Abstract. Urbanization and climate change are the critical challenges in the 21st century. Flooding by extreme weather events and human activities can lead to catastrophic impacts in fast-urbanizing areas. However, high uncertainty in climate change and future urban growth limit the ability of cities to adapt to flood risk. This study presents a multi-scenario risk assessment method that couples the future land use simulation model (FLUS) and floodplain inundation model (LISFLOOD-FP) to simulate and evaluate the impacts of future urban growth scenarios with flooding under climate change (two representative concentration pathways (RCPs 2.6 and 8.5)). By taking coastal city of Shanghai as an example, we then quantify the role of urban planning policies in future urban development to compare urban development under multiple policy scenarios (Business as usual; Growth as planned; Growth as eco-constraints). Geospatial databases related to anthropogenic flood protection facilities, land subsidence, and storm surge are developed and used as inputs to the LISFLOOD-FP model to estimate flood risk under various urbanization and climate change scenarios. The results show that urban growth under the three scenario models manifests significant differences in expansion trajectories, influenced by key factors such as infrastructure development and policy constraints. Comparing the urban inundation results for the RCP2.6 and RCP8.5 scenarios, the urban inundation area under the growth as eco-constraints scenario is less than that under the business as usual scenario, but more than that under the growth as planned scenario. We also find that urbanization tends to expand more towards flood-prone areas under the restriction of ecological environment protection. The increasing flood risk information determined by model simulations help to understand the spatial distribution of future flood-prone urban areas and promote the re-formulation of urban planning in high-risk locations.

30 1 Introduction

31 Climate change and urbanization are the global challenges for the 21st century (Ramaswami et al., 2016; Pecl et al., 2017).
32 Floods have been key threats for many cities around the world driven by global climate change (Hallegatte et al., 2013; IPCC,
33 2014; Fang et al., 2020). Currently, more than 600 million people worldwide live in coastal cities that are less than 10 m
34 above sea level (United Nations, 2017). The United Nations reports that the global population living in cities is projected to
35 reach 6.7 billion by 2050 (United Nations, 2018), especially in low elevation coastal areas, the population density is expected
36 to be twice the current population density (Van Coppenolle and Temmerman, 2019), which means that the population of
37 coastal cities will become increasingly concentrated in the future and impervious surfaces will become more numerous
38 (Chen et al., 2020; He et al., 2021). On the other hand, the National Oceanic and Atmospheric Administration (NOAA)
39 report suggests that global mean sea level will rise around 0.2 m to 2.0 m by 2100 under a continuing global warming trend
40 (Parris et al., 2012). Additionally, properties and populations in many coastal areas will suffer more severely in the future if
41 the effects of land subsidence are taken into account (Vousdoukas et al., 2018).

42 However, high uncertainty in flood risk and urban growth leads to a lack of capacity of cities to respond to the flooding
43 arising from future climate change (Du et al., 2015; Tessler et al., 2015; Fang et al., 2021). Therefore, there is an urgent need
44 for specialist knowledge and techniques to address the conflict between urbanization and flood risk (Wang et al., 2015; Lai
45 et al., 2016; Bouwer, 2018; Haynes et al., 2018). Studies on urban flood risk assessment are more likely to simulate flood
46 risk using different climate change scenarios or integrating different flood sources (Huong and Pathirana, 2013; Muis et al.,
47 2015; Dullo et al., 2021). For example, Zhou et al. examine the impact of urban flood volumes and associated risks under
48 RCP2.6 and RCP8.5 scenarios (Zhou et al., 2019). Parodi et al. integrate the compound flood scenarios such as wave height,
49 storm surge, and extreme sea level due to sea level rise to assess coastal flood risk (Parodi et al., 2020). However, ignoring
50 the uncertainty of urban growth in urban flood risk assessment reduces the validity of the assessment (Gori et al., 2019), and
51 hence an increased understanding of possible urban growth scenarios is needed, otherwise there is a lack of understanding of
52 the consequences of future flooding (Zhao et al., 2017; Kim and Newman, 2020). Although there are some studies have
53 quantified urban growth and assessed flood risk, such as Chennai (Nithila Devi et al., 2019), Guangzhou (Lin et al., 2020),
54 Shanghai (Shan et al., 2022), these studies have not considered the development of urban areas under different growth
55 scenarios and the assessment of flood impacts after the implementation of these scenarios. In addition, the failure to integrate
56 with broader climate change-related scenarios and possible extreme-case flood risks has led to underinvestment in climate
57 adaptation actions by governments that do not well address the spatial consequences of future floods (Reckien et al., 2018;
58 Berke et al., 2019). Thus, there is an urgent need to adopt a more comprehensive approach to assess the complexity of
59 multiple possible scenarios of urbanization and dynamic flood risk in an integrated manner.

60 This paper uses the coupling of the future land use simulation model (FLUS) and the 2D floodplain inundation model
61 (LISFLOOD-FP) to explore the possible interaction between different urbanization development scenarios and climate
62 change scenarios. The FLUS model improves the simulation accuracy of the model by combining artificial neural network

