Abstract. The main object of the present work was to study the role of morphodynamic changes in the flooding of a dissipative beach with microtidal regime, considering the simultaneous and individual effects of erosion and flooding in scenarios of long-term mean sea level rise. For this analysis, we selected a sector of the Colombian Caribbean coast with great touristic, historical, economic, cultural and social importance, namely, Cartagena de Indias; specifically, the beach of Bocagrande. By simultaneously considering erosion and flood processes associated with highly energetic waves, the study facilitates the construction of more precise models for assessing threats to coastal zones. SWAN and XBeach nested models were carried out in order to predict morphological changes and flooding during selected cold fronts and hurricanes that affected Cartagena de Indias; those numerical models were calibrated using field campaigns data (pre- and post-storm). The results of this research indicate that flooding on microtidal dissipative beaches under extreme wave conditions should be approached by considering morphodynamics, because ignoring them can underestimate flooding by ~15%. The erosion and flood effects are intensified by sea level rise, resulting in the most unfavorable condition when extreme events are contemporaneous with high tides.

1 Introduction

25 The impact of extreme storms on a coast has important consequences for coastal communities associated with loss of life and injuries, as well as significant direct and indirect economic losses (Kron, 2013; Bertin et al., 2014; Sills et al., 2008). In highly urbanized coastal areas, such as the coastal area of Cartagena de Indias (Colombia), where different types of infrastructure (homes, hotels, and businesses) are located near the coast, such storms generally damage or destroy exposed elements. These effects are the integrated consequences of two storm-induced coastal hazards, flooding and erosion (Sanuy and Jiménez, 2019; Guimaraes et al., 2015). In this context, an adequate quantification of these hazards is an essential part of risk management (e.g., Ciavola et al., 2011; Jiménez et al., 2018; Plomaritis et al., 2018; Harley et al., 2017; Sanuy and Jiménez, 2019). The use of process-oriented numerical models to forecast storm-induced morphodynamic changes in given scenarios is a widespread and widely accepted methodological practice (e.g., Roelvink et al., 2009; McCall et al., 2010; Dissanayake et al., 2014; Annette et al., 2020).

30

35

Predicting flooding associated with storm impacts accompanied by intense erosion can pose a problem on multiple scales, governed by complex interactions between a great variety of hydrodynamic processes and of sediment transport (Wu et al., 2011; Christensen et al., 2013; He et al., 2015). Among the most important factors for the prediction are: (i) increase in sea level associated with climate change, which increases the exposure of the coast during extreme events; (ii) beach erosion; (iii) flooding during and after a storm (Elsayed and Oumeraci, 2016).

40

The traditional approach to the study of flooding and erosion caused by storms has been to investigate the two coastal threats separately, i.e., flooding (e.g., Ruju et al., 2014; Guimaraes et al., 2015; Medellín et al., 2016; Lerma et al. 2017; Fiedler et al., 2018) and erosion (Schambach et al., 2018). Particularly for the area of the Colombian Caribbean coast, works have focused on evaluating the threat of flooding from extreme waves, without considering changes in beach morphology produced by the studied storm (Andrade et al., 2013; Orejarena et al., 2019). However, recent studies have examined the impact of both threats simultaneously, basically using the eXtreme Beach Behavior (XBeach) model as a tool (Stockdon et al., 2014; de Santiago et al., 2017; Sanuy and Jiménez, 2019; Enríquez et al., 2019). This model solves hydrodynamic processes associated with gravity (Sea – Swell) waves (refraction, shoaling and breaking), infragravity (Igrav) waves, setup induced by waves and currents, and morphodynamic processes such as dune erosion and sediment transport (Roelvink et al., 2009).

45

50

Extreme wave events on the Colombian Caribbean coast are associated with hurricanes and cold fronts (Ortiz, 2007; Ortiz et al., 2013; Otero et al., 2016; Cueto and Otero, 2020). The meteo-marine event that most affected the central coast of Colombia in the last decade was the cold front of March 2009, which collapsed a 200-m section of the old Puerto Colombia pier (Ortiz et al., 2014). Although Colombia is in a fortunate location in the Caribbean regarding the trajectory of hurricanes, it is not exempt from the consequences of a devastating passage. Hurricanes such as Joan (1988) (Ortiz, 2008), Lenny (1999) (Ortiz, 2009), and more recently Matthew (2016) (Cueto and Otero, 2020) and Iota (2020), among others, have impacted the Colombian Caribbean coasts, causing flooding and erosion along the coastline. After an analysis of 1980–2014 satellite images and field measurements, Rangel-Buitrago et al. (2015) estimated that 48.3% (1182 km) of the Caribbean Colombian coast had serious erosion problems. Only 33.2% (812.6 km) could be considered stable and the remaining 18.4% (450.5 km) showed accretion. The erosive dynamics found along the northern coasts of Colombia have been influenced by different factors, among which are extreme wave events (Rangel-Buitrago et al., 2015; Otero et al., 2016). In the particular case of the coastal area of Cartagena de Indias, the coastline experienced setbacks of as much as 50 meters because of an anomalous succession of extreme events (hurricanes and cold fronts) between January 2010 and January 2011 (Bernal et al., 2016). This forced the execution of an emergency procedure for recovery of the beaches using hydraulic fill. Moreover, flood events due to extreme waves caused by dry-season cold frontal passages affecting the city of Cartagena de Indias have become increasingly frequent (Andrade et al., 2013; Otero et al., 2016). This is because it has been established that the rate of rise in mean sea level in this

