is located close by an Island with of the same name. The second is located in the open ocean almost in the middle of the Viséay gulf Bay of Biscay.

Table 2: Goodness of fit for the tideswater level and waves stations measurements compared with the results from of Delft3D-SWAN coupling.

Station	RMSE (m)	$\rho$	RRMSE
Gazconye	1.5434	0.6228	0.10679
Yeu Nord	0.8668	0.6985	0.11116
Les Sables	0.4959	0.9197	0.1381
La Rochelle	0.4991	0.9157	0.1374

#### 2.4 Damage curves

Damage curves express the amount of damage experienced by a structure, relative to the structure's total insured value. It connects More specifically, relates The cumulative distribution function, usually in terms of the standardized normal distribution function with the damages (Suppasri et al., 2013; Sihombing and Torbol, 2016) is shown in Equation (2).

$$225 \quad P(x) = \Phi \left[ \frac{x-\mu}{\sigma} \right], \quad (2)$$

where  $P(x)$  is the cumulative probability of the damage ratio with values between 0 and 1, and level  $x$  is the hydrodynamic variable,  $\Phi$  is the standardized normal distribution,  $\mu$  is the median and  $\sigma$  the standard deviation (Tsubaki et al., 2016). It is also very common to express the previous equation (1) as a logarithmic function in order to obtain easily the parameters of the distribution with least square fitting as proposed by Suppasri et al. (2013). In the present paper, the parameters are assessed using the L-moments package within the open source program R. In this way, it is possible to relate different hydrodynamic variables with the damage ratio. From the 423 claims data within our domain, approximately 185 are on Ille du Re, and the remaining 238 in the towns of La Rochelle, Aytré, Yves, Châtelailleur-Plage and Fouras. At everyeach claim -

### 235 3 Results

After determining the model hydrodynamic and wave results (Figure 6) at the location of each claim location, the data were subdivided into ten categories according to damage ratio level, and Box-Whisker plots were built to display the entire dataset and analyse the trend of the data (Appendix A). Among the flow-only variables, the unit discharge ( $hv$ ) appears to have the clearest trend and least scatter. From the variables related to both flow and waves, the total force ( $\frac{E_f}{c_g} + \rho hv^2$ )

240 appears to have the clearest trend and correlation with the damage ratio. To better understand which of the variables fit damage functions best, three accuracy indicators are assessed: root mean square error (RMSE, Equation 3), Relative root square error (RRSE, Equation 4), and the Pearson correlation coefficient ( $\rho$ , Equation 5).

$$RMSE = \sqrt{\frac{\sum_{i=1}^T (y_i - \bar{y})^2}{T}}, \quad (3)$$

$$RRSE = \sqrt{\frac{\sum_{i=1}^T (y_i - \bar{y})^2}{\sum_{i=1}^T (y_i - \bar{y})^2}}, \quad \bar{y} = \frac{\sum_{i=1}^T y_i}{T} \quad (4)$$

$$\rho_{y\bar{y}} = \frac{cov(y, \bar{y})}{\sigma_y \sigma_{\bar{y}}}, \quad (5)$$

245 Where  $\bar{y}$  is the predicted value,  $y$  is the actual value and  $\bar{y}$  is the average of the actual values to predict,  $T$  is the number of values, and  $\sigma$  indicate the standard deviation

At In a Appendix B a comparison for other 2 typical distribution functions is made carried out. At the same it can be seen that the Gamma and GNO distributions have similar goodness of fit indicators, and while the Log Normal distribution performs a bit worse slightly worse overall, but for some variables have the best fit. An analysis on the uncertainty due to the statistical distribution selection or the inclusion of properties with no damages can be found at Fuchs, S. et al., 2019.

**Comment [H31]:** Comment of editor and reviewer 1 on the statistical distribution comparison and reviewer 2 on the no damage data

## 280 4 Discussion

The present paper considered the influence of flow-only variables ( $h, v, hv, \rho hv^2$ ), and combined flow-wave parameters ( $H_{sig}, h + H_{sig}, E_f, \frac{E_f}{c_g} + \rho hv^2$ ). Flow depth and total (flow plus wave) force produce the best fits with analytical functions. Goodness of fit to damage curves improves with quality of the topographic data used (Table 1). However, when applying damage curves in practice, it is important to base predictions off a similar model setup to that used when calculating the damage curves in the first place (Brussee et al., 2021). For example, if damage curves are built using coarse

**Comment [MDL32]:** Comment reviewer 2 line 164

topography that neglects the presence of thin seawalls (i.e. sheetpile/cantilever walls, or T- or L- walls), then the buildings protected by these walls might experience more intense hydrodynamic conditions in the simulation than if the walls had been present in the simulation. Since the actual recorded damage does not depend on the model used to calculate the hydrodynamic forcing conditions, damage curves developed using the coarse resolution topography will be shifted to the right relative to damage curves generated with the thin floodwalls present. If these damage curves generated using a coarse resolution simulation are then applied for damage prediction by an external user who applies a high resolution simulation that resolves floodwalls, the reduced forcing (due to the presence of these floodwalls) will generate a non-conservative result (too little damage), because the damage curves had been generated using forcing data from a simulation where the floodwalls had not been present. Therefore, when damage curves are reported in the literature, it is important to quantify how these vary with the topography used in the simulations on which the damage curves are based. However, in the current paper, Figure 7 shows that damage curves do not vary consistently leftward or rightward as topographic data are improved. This is because the response of forcing to the presence of these walls is more complex than simply reducing wave height. If not overfilled, walls reduce damage greatly. However, water depth can be exacerbated in front of walls, and flow can be channelled and intensified along walls, all increasing hydrodynamic forcing in some locations, preventing a simple relation between topographic resolution and damage curve robustness.