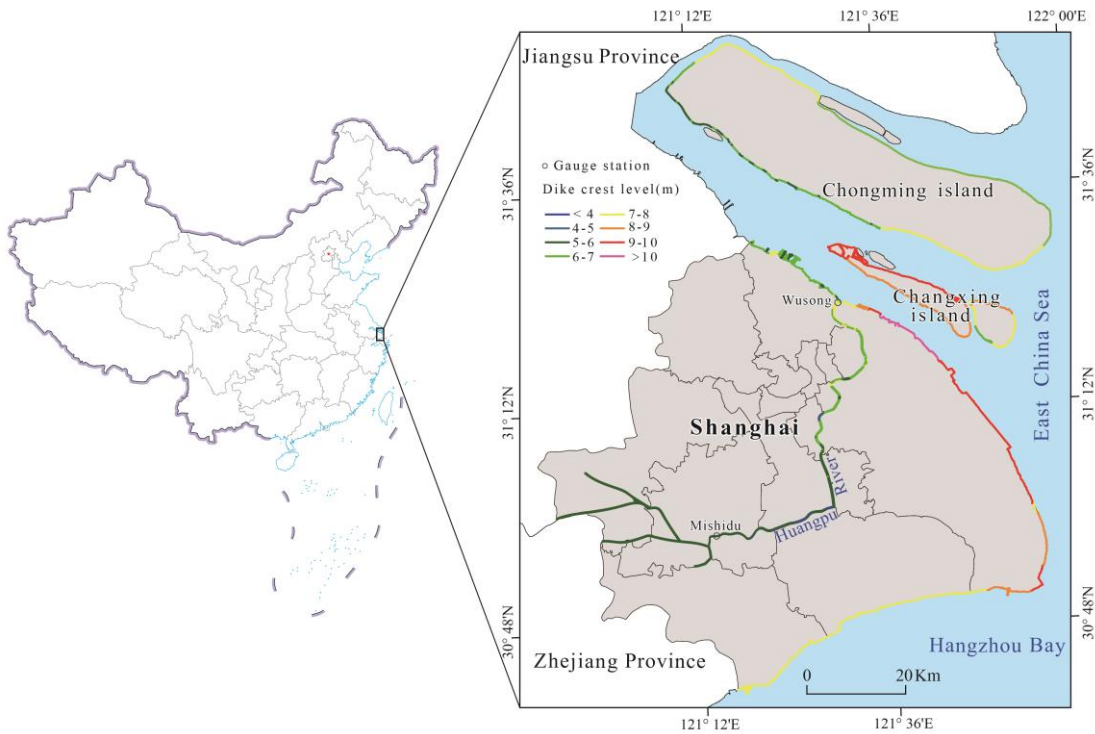

(ANN) and Cellular automata (CA) model to simulate nonlinear land use changes while considering parameters related to environment, society, climate change, etc. (Liu et al., 2017; Zhai et al., 2020). The LISFLOOD-FP model has become a mature hydrodynamic model that can predict potential flood events in near real-time and is widely used in engineering applications (Wing et al., 2019; Sosa et al., 2020). The coastal metropolitan Area of Shanghai in the Yangtze River Delta in China, one of the fastest urbanizing cities in the world, is used as a case study.

The paper asks, how different urban growth scenarios combined with climate change scenario analysis may help to inform preparedness for flood risks from climate change in urban flood risk assessments? To answer this question, we first assume some future simulation scenario by considering the factors that influence urban growth and lead to flood risk. Secondly, we coupled urban growth and flood risk scenarios and compared them using climate change scenarios from two representative concentrated pathways (RCP 2.6 and 8.5) proposed by the Intergovernmental Panel on Climate Change (IPCC). Finally, we assessed the risk of flooding in different urban development scenarios. The research illustrates the importance of assessing the performance of different future urban development scenarios in response to climate change, and the simulation study of urban risks will prove to decision-makers that incorporating disaster prevention measures into urban development plans will help to reduce disaster losses and improve the ability of urban systems to respond to floods.

2 Study area and datasets

2.1 Study area

As the alluvial plain of the Yangtze River Delta, Shanghai is located on the coast of the East China Sea between 30°40′–31°53′N and 120°52′–122°12′E, which borders the provinces of Jiangsu and Zhejiang to the West (Fig. 1). It's a typical middle latitude transition belt, marine land transitional zone and also a typical estuarine and coastal city with a fragile ecological environment. The land area of Shanghai is about 6340.50 km², accounting for 0.06 % of the total area of China, and has 213 km of coastlines. The Shanghai metropolitan area has undergone rapid urban expansion in the past decades and has become one of the largest urban areas in the world in both size and population (Sun et al., 2020). However, Shanghai's topography is low, with an average elevation of 4 m above sea level, and there is no natural barrier against storm surges. In 1905, one of the deadliest storm surges occurred in Shanghai, killing more than 29,000 people. Two years later, Typhoon Winnie made landfall in Shanghai, flooded more than 5,000 households (Du et al., 2020). The reasons for Shanghai's greater vulnerability maybe include the multiple effects of sea level rise due to climate warming, ground subsidence and storm surge water gain

93 2.2 Data

94 The research used three main categories of data, including basic data, scenarios constraints data and flood simulation data
 95 (Table 1). The basic data include land use, topography, traffic network, traffic site, socio-economic data. The land use data
 96 with a resolution of 100 m×100 m from the Resource and Environmental Science and Data Center of the Chinese Academy
 97 of Sciences is currently the most accurate land use remote sensing monitoring data product in China (Liu et al., 2014). The
 98 data for 2005 and 2010 were derived from Landsat-TM/ETM remote sensing image data respectively, and the data for 2015
 99 were interpreted using Landsat 8 remote sensing image. After the data were corrected and visually interpreted, the
 100 comprehensive evaluation accuracy of the interpretation accuracy of the first-class types of cultivated land, woodland,
 101 grassland, water area, urban land, and unused land reached more than 94.30 %, and the discrimination accuracy rate on the
 102 map patches reached 98.70 % (Xu et al., 2017). Within the allowable error range, it can be used as the basic data for
 103 analyzing land use changes.

104 Topography factors (DEM, slope), traffic network factors (distance to railway, highway, subway, and main roads), traffic
 105 site factors (distance to the city center, train station, and airports) and socio-economic factors (population, GDP), etc. as well
 106 as planning constraints, were determined to be spatial influence factors of the flood risk assessment of the Shanghai area.
 107 The Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER) digital elevation model (DEM), which

has 30-meter resolution, served as the basis data for terrain heights and slopes. ASTER-DEM has been shown to be the most stable data performer among six types of open access DEM products (SRTM, ASTER-DEM, AW3D, MERIT, NASADEM and CoastalDEM) for flood inundation simulations with different return periods (Xu et al., 2021). Traffic network and site were collected from open-source data retrieved from OpenStreetMap (OSM) and POI data were extracted from Tencent Map. Euclidean distance was calculated for all vector data. The data of population and gross domestic product (GDP), were provided by the Resource and Environmental Science and Data Center of the Chinese Academy of Sciences (Xu, 2017a, 2017b), and their time span was consistent with the land use data. According to the simulation forecast demand, all materials were converted into 100×100 m grid by resampling. The spatial limiting factors were the basic ecological control line, permanent basic cropland and cultural protection control line as outlined in the 2017–2035 Shanghai City Master Plan. All the impact factor data were normalized, and the range of the value is between 0 and 1 to subsequent data mining. The storm surge data are derived from the Global Tide and Surge Reanalysis (GTSR) dataset, which is the values of storm surge and extreme water levels for different return periods simulated using hydrodynamic modelling based on the water levels of global tide stations from 1979-2016. The data are vector data covering the global coastline and were obtained from 4TU.ResearchData (see Supplementary Figure 1 for GTSR data in this study area). This dataset has been widely used in different regions of the world and has been validated to be of good accuracy (Muis et al., 2016). In addition, man-made flood defenses have been considered to reasonably evaluate the inundation impact of the flooding. The man-made flood defenses data was obtained from the historical archival of the Shanghai Water Authority for Shanghai (Yin et al., 2020). All data sources are listed in the table below.