55

60

65

region was 5.6 mm/year during the period 1950–2009 (Torres and Tsimplis, 2012), which has aggravated the impact of the aforementioned phenomena in the region (Orejarena et al., 2019).

70

Per the above, the main object of the present work was to study the role of morphodynamic changes in the flooding of a dissipative beach with microtidal regime, considering the simultaneous and individual effects of erosion and flooding in scenarios of long-term mean sea level rise. For this analysis, we selected a sector of the Colombian Caribbean coast with great touristic, historical, economic, cultural and social importance, namely, Cartagena de Indias. By simultaneously considering erosion and flood processes associated with highly energetic waves, the study facilitates the construction of more precise models for assessing threats to coastal zones and identification of the implications of not including the effects of morphodynamic changes on the flooding. This will enable the design of plans with more robust criteria for the management of irrigation and mitigation actions, in order to protect the population and infrastructure from threats by the sea.

75

2 Data and methods

80 The methods used and their respective steps are detailed in the following subsections.

2.1 Description of study area

The study area is comprised of Bocagrande Beach (Figure 1), which forms a section of the coastline of the city of Cartagena de Indias in the central Colombian Caribbean. Regarding morphology, Bocagrande has a dissipative profile (Figure 2), with an offshore slope of 0.3% and foreshore slope of 1.8%. Furthermore, it is composed of fine sands with grain sizes between 0.08 and 0.42 mm (Conde *et al.*, 2017a; b). Within the study domain of Bocagrande, there are six groins that extend between 50 and 100 m within the area of breakers, being oriented perpendicular to the coast. The tide in the study area fluctuates between 20 and 30 cm, classifying Bocagrande as a microtidal beach (Restrepo *et al.*, 2012; Restrepo *et al.*, 2016).

85

Detailed bathymetries were determined along with control profiles in field campaigns developed before and after a succession of cold fronts between November 2014 and February 2015. In these campaigns, hydrodynamic data were also acquired, using a cross-shore arrangement of four current meters (S5, S4, S3 and S2) and a pressure sensor (S1). A detailed description of the sections referring to these field campaigns is given in Cueto & Otero (2020).