In addition to the general sensitivity of damage curves to topographic data quality, the damage curves displayed in Figure 7 do not consider certain physical wave-driven phenomena such as wave overtopping of structures (Lashley et al., 2020a; [Ke et al., 2021](#)) or infragravity waves generated by waves breaking in shallow water (Roeber and Bricker, 2015). For instance Lashley et al. (2019) discussed the importance of dike overtopping due to infragravity waves on nearshore developments that can induce wave-driven coastal inundation. The wave model used here, SWAN, does not include infragravity waves, nor does the combined Delft3D/SWAN flow/wave model simulate wave overtopping of dikes, possibly leading to an underestimation of the hydrodynamic forces on buildings, which would affect the resulting damage functions. However, consideration of wave overtopping and infragravity effects requires either phase-resolving wave simulations or empirical relations specific to the local topography (Lashley et al., 2020b), though this is beyond the scope of the current study, and is similarly neglected by most other large-scale inundation studies (i.e., Sebastian et al., 2014; Kress et al., 2016; Kowaleski et al., 2020). Nonetheless, the effect of infragravity oscillations and wave overtopping on resulting damage is an important item for future research.

[Another important factor mentioned ~~on~~by Bertin et al., \(2015,\)](#) was the particular track direction of the storm that for the ~~X~~ynthia event induced a young sea state, enhancing the surface stresses, and adding up to 40 cm to the theoretical surge and tide of their model.

[The uncertainty and variability within this methodology can be explained by two factors: 1\) the hydrodynamic modelling, and consequently, uncertainty in the hydrodynamic variables, and 2\) uncertainty in the claims data. Regarding the first point,](#)

320 there is a trend that indicates that better topography/bathymetry data gives hydrodynamic variables that correlate better with the damage ratio. The explanation of this is basically because higher resolution data brings generally more accurate results of the real flood conditions (Luppichini et al., 2019 and Ettritcha et al., 2018). Damage curves developed with a better representation of the topography (IGN + structures) improve the accuracy indicators (Table 3Table 3Table 2), though scatter in the data itself (Figures A1, A2 or A3) is large for all topographies. Inside this first point we can also mention the mesh resolution and the roughness coefficient assignation, since has been proven that these two variables can influence the hydrodynamic variables assessment. The second point, deals with the quality of the damage ratio data. It is well identifiedknown that insurance claims arecan sometimes be subject to fraud andor information distortion. Also variables related with the vulnerability of the assets like the construction characteristics, the materials, the quality and the age of the structures (Paprotny et al., 2021) play an important role in whether for a particular hydrodynamic variable value damage occurs or not. This adds a degree of complexity to the analysis

Comment [MDL33]: Line 99 reviewer 2 comment

## 5 Conclusions

335 Using insurance claims to build damage curves from the structures located in La Rochelle and surroundings provides valuable information on the future damages that can be expected from an extratropical storm strike on the French Atlantic coast. In the present study, the best correlation between the damage ratio and the hydrodynamic variables are the flow depth and the total (flow plus wave) force for the aforementioned flow-only and flow-plus-wave variables respectively. I

340 The uncertainty and variability within this methodology can be explained by two factors: 1) the hydrodynamic modelling, and consequently, uncertainty in the hydrodynamic variables, and 2) uncertainty in the claims data. Regarding the first point, there is a trend that indicates that better topography/bathymetry data gives hydrodynamic variables that correlate better with the damage ratio. The explanation of this is basically because higher resolution data brings generally more accurate results of the real flood conditions (Luppichini et al., 2019 and Ettritcha et al., 2018). Damage curves developed with a better representation of the topography (IGN + structures) improve the accuracy indicators (Table 2), though scatter in the data itself (Figures A1, A2 or A3) is large for all topographies. The second point, deals with the quality of the damage ratio data. It is well identified that claims are subject to fraud and information distortion. Also variables related with the vulnerability of the assets like the construction characteristics, the materials, the quality and the age of the structures (Paprotny et al., 2021) play an important role in whether for a particular hydrodynamic variable value damage occurs or not. This adds a degree of complexity to the analysis

Comment [MDL35]: Comment 8 reviewer 1

350 In addition to the sensitivity of results to resolution of the topographic and bathymetric data, the inclusion of thin flood walls via a land survey carried out by the authors also had a significant effect on the damage functions generated. This is

important to note, as thin steel or concrete structures like flood walls ~~at-are~~ typically only a few ~~10's of centdecimetres~~ thick, and ~~sotherefore~~ do not appear in digital elevation models. The effect of these thin structures on the resulting damage functions shows the importance of locally sourcing elevation data for the thin structures that are present, when conducting 355 risk analyses for coastal regions, though it is imperative to keep in mind agreement between the simulations used for developing the damage relations in the first place, with those where the damage relations are applied for further risk analysis.