Table 1. Data required and sources. The list details the resolution and sources of the data in the study.

Category	Data Type	Resolution	Source
Basic data	Land use	100 m × 100m	Resource and Environmental Science and Data Center (http://www.resdc.cn)
	Topography	Vector line	ASTER GDEM (https://earthexplorer.usgs.gov/)
	Traffic network	Vector line	OpenStreetMap (https://www.openstreetmap.org)
	Traffic site	Vector point	Tencent Map (https://map.qq.com/)
	Social economy	1 km × 1 km	Resource and Environmental Science and Data Center
Scenarios constraints	Ecological control line	Vector line	《2017-2035 Shanghai City Master Plan》
	Permanent basic cropland control line	Vector line	
	Cultural protection control line	Vector line	

Flood data	Floodwalls	Vector line	Shanghai Water Authority (http://swj.sh.gov.cn/)
	Storm surge	Vector line	GTSR (http://data.4tu.nl/)

127 **3 Methodology**

128 The presented approach for relative sea level rise scenario flood risk assessment is the integration of the FLUS model,
129 LISFLOOD-FP model. In the framework, the FLUS model combined with Markov chain model are designed to stimulate
130 complex land-use change processes in three different scenarios through 2030 to 2050, which include Business as usual (BU),
131 Growth as planned (GP), Growth as eco-constraints (GE) scenarios. A Markov chain model is used to predict land-use
132 demand in 2030 and 2050, combining planning policy factors, which is one of the crucial data inputs in the FLUS model.
133 Next, the LISFLOOD-FP two-dimensional flood model is used to explore the potential flooding areas under the RCP 2.6 and
134 8.5 scenarios in 2030 and 2050, to avoid the overestimation of the submerged range based on the GIS-based elevation area
135 method. This model also considers the compound influence of sea-level rise, storm surge, and land subsidence. Finally, via
136 ArcGIS spatial comprehensive analysis, the flooding of different land types is calculated employing different flooding
137 scenarios. The overall flow chart of research is illustrated in Fig. 2.

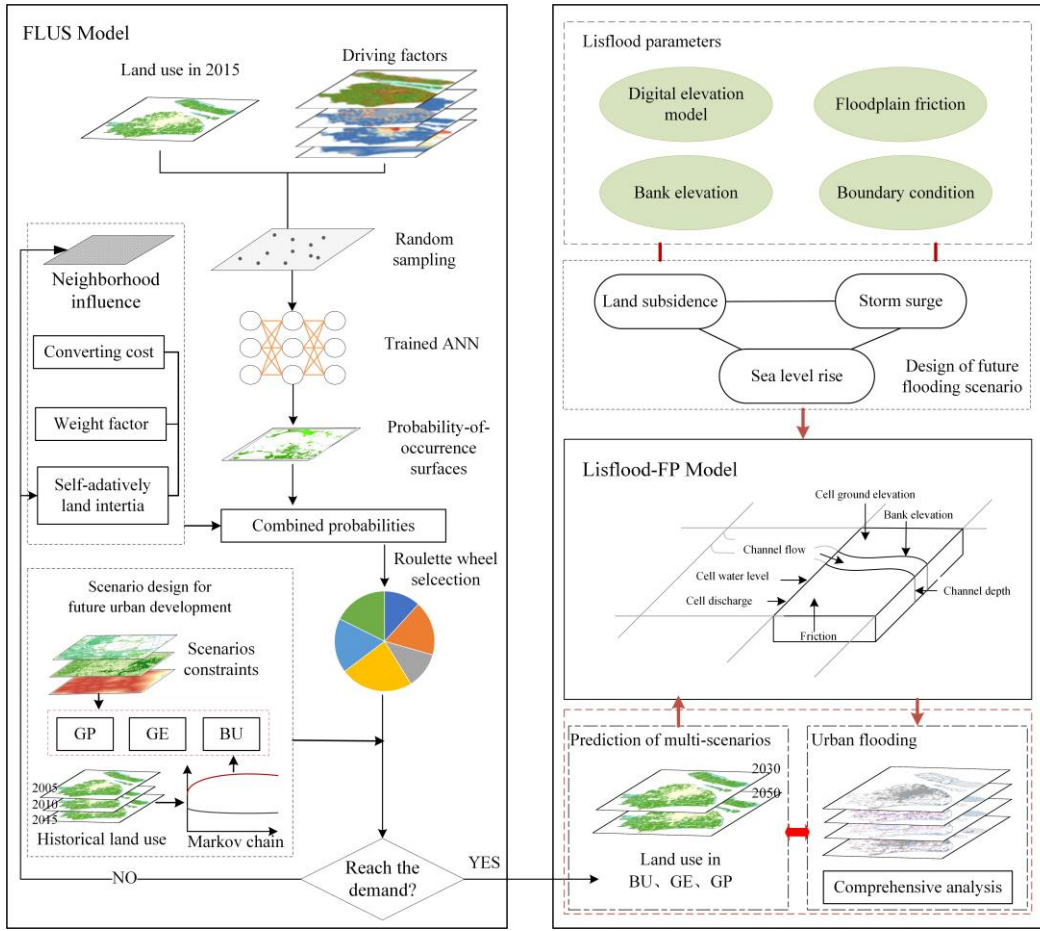

Figure 2: The overall flow chart of research.

3.1 Markov chain model

Markov chain model refers to the random transition process of state from one state to another, and its future state is only related to the state at previous moment. In the study of land use change, the type of land use at a certain moment is only related to the type of land use at the previous moment. Therefore, land-use change is a typical Markov process and has widely used in the prediction of land-use changes (Zhou et al., 2020). We predicted future land use by Eq. (1):

$$S_{(t+1)} = P_{i,j} \times S_t \quad (1)$$

where S_t and S_{t+1} represent the land use at times t and $t+1$, and $P_{i,j}$ is a state transition matrix that land-use type i is converted to land-use type j . This model has a good predictive effect on the process state (Gounaridis et al., 2019). Therefore, we use the Markov chain to calculate the probability of the conversion of various land types, and then predict the number of future land changes.