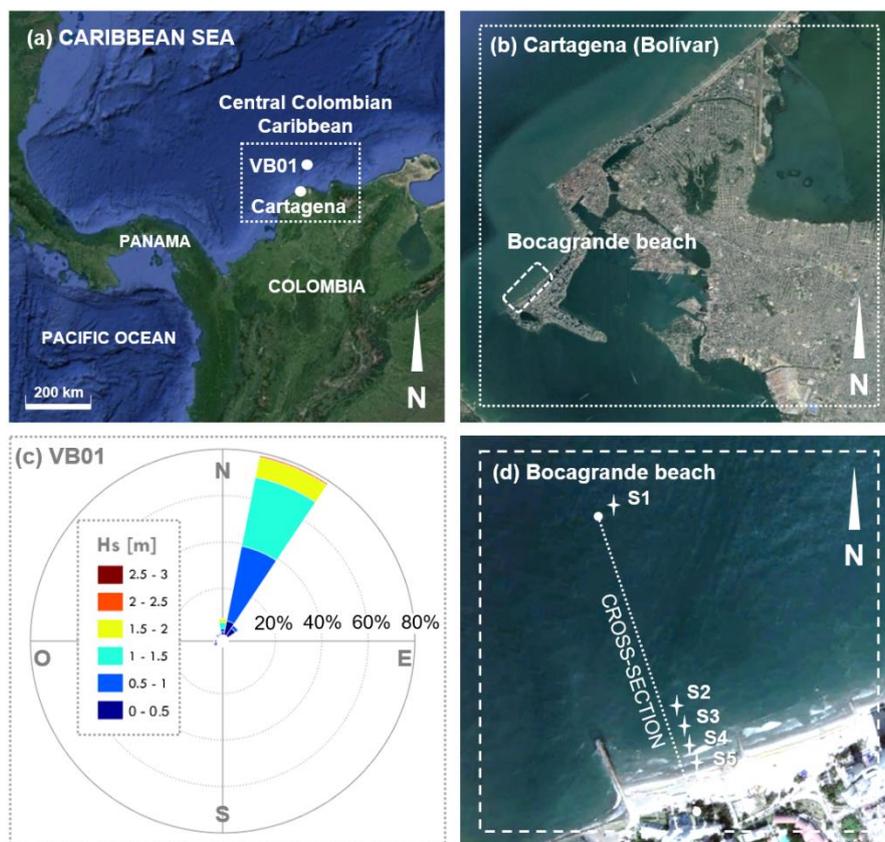

90

Owing to its location in the Caribbean, the hydro-climatology of the study area is also influenced by the migration of the Intertropical Convergence Zone (ITCZ) (Poveda, 2004; Pérez *et al.*, 2018). The ITCZ is an area of the globe where the trade winds of the northern and southern hemispheres converge, generating a low-pressure belt around the equator that oscillates seasonally. The Colombian Caribbean is governed climatically by this movement (Poveda, 2004), producing a bimodal regime with two dry seasons (December–March and June–July) and two wet seasons (April–May and August–November). During dry periods, winds tend to be stronger; from December to March, the trade winds from the north predominate, while between June and July the prevailing winds are from the southeast. In contrast, the rainy months have weaker winds.