150 3.2 The FLUS land use simulation model

151 The FLUS model is an upgraded version of a cellular automata model (Liu et al., 2017) which can solve the complex land
152 use simulation problems by self-adaptive inertia and competition mechanism. The FLUS shows the highest current
153 performances than other simulation models such as CLEU-S, SLEUTH, and LTM and has been applied to land use change
154 simulation research at different scales and for different purposes (Liang et al., 2018; Lin et al., 2020).

155 As the most important scheme to manage the space of the urban area, an urban land use plan can reflect the general
156 arrangement of land use in the future (Xu and Yang, 2019). In this research, three categories of urban growth scenarios are
157 simulated through the FLUS model. The similarity of the three scenarios is that they use factors that affect urban
158 development and changes, such as population, GDP, traffic, and slope, as the main spatial driving factors. The difference are
159 as follows:

160 (i) Business as usual (BU): BU is natural growth without development laws and regulations. Its development is based on the
161 premise of the current urban development patterns. Therefore, the land demand predicted by Markov is used as the constraint
162 condition for the iteration of CA model in the subsequent application of the scenario.

163 (ii) Growth as planned (GP): Under the GP scenario, the urban growth projection that closely link to the master plan for
164 Shanghai in terms of quantity, reflecting how the city government prefer to develop. The master plan requires that the total
165 area of planned urban construction land does not exceed 3,200 km² in 2035. We choose an urban area of 2768 km² in 2030
166 and 3200 km² in 2050 as the constraints under the GP scenario. The reason is that the Markov chain model projections result
167 in an urban area is 2768 km² in 2030 and 3270 km² in 2050, and the total urban construction land area in 2035 of the
168 Shanghai Master Plan does not exceed 3200 km².

169 (iii) Growth as eco-constraints (GE): The GE scenario is an eco-environmental protection scenario in which development is
170 limited by ecological environment protection. Combined with Shanghai's ecological and environmental protection
171 requirements and the distribution of permanent basic farmland, sensitive areas restricted for development are identified in the
172 scenario, and we also establish a cultural protection control line for strengthening historical and cultural protection. In
173 addition, the number of areas of future urban growth in the GE scenario also combines the requirements given in the urban
174 master plan to enhance the reality of the scenario.

175 Therefore, the FLUS model is used to simulate future urban growth combining various scenarios. First, the driving factors
176 and land-use data are trained by an ANN model to obtain a probability-of-occurrence map, and then incorporate with the
177 self-adaptive land inertial, conversion cost, and neighborhood competition among the different land use types to estimate the
178 combined probability for each grid. Next, combining the number of various types of land predicted by the Markov Chain
179 model and considering the constraints of each scenario to predicted urban growth in 2030 and 2050. To better validate the
180 model before predicting future change, we compared the output with the actual land use 2015. Note that the number of
181 iterations in each scenario is set to 5000, which is much higher than the default value to show higher prediction accuracy.

182 3.3 The LISFLOOD-FP flood inundation model

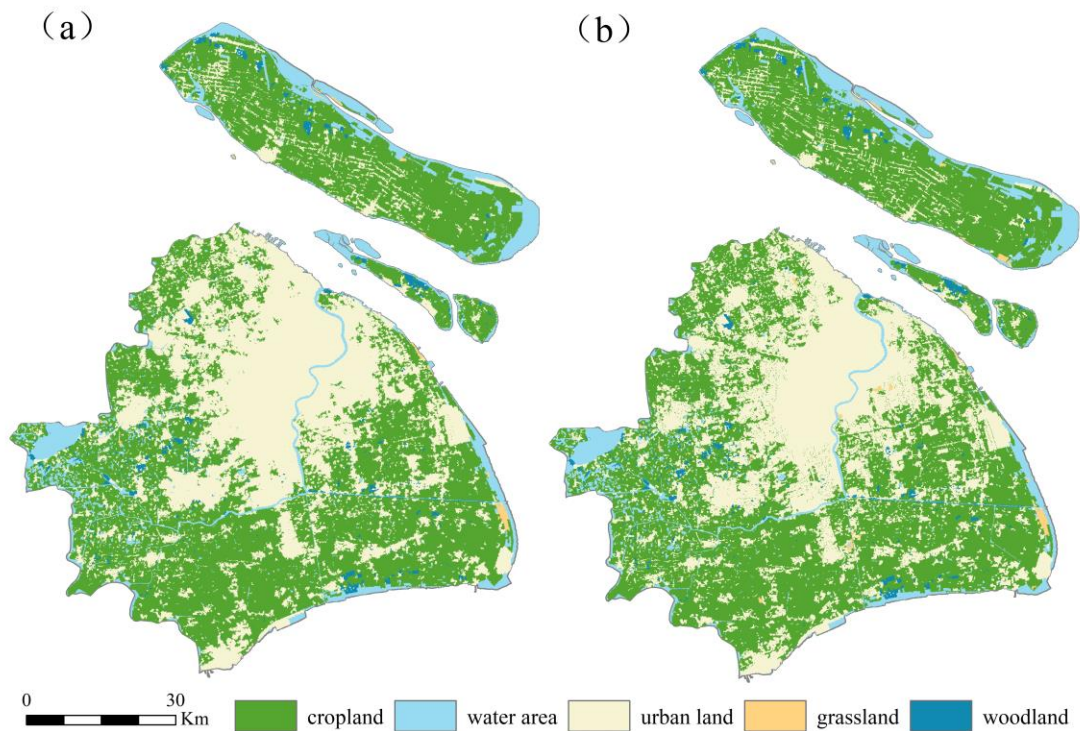

183 LISFLOOD-FP is a 2D hydraulic model based on a raster grid (Bates et al., 2010), which can efficiently simulate the
184 dynamic propagation of flood waves over fluvial and estuarine floodplains and show real-time changes in water depth of
185 complex terrain. LISFLOOD-FP model solves the Saint-Venant equations at very low computational cost by omitting only
186 the convective acceleration term over a structured grid using a highly efficient explicit finite difference scheme to produce a
187 two-dimensional simulation of floodplain hydrodynamics (O’Loughlin et al., 2020). The model has been widely used in the
188 applications of small-scale and large-scale urban waterlogging and flooding (Hoch et al., 2019; Rajib et al., 2020; Zhao et al.,
189 2020).