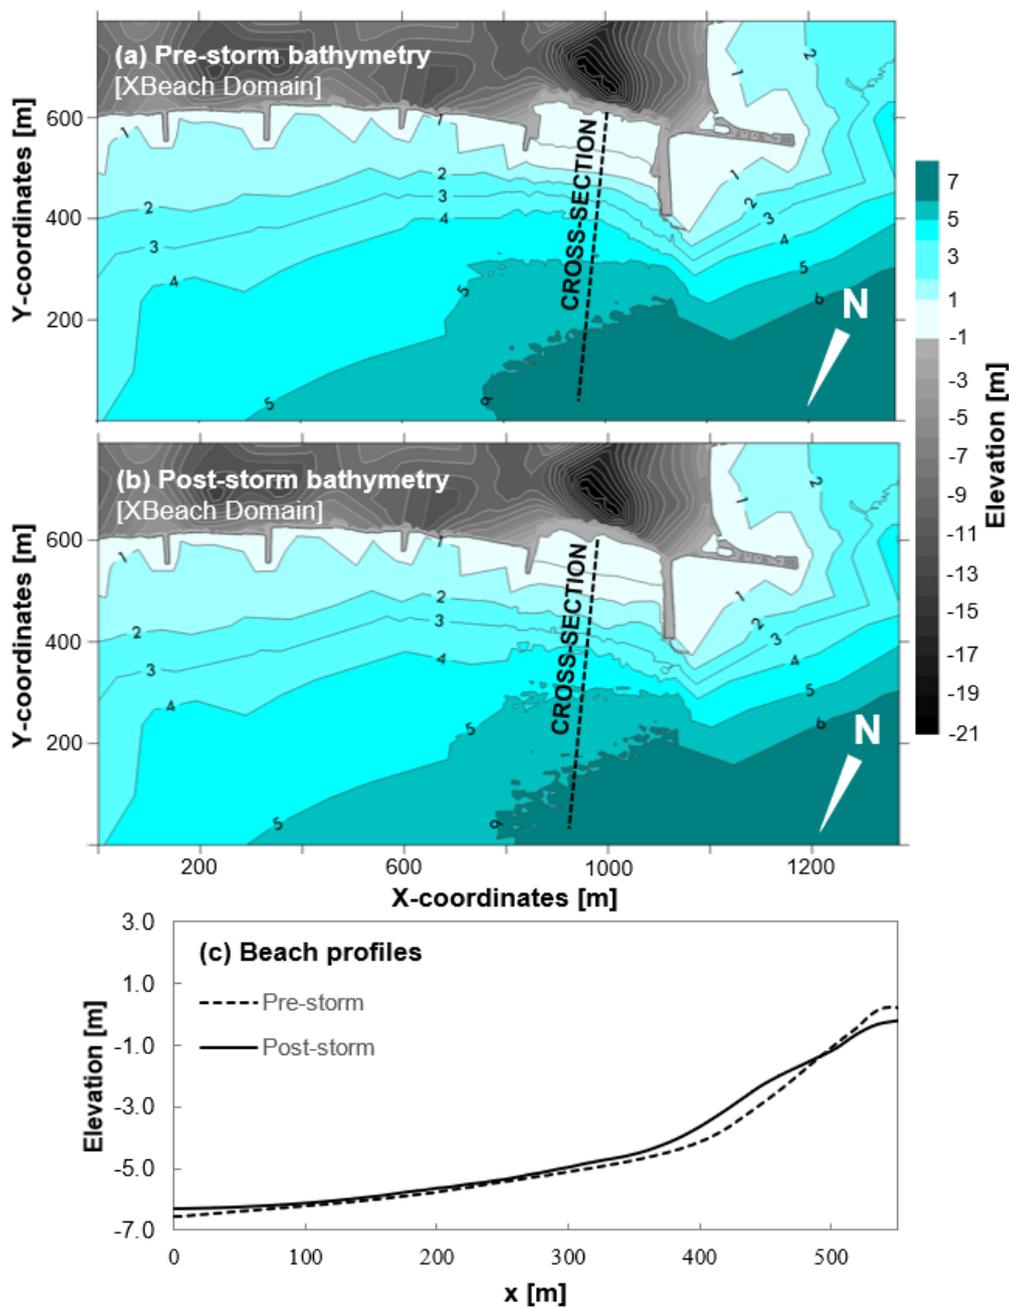

95

100 The influence of the trade winds in times of drought produces waves with strong energy, the northeast direction being the component with the highest probability of occurrence (32%) (Ortiz, 2012; Restrepo *et al.*, 2012). With less probability (~15%), waves arrive from the east-northeast, north and north-northeast directions. Waves originating outside these directions are generated by local winds and have a low probability of occurrence in the area.

105 **Figure 1: Location of study area: (a) location of Cartagena in the Colombian Central Caribbean and Virtual Buoy 01 [VB01] ($10^{\circ}40'1.12''N$, $75^{\circ}30'0.00''W$); (b) location of Bocagrande Beach in Cartagena de Indias; (c) wave rose extracted from VB01; (d) instrumental setup during field campaigns. 110 **Figure 2: (a) Pre-storm detailed bathymetry; (b) post-storm detailed bathymetry; (c) pre- and post-storm beach profiles at Bocagrande (Cartagena de Indias).**

2.2 Selected events

In order to identify extreme wave events in Bocagrande, wave series were extracted from the Virtual Buoy 01 (VB01) in the central Colombian Caribbean, near the coast of Cartagena de Indias (Figure 1a). These reanalysis series were obtained from a

115 NOAA database that used the third-generation model WAVEWATCH III as a source (Chawla et al. 2013). This database was
adjusted to the conditions of the Colombian Caribbean by Vega (2018). It is well known that the wave reanalysis information
tends to underestimate wave heights associated with extreme events. However, with the adjustment of Vega (2018), errors do
not exceed 5% for significant wave height calculations.

120 Subsequently, the series extracted for each area of interest were compared with the exact dates on which hurricanes and cold
fronts occurred in the Colombian Caribbean over the last four decades (Ortiz, 2012; Ortiz et al., 2013; Bernal et al., 2016;
Otero et al., 2016). We thereby constructed a detailed inventory of extreme wave events in the study area. From this, we
selected case studies for subsequent hydro-morphodynamic modeling. As selection criteria, we considered events that strongly
affected the Cartagena de Indias area, analyzing the energy contents, impacts, and proximity to the coast of each storm (Ortiz,
2012; Ortiz et al., 2013; Bernal et al., 2016; Otero et al., 2016). The inventory of hurricanes and cold fronts was integrated
125 with conditions of sea level rise (SLR) for the coming decades at Bocagrande Beach, as predicted and discussed by Orejarena
et al. (2019). This was done to investigate the combined effects of erosion and flooding following the impact of storms in
future scenarios with higher sea levels.

The inventory with some of the most important hurricanes and cold fronts affecting Cartagena over the last 40 years is shown
130 in Table 1. Among the data from VB01, there are noteworthy maximum wave heights of 2.76 and 3.53 m. These values were
recorded during the passage of Hurricane Lenny (1999) and the cold front of December 2017, respectively. Lenny traversed
the study area as a tropical storm, producing extreme waves during approximately two days. In contrast, the cold front of
December 2017 persisted longer in the study area, generating an increase in wave heights over five days. Both events were
selected to evaluate the morphodynamic response of Bocagrande Beach.

135 Analogously, the extreme events of 2010 reported by Bernal et al. (2016) were chosen for case study. According to
Bocagrande's historical records, this set of storms generated unprecedented recessions along the coastline (50 m in one year)
and was particularly associated with the 2010 Atlantic hurricane season (Bernal et al., 2016). We especially emphasize three
cold fronts during March 2010, which most influenced the erosive processes of that year (25–30 m retreat in less than a month).
140 Between the first and the second cold front of that month there was a period of six days with moderate waves. Between the
second and third cold front there were moderate waves over eight days. SLR was considered for future scenarios following
the projections of Orejarena et al. (2019) for the Cartagena de Indias area. These projections were prepared according to data
from the Integrated Climate Data Center of the University of Hamburg. The aforementioned authors projected a SLR of 0.11
(2025), 0.24 (2050), 0.38 (2075), and 0.52 m (2100) at Bocagrande. The selected events from which the case studies were
145 formulated are shown in italics in Table 1.

Table 1: Analyzed storms from VB01 (Bocagrande) wave series. Maximum significant wave height (H_s), peak period (T_p), and mean direction (D_m) are displayed. * Denotes duration of effect across study area.