190 In the present study, the LISFLOOD-FP model is used to simulate storm surge floods along the coast of Shanghai and floods
191 along the Huangpu River. The effectiveness of the model in the study area has been verified by another article of our group
192 members and shows good simulation results (Xu et al., 2021). In addition, the validated relationship between the simulated
193 and observed values of water levels at the tidal station was plotted using the observed records of Huangpu Park tidal station
194 for comparison (with reference to the recorded values of Yin (Yin et al., 2013)), and the results showed a reasonable match
195 (Supplementary Fig. 2). In the Manning coefficient of the model, we assigned friction coefficients of 0.05, 0.15, 0.035 and
196 0.2 for cropland, woodland, grassland and urban land respectively, based on the study of Dabrowa et al (Dabrowa et al.,
197 2015). In the boundary condition of model, hydrological stations and global storm surge data are respectively employed as
198 the input of the scenario design. However, Shanghai Geological Environmental Bulletin and land subsidence control plan
199 show that land subsidence has a significant contribution to the flood hazards in Shanghai (Xian et al., 2018). Land
200 subsidence in Shanghai is mainly caused by tectonic subsidence and compaction of sediments due to geological structure
201 conditions and human activities. With reference to the long-term tectonic subsidence monitoring data of the very long
202 baseline interferometer (VLBI) in the Sheshan bedrock and the land subsidence analysis rules of Yin et al. (Yin et al., 2013).
203 therefore, the total land subsidence is predicted to be 0.12 m and 0.24 m by 2030 and 2050, respectively. However, due to
204 the uncertainty of future anthropogenic activities and spatial distribution, there could be large variations in the projection.
205 This study also combines the storyline of the future scenarios of the IPCC, namely the Representative Concentration
206 Pathway (RCP) scenarios, and selects conservative (RCP2.6) and largest magnitude (RCP8.5) climate-change scenarios,
207 with values from Kopp et al (Kopp et al., 2017). For the simulation of the Huangpu River flood, we conducted experiments
208 for a 50-year return period under the RCP2.6 scenario and a 100-year return period under the RCP8.5 scenario respectively
209 during 2030 to 2050, with values from Yin et al (Yin et al., 2020). For the 2030 and 2050, both Huangpu River and the
210 coastal floods are following the RCP2.6 and RCP8.5 scenarios. Finally, we combine land subsidence and the RCP data to
211 control the flood inundation simulation.

212 **4 Results**

213 **4.1 Model validity**

214 Model verification is the prerequisite for model operation, and the operation can only be carried out after confirming the
215 model to be valid. The applicability of the proposed model was tested by simulating land use/cover changes (LUCC) in 2015
216 at Shanghai. The spatial simulation result shows that the simulated result and the actual land use have a high consistency
217 (Fig. 3). We compared the actual land use and the simulated result pixel by pixel in our study and found the overall accuracy
218 (OA) was 93.20 %, the kappa coefficient (kappa) was 0.89. The discrepancy of the actual land use and simulated result is
219 likely due to the neighborhood interaction in the CA model, in which grid cells in more urbanized neighborhoods have a
220 higher probability to convert to urban, whereas the grid cells are less likely to change to urban in less urbanized
221 neighborhoods. Overall, the measured model accuracy outputs showed an acceptable or good level of prediction, therefore
222 the model is suitable for predicting changes in land use of the Shanghai area.

223
224 **Figure 3: Comparing the simulation results of Shanghai urban expansion with the actual situation, (a) simulation result in 2015; (b)**
225 **actual land use in 2015.**

226 **4.2 Future land use changes**

227 Based on the conditions under three different development scenarios, we predicted the development of future urban land use
228 change in 2030 and 2050. The prediction result shows different development patterns for each scenario (Fig. 4). Future urban
229 growth under the BU scenario is primarily located in northwestern with some development in the central regions, and under
230 the GP scenario the urban growth involves evenly distributed development. Urban growth in the GE scenario, however,
231 Chongming Island regions have seen more urban growth, and the downtown area is not fully occupied by urban expansion
232 due to restrictions.

233 Due to the impact of infrastructure construction, distance to the city center, and policy restrictions, Shanghai's overall urban
234 expansion model shows a center-peripheral expansion. The built-up land areas in 2030 and 2050 are respectively projected to
235 increase by about 6 % and 13 % as compared to 2015, the most significant reduction is found for cultivated land and
236 woodland. Specifically, the built-up land areas in 2030 are respectively projected to increase by 427.32 km², 428.27 km² and
237 429.12 km² at BU, GP and GE scenarios, the built-up land areas in 2050 are respectively projected to increase by 926.38 km²,
238 857.63 km² and 751.47 km² at BU, GP and GE scenarios. The most significant reduction is found for cropland, which is
239 predicting in 2050 to decrease by 876.97 km², 857.63 km² and 723.59 km² as compared to 2015 in BU, GP and GE scenarios.
240 The southwestern region is not suitable for large-scale urban development, since large amounts of farmland in the region are
241 listed as ecological protection areas, so the slow growth of these areas is not expected. The simulation maps show, as
242 expected, land use changes under different planning scenarios, especially the urban sprawl trend at the GE scenario, creating
243 new development areas in suburbs. To sum up, the urban expansion trajectory under BU, GP and GE shows significant
244 differences, and these changes mainly at the expense of the cropland.

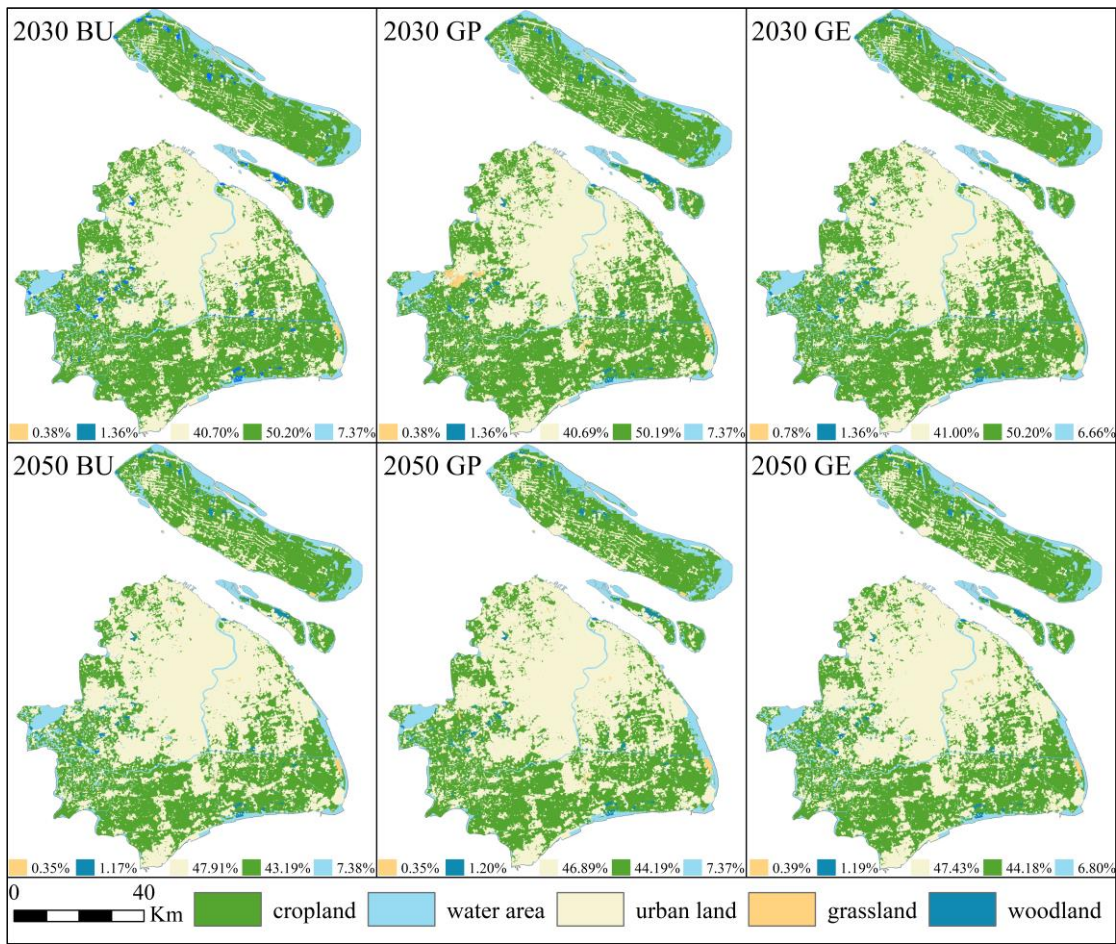

Figure 4: Simulation results of different scenarios in 2030 (top) and 2050 (bottom). Each image shows the spatial distribution and the proportion of area of different land use types in the simulated scenario.

4.3 Changing flood hazard in the future

The LISFLOOD-FP model is used to simulate the flood evolution process under RCP2.6 and RCP8.5 scenarios (the inundation results are plotted in Supplementary Figure 3), and the submerged depth and area under different scenarios are statistically analyzed to explore the future flood risk under different RCP scenarios. First, the maximum water depth risk of the submerged area is counted, and the submerged area is divided into four depth levels: the submerged water depth is less than 0.5 m as shallow water, water depth is 0.5-1 m as medium water, the water depth is 1-2 m as deep water, and submerged water depth is above 2 m as the extremely deep. The area and proportion of each water depth level are calculated. By comparing the scenarios in RCP2.6 and RCP8.5, it is evident that the submerged area is increasing with time (Table 2). The total flooded area increased by 162.43 km² and 189.44 km² under RCP2.6 and RCP8.5 scenarios from 2030 to 2050, respectively. Additionally, the depth of submergence and the extent of submergence will gradually increase as the floodwater

spreads. Taking the area with submergence depth above 2 m as an example, under RCP2.6 scenario the area with submergence is 353.69 km² and 401.57 km² respectively in 2030 and 2050, and under RCP8.5 scenario the area with submergence is 356.28 km² and 418.36 km² respectively in 2030 and 2050. It shows that Shanghai will still face great flood risk under these two scenarios.

Table 2. Statistics of flood depth.

Category	<0.5 m		0.5-1 m		1-2 m		>2 m		Total /km ²
	Area/ km ²	Ratio/ %	Area/ km ²	Ratio/ %	Area/ km ²	Ratio/ %	Area/ km ²	Ratio/ %	
2030 RCP2.6	138.61	14.54	164.07	17.21	296.98	31.15	353.69	37.10	953.35
2030 RCP8.5	137.13	14.23	169.76	17.61	300.82	31.21	356.28	36.96	963.99
2050 RCP2.6	125.04	11.21	229.81	20.60	359.36	32.21	401.57	35.99	1115.78
2050 RCP8.5	141.72	12.29	219.58	19.04	373.77	32.41	418.36	36.27	1153.43

4.4 Future changes in urban flood risk

The flood risk of the urban area is calculated by overlapping existing urban and projected future urban scenarios with future flood risk zones. First, in the existing urban exposure to future flood risk scenarios (the upper left in Fig. 5), more urban areas with flood wall will be vulnerable to flood risk in the context of global climate change. The four pie charts for the EU scenarios represent the proportion of the existing urban area affected by the future flood risk scenario. Under the RCP 2.6 scenario, 4.68 % and 5.96 % of the total existing urban areas in 2030 and 2050 would be susceptible to flood risk, respectively. In the 2030 and 2050 of the RCP8.5 scenarios the area of existing urban land which would be vulnerable to future flood risks are 110.27 km² and 146.23 km², respectively. Many urban areas will be flooded under sea level rise caused by climate change even when protected by levees, and more than 5 % of urban areas in Shanghai are still in the floodplain (Fig. 5).