Hurricane	Duration (days)*	VB01

2.3 Numerical modelling

This section outlines the numerical modeling approach to determine wave propagation from deep waters, using the Simulating Waves Nearshore (SWAN) numerical model (Boij & Holthuijsen, 1999) and its subsequent nesting with the XBeach model (Roelvink et al., 2009) to represent the hydrodynamics and morphodynamics of the Cartagena de Indias coastal zone.

155 2.3.1 From deep waters to the coast: Wave propagation using SWAN

Propagation from deep waters during the selected events was determined by the SWAN model, originally developed by Booij & Holthuijsen (1999). The wave series of the events were propagated from the location of virtual buoy VB01 in deep waters (Figure 1a) to ~1 km from the Bocagrande coast (collocated with the offshore boundary of the computational domain used in XBeach).

160

SWAN was calibrated for the study area by Cueto & Otero (2020), taking into account in situ wave data measured in field campaigns before and after storms, following parameters established by Conde et al. (2017a). Table 2 shows the computational domain used for SWAN modeling of Cartagena, and Table 3 the error parameters calculated by Cueto & Otero (2020) for model performance at Bocagrande.

165

Table 2: SWAN and XBeach computational domain for Bocagrande Beach.

GRID	SWAN	XBeach
Cell size [m]	100	5-3-1
X [nodes]	334	790
And [nodes]	280	1570
Area (km ²)	935.2	1.24

Table 3: SWAN error parameters for Bocagrande (Cueto & Otero, 2020).

Parameter	Bocagrande	
	Pre-storm	Post-storm
Bias	-0.05	0.01
r ²	0.91	0.87
Willmott	0.96	0.95

170

2.3.2 Beach morphodynamics: XBeach

A representation of hydrodynamics, flooding and morphodynamic response to extreme wave events, considering SLR scenarios at Bocagrande, was realized using XBeach (Roelvink et al., 2009).

175 XBeach is an open-source numerical model originally developed by the University of Delft to simulate hydrodynamic and morphodynamic processes on sandy beaches, using a domain of kilometers and the timescale of storms. This includes hydrodynamic processes such as (Sea – Swell) SS wave transformation (refraction, shoaling and breaking), Igrav wave (generation, propagation and dissipation), wave-induced setup and non-stationary currents, and overwash and flooding. The morphodynamic processes that XBeach solves include suspended sediment and bottom transport, dune erosion, bottom
180 updating, and breaching (Roelvink et al., 2009). The model can be used in three modes, i.e., phase-averaged, surfbeat and nonhydrostatic. In the present study we used the surfbeat mode.

The model includes solvers for NLSWE and morphodynamics, so its application can be extended to simulate coastal flooding together with erosion processes, using a single mesh calculation for both modules. This approach offers the advantages of
185 simulating the mutual interaction between hydrodynamics and morphodynamics.

The computational domain defined for hydro-morphodynamic modeling of Bocagrande Beach using XBeach (Figure 2) covers an area of 1.24 km² (1.57 km alongshore and 0.79 km cross-shore). The domain is distributed on a mesh of rectangular cells

with variable sizes, ranging from 5 m wide in the areas furthest from the coast to 1 m in the closest areas. Characteristics of
190 the computational domain used with XBeach are shown in Table 2.

The model was calibrated based on experimental data (topo-bathymetric and hydrodynamic) collected during field campaigns
pre- and post-storm. Cueto & Otero (2020) described this calibration for the study area in detail, following the two-step
methodology presented by Nederhoff (2014) and aspects from more extensive calibrations carried out by Ranasinghe et al.
195 (2011) and Luijndendijk et al. (2017) (Table 4). The latter calibration procedures also include morphological processes on
timescales greater than those of storms. Table 4 shows a summary of the calibration procedure results by Cueto & Otero (2020).
The best morphologic representations were obtained when using a *facua* (factor *ua*) parameter of 0.35 and 0.45, combined with
a Chezy friction coefficient of 45 m^{1/2}/s. According to the classification elaborated by van Rijn (2004), which includes a
qualitative scale for morphological representation based on different Brier Skill Scores (BSS) (BSS = 1, perfect representation;
200 BSS = 0, poor representation), the model approximation was qualified as “Excellent”.

Table 4: XBeach morphodynamic parameters and performance for Bocagrande.

Profile	<i>facua</i>	Chezy [m ^{1/2} /s]	BSS	Qualification
A	0.05	45	0.41	Reasonable
B	0.20	45	0.67	Good
C	0.35	45	0.89	Excellent
D	0.45	45	0.80	Excellent

For the hydro-morphodynamic modeling with XBeach, the study cases shown in Table 5 were established. The sediment
205 transport module in XBeach was turned on and off for each case study. In this way, the influence of erosive processes on
flooding was checked. The models included a non-erodible layer to simulate the hard structures present on Bocagrande Beach.