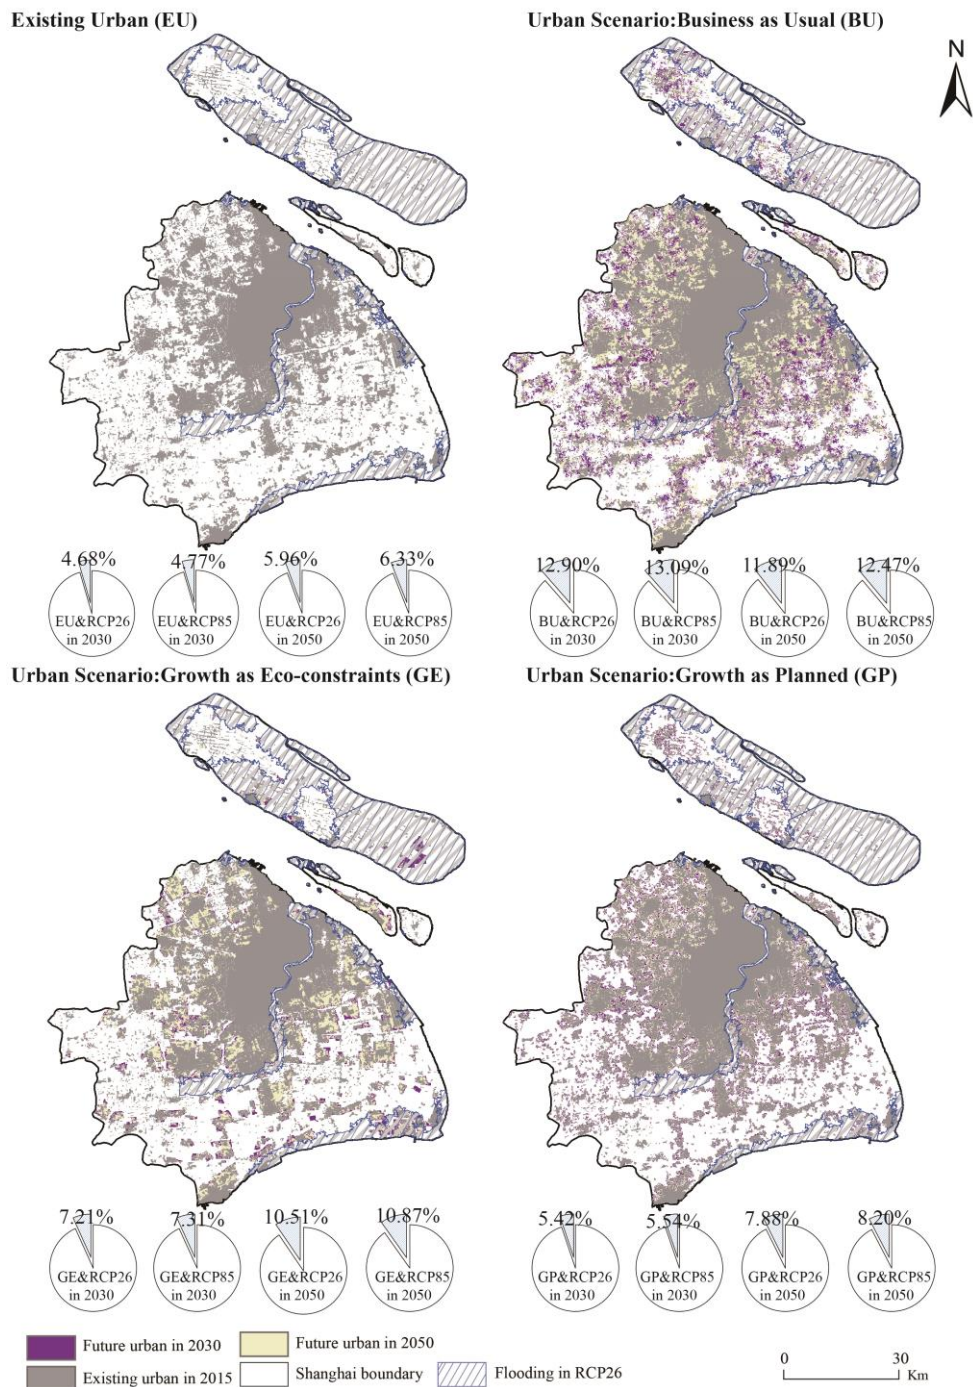

Figure 5: Flood exposure of existing urban and future urban growth scenarios. The four pie charts for the BU, GE, and GP scenarios represent the proportion of new grown urban area exposed to flooding under the 2030 RCP2.6, 2030 RCP8.5, 2050 RCP2.6, and 2050 RCP8.5 scenarios, respectively. The four pie charts for the EU scenarios represent the proportion of the existing urban area affected by the future flood risk scenario.

278 Future urban development would occur in the flood zone, with a rapid expansion of the urban area. Fig. 5 also shows the
 279 comprehensive analysis results of the three urban growth scenarios under different climate change scenarios. Under the
 280 RCP2.6 scenario, new growth in urban land area affected by flooding in 2030 are respectively 55.11 km², 23.22 km², and
 281 30.92 km² at BU, GP and GE scenarios. Under the RCP8.5 scenario, future more urban growth areas would be affected by
 282 the flooding, which will reach 115.53 km², 70.36 km², and 81.71 km² at BU, GP and GE scenarios in 2050, respectively. In
 283 general, the higher the sea level rises, the greater the risk of flooding in future urban areas. Small changes in sea level rise
 284 will affect a large amount of land, since the average altitude of Shanghai is only around 4 m.
 285 **Table 3. Inundation of each land use type under different scenarios. The inundated areas of different land use types, including**
 286 **cropland, woodland, grassland and urban land, were calculated for each scenario, where ^a indicates new grown areas of the urban**
 287 **class affected by flooding.**

Time	Category	Urban scenario	Inundated areas (km ²)			
			Cropland	Woodland	Grassland	Urban land ^a
2030	RCP2.6	BU	595.05	10.05	5.60	55.11
		GE	618.95	12.12	5.84	30.92
		GP	597.71	12.40	5.91	23.22
	RCP8.5	BU	602.38	10.23	5.67	55.92
		GE	625.97	12.29	5.91	31.23
		GP	604.32	12.59	5.98	23.72
2050	RCP2.6	BU	662.64	13.56	5.25	110.19
		GE	677.59	16.74	5.95	78.95
		GP	651.24	15.66	5.46	67.55
	RCP8.5	BU	683.56	15.06	5.70	115.53
		GE	698.98	18.05	6.40	81.71
		GP	672.30	16.85	5.91	70.36

288
 289 The research found that the cultivated land is the most affected land type by flooding relative to urban areas, woodland and
 290 grassland (Table 3). Under the GE scenario, the flooded area of cultivated land is 618.95 km² and 625.97 km² at the RCP2.6
 291 and RCP8.5 in 2030, and 677.59 km² and 698.98 km² at the RCP2.6 and RCP8.5 in 2050. Further, the exposure of various
 292 types of land is increasing with time, but urban land and cropland will be the most impacted land types in the future.
 293 Comparing the three scenarios we can find that the urban development area under the planning scenario is less affected by

294 flooding, as compared to the business-as-usual development scenario. Comparing the inundation of the two planning
295 scenarios (GE and GP), it also reflects the decision-makers' trade-off between economic development and ecological
296 protection. The inundation area of the urban land under the GP scenario is less than that of the GE, which means that under
297 the planning constraint of protecting ecological and cultural areas, urban built-up areas will develop on low-protection areas,
298 which are more vulnerable to flooding. In conclusion, from reducing the risk of future flooding in urban areas, GE scenario
299 shows to be better than BU scenario, but worse than GP scenario.