210

215

Table 5: Selected study cases for evaluation through numerical modeling of Bocagrande Beach. * Indicates that between cold fronts there was a six-day period of average wave conditions between A and B, and eight days between B and C. ** Indicates that the additional effect of a +0.25 m high tide was included, without considering the storm surge.

3 Results

This section presents the results of numerical modeling to evaluate the threat posed by the combined effect of erosion and flooding on the studied beach under extreme wave and SLR conditions.

225 Figures 3–6 show the maximum extent of flooding (with the transport module sediment on and off) and post-storm shorelines simulated by XBeach after the passage of storms with characteristics similar to Lenny 1999, the 2010 cold front succession and 2017 cold front, incorporating different SLR scenarios and using the current Bocagrande bathymetry. Figure 7 shows the control profile of Bocagrande Beach evaluated for different case studies with obtained beach retreats. Table 6 summarizes the most important results of each case study.

230 3.1 Hurricane Lenny 1999

In case study A1 (Figure 3a), the coastline retreat varied between 15 and 18 m, with erosion more evident along beach sections between groins 3 and 4 and 4 and 5. In case studies A2 (Figure 3b) and A3 (Figure 3c), with SLRs of +0.11 and +0.24 m respectively, the erosive processes became more aggressive, especially in the latter case. The coastline retreated between 19 and 24 m in the XBeach simulations for case A2, whereas in the most extreme scenario (A3), erosion was able to cause the
235 loss of as much as 32 m of beach in the most critical section (between groins 4 and 5). In Figure 7a, one sees changes in the Bocagrande control profile (which is in the most critical section) after storm simulation with various SLRs, indicating retreats of 15 (A1), 22 (A2) and 30 m (A3).

The maximum flooding extent in all case studies was greater for simulations in which XBeach had the sediment transport
240 module activated (sed-on). With this module turned on, the maximum range of the water layer during the storm was 95, 110 and 135 m for cases A1, A2 and A3, respectively. In cases A2 and A3 (both with sed-on) the results showed partial flooding in the urban area of Bocagrande, penetrating 31 m with the SLR conditions of 2025, and 41 m with the SLR of 2050 (measured from the first street located next to the beach). Flooding in the sed-off simulations did not extend beyond that boundary street.

245 **Figure 3: Maximum flood range (with sediment transport module on and off) and post-storm shorelines simulated by XBeach for a storm similar to Lenny 1999 with different SLR conditions. Map base images retrieved from © Google Earth and modified by the authors.**

3.2 2010 cold fronts

The results of case B1 (Figure 4a) indicate maximum retreats of nearly 30 m in the section between groins 4 and 5. In the remaining Bocagrande sections, erosion consumed an average 25 m of beach. Upon applying the 2025 SLR conditions in the model (Figure 4b), the losses of coastline began to exceed 35 m and the erosion was accentuated in every Bocagrande section. In the most severe case (B3) (Figure 4c), the retreats reached ~50 m, as occurred between groins 2 and 3 in the most critical transect. Figure 7b reveals variations in the control profile after the passage of cold fronts, showing beach losses of 28 (B1), 33 (B2) and 45 m (B3).

255

Regarding maximum flood extent, XBeach calculated that with an SLR of +0.24 m and a succession of cold fronts similar to that of 2010 (B3), the water line penetrated widely in the urban area of Bocagrande (96 m measured from the beginning of the first street with sed-on, and 67 m with sed-off). This particular case study was that with the greatest erosion and flooding in

the analysis area. Measured from the shoreline, the maximum range of the water sheet with a non-static bottom was 109, 141 and 184 m in cases B1, B2 and B3, respectively. In cases B1 and B2, flooding also occurred in the urban area when sed-on was used, with maximum intrusions up to 11 m in the first case and 50 m in the second (measured from the first street). With sed-off, the flood penetrated 94 m inland in case B1 (not exceeding the urban limit) and 113 m in B2 (both measured from the coastline).