300 **5 Discussions**

301 **5.1 Source of uncertainties**

302 There are some limitations in our study, which is what we need to improve in the future. First, there is still more room to
303 improve the accuracy of model prediction. In this study, the performance of the FLUS model is tested by kappa and OA
304 measures, which shows a good range of prediction accuracy. In addition, this study proves that 16 driving factors contribute
305 to the simulation and prediction of urban growth in Shanghai. The relationship between human and natural driving factors
306 and land use change can be effectively integrated through the FLUS model embedded with an ANN, to obtain more realistic
307 simulation results. However, if more influential drivers and the latest land cover are employed, the prediction would be
308 having higher accuracy. Second, future flood risks in coastal areas are also not fully reflected through the use of
309 hydrodynamic models, although it shows higher accuracy than the elevation area submergence method. On the one hand, the
310 LISFLOOD-FP model quickly simulates surface water dynamics at relatively low computational cost through simplified
311 shallow water equations (SWE), however, this also means that it cannot adequately capture flood shock waves, which affects
312 the accuracy of 2D flood model simulations. On the other hand, this study is based on the modeling results of DEM data,
313 which may overestimate or underestimate the simulation effect due to the error of DEM data. In addition, extreme storm
314 surge and land subsidence data are combined to enhance the reliability of the extreme flood forecast in this study. However,
315 the change of the impervious surface that affects hydrology is not yet considered in this study. When other land uses are
316 converted to urban land uses, the risk of flooding will also greatly increase due to changes the of impervious surfaces.
317 Therefore, it is necessary to dynamically adjust relevant factors affecting flood peak flows and risk in future forecasts to
318 enhance the accuracy of prediction.

319 In the context of global climate change, extreme weather in the future may become more and more serious, so it is necessary
320 to dynamically combine climate scenarios to develop more accurate flood risk delineation methods to guide urban planning
321 in the future, and rely on new technology and equipment to provide data support. For example, unmanned aviation vehicles
322 (UAVs) are deployed around the coastline to generate real-time information about weather conditions and sea-level changes
323 (Cochrane et al., 2017). These tools will act as a complement to existing information and early warning systems, which also
324 can provide guidance for coastal flood risk management and urban planning in the future. Overall, although uncertainty

cannot be avoided when assessing coastal flood risk, the deviation of the proposed model output is within an acceptable range, which ensures the accuracy of coastal flood risk assessments.

5.2 Recommendations on strategies and policies for urban adaptation to flooding

In the twenty-first century, adapting to climate change and coastal flooding is a critical challenge for coastal cities. Human response to the impacts of flooding largely depends on the allocation of urban facilities and managers' planning for future urban development (Hunt and Watkiss, 2011; Jia et al., 2022). Shanghai is considered one of the most protected Chinese cities in terms of flood protection, yet it's the EAD/GDP (the Expected Annual Disruption, EAD), that is the direct damage to buildings and vehicles) ratio, which is as much as five times than in New York (Aerts et al., 2014). Therefore, there is an urgent need to adopt flood risk adaptation strategies in Shanghai.

We conducted a set of comparative experiments to analyze the coastal flood damage in Shanghai with and without flood walls (hard adaptation strategies). Our analysis considered the important effects of land subsidence and sea level rise on flood risk. We found that the current flood protection wall can reduce the flood losses due to climate change to a relatively low level (Supplementary Figure 4). In comparison, the flood protection wall constructed for the current conditions would reduce the flooded area under the RCP8.5 scenario by about 35 % and 36 % in 2030 and 2050, respectively. Furthermore, our results show that the area of future urban flood risk varies by scenario. Although the GE scenario performs higher than the GP scenario in terms of flood inundation area, this does not mean that the GE scenario is worse. From the cases of advanced flood risk management countries such as the Netherlands (Kabat et al., 2009; Song et al., 2018), an important success lesson for future flood protection design is to leave enough space along coasts for wetland migration and leave space for nature. In other words, "soft strategies" such as "working with rivers and nature" are considered in the flood protection measures. Therefore, from this perspective the GE scenario may be a more likely future development scenario among these three scenarios. Future, it is necessary to learn from the practical experience of advanced countries to strengthen the development and construction of coastal wetlands and tidal flat ecosystems, and further reduce the residual risk through the adaptive regulation of coastal ecosystems and other soft strategies. In addition, the implementation of "soft strategies" can increase the value of ecosystem services, increase biodiversity and carbon sequestration, and improve social welfare (Du et al., 2020).

6 Conclusion

Scenario-based assessment has been found to be a powerful approach in numerous flood risk studies. This study combines an urban growth model with a two-dimensional flood inundation model to not only simulate urban development dynamics more accurately, but also to discard the shortcomings of the traditional elevation inundation method of overestimating inundation areas. We have also tested the resilience of Shanghai to future different climate scenarios with the current flood wall. The

355 results of the study are beneficial to local planners and coastal managers in making decisions of future protected areas and
356 developments.

357 This study employed three urban development scenarios and detected the relationships of urbanization and climate changes
358 in 2030 and 2050. The results of the study show that urban growth under the three scenario models manifests significant
359 differences in expansion trajectories, influenced by key factors such as infrastructure development and policy constraints.
360 According to the predicted results of flood, new built-up areas are also potentially vulnerable areas of flood risk. New built-
361 up areas under different scenarios show significant vulnerability and exposure risk under different climate scenarios, even
362 with the support of flood bank and other hard structures. Additionally, the research provided significant insights into the
363 range and spatial distribution of flood risk in future urban areas.

364 The current study is based on the multi-scenario analysis of RCP global warming scenarios. In the future, the shared
365 socioeconomic pathways (SSPs) can be combined to predict land use change, which make urban development scenarios
366 more realistic choices. The results of this study estimate the future urban flood exposure areas, but this does not mean that all
367 flood-vulnerable areas will be flooded, only that in these areas, the probability of each possible occurrence is greater.
368 Therefore, proper preparations (such as definition restricted development zones) can reduce the damage risk of future flood
369 and build more resilient cities.

370 **Author contributions**

371 Q. Sun and J. Fang designed the research; Q. Sun, K. Xu and X. Dang collected the data and carried out the experiments; Q.
372 Sun wrote the draft; J. Fang, X. Dang, Y. Fang and M. Liu revised the manuscript; J. Fang, X. Li and M. Liu supervised and
373 provided critical feedback. All authors contributed to the final version of the manuscript.