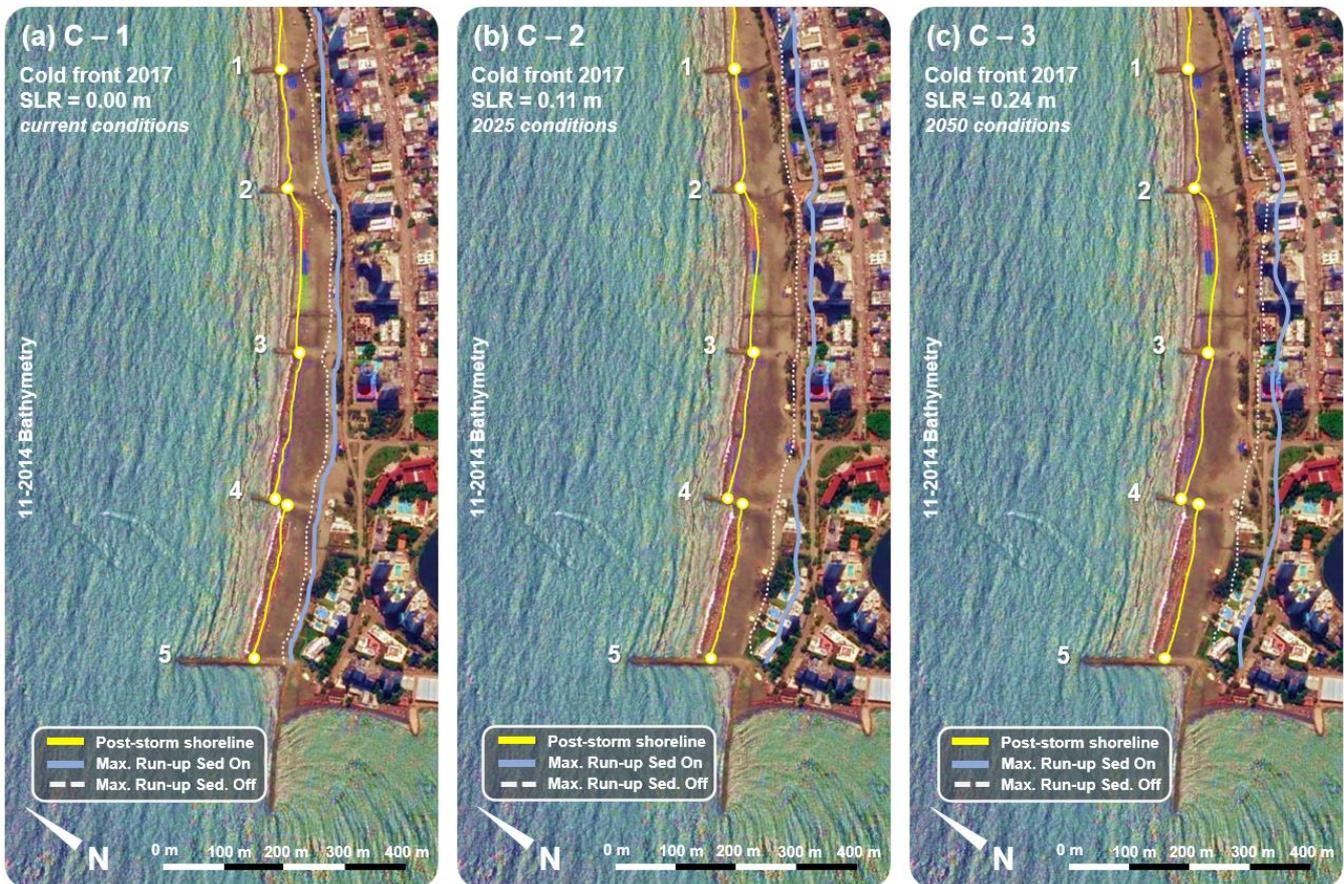

265 **Figure 4: Maximum flood reach (with sediment transport module on and off) and post-storm shorelines simulated by XBeach for 2010 cold front succession with different SLR conditions. Map base images retrieved from © Google Earth and modified by the authors.**

3.3 2017 cold front

From analysis of a storm similar to the cold front of 2017 with varying SLR conditions, the greatest coastline retreat calculated by XBeach exceeded 30 m. This was in the section between groins 2 and 3, after applying a SLR of +0.24 m (case C3, Figure 5c). In cases C1 (Figure 5a) and C2 (Figure 5b), beach losses calculated by the model were smaller, 19 and 26 m, respectively, in the sections where erosion was more severe. Figure 7c illustrates beach losses in the control profile after cold frontal passage, with retreats of 23 (C1), 28 (C2) and 34 m (C3).

275 The flooding under current SLR conditions reached 97 m with sed-on and 88 m with sed-off, failing to reach the streets of Bocagrande. On the other hand, the maximum range of the water layer was 113 m (94 m with sed-off) under 2025 SLR conditions, and 148 m (119 m with sed-off) under SLR 2050 conditions. In cases C2 and C3 with sed-on, the water penetrated 36 and 49 m beyond the beginning of the first street.

280 **Figure 5: Maximum flood range (with sediment transport module on and off) and post-storm shorelines simulated by XBeach for a storm similar to 2017 cold front with different SLR conditions. Map base images retrieved from © Google Earth and modified by the authors.**

3.4 Extreme events: high tide +0.25 m

In case study A4 (Figure 6a), which corresponds to Hurricane Lenny with a SLR of +0.24 m plus high-tide effects (+0.25 m),
285 the coastline receded between 20 and 34 m, erosion becoming more aggressive in beach sections between groins 3 and 4 and 4 and 5. In the case of the 2010 succession of cold fronts, including a SLR projected for the year 2050 and high tide (B4) (Figure 6b), erosion was severe, with beach losses up to and exceeding 50 m in most sections that comprise the XBeach computational domain. The results for the 2017 cold front with SLR of +0.24 m and high tide (Figure 6c) indicate notable

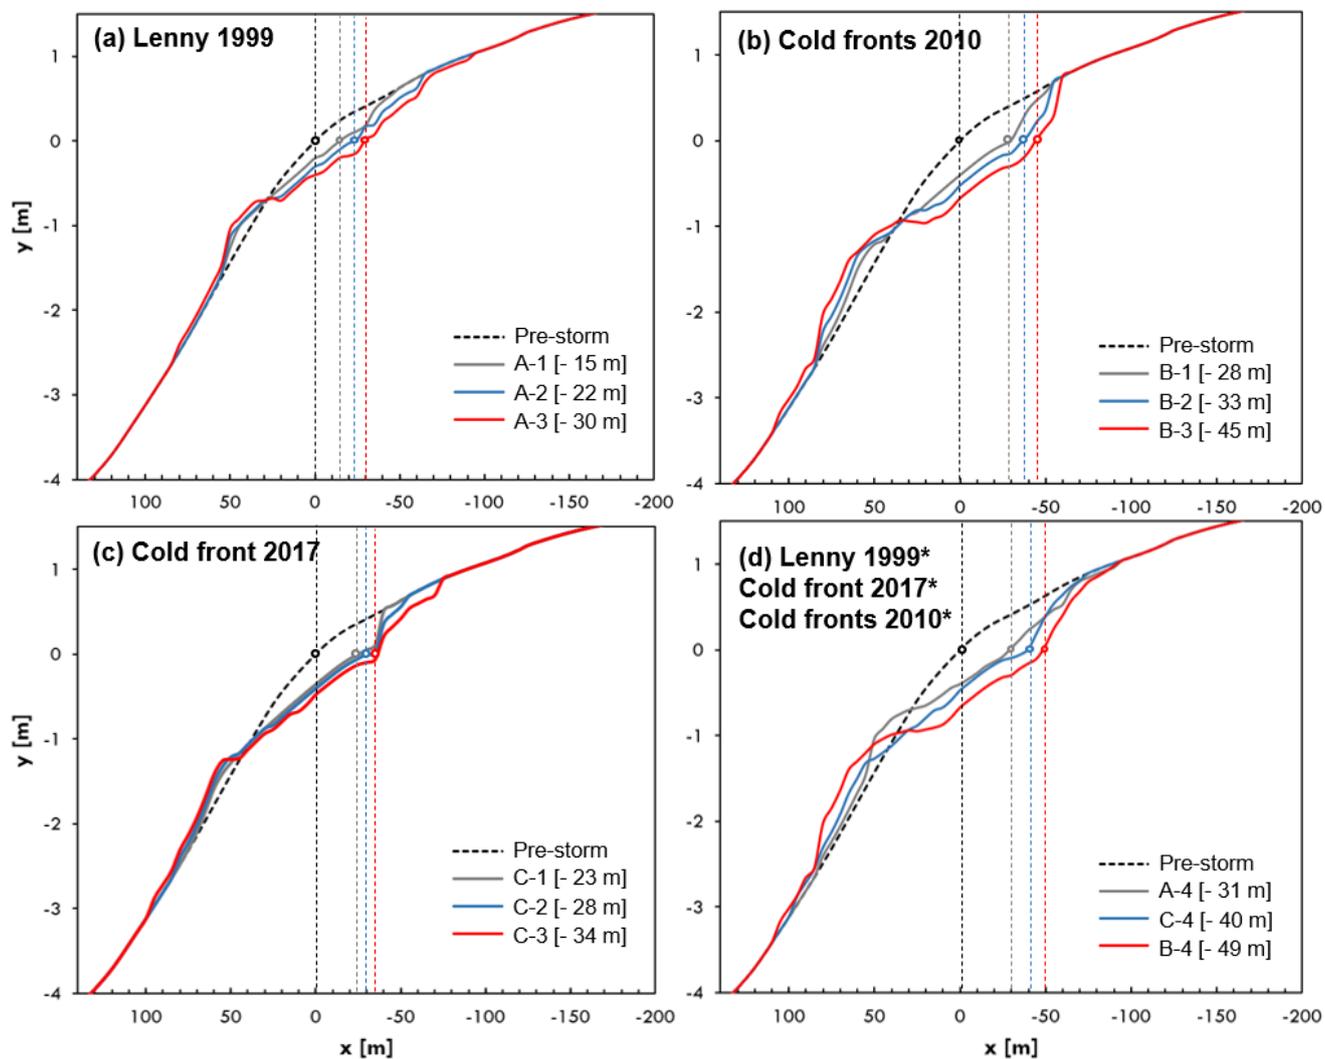

290 retreats of as much as 40 m in the beach sections between groins 2 and 3, 3 and 4, and 4 and 5. Figure 7d shows beach losses

The results also show that the maximum flood extent occurred when erosive processes were included in XBeach. The sea produced inland flooding as far as 147, 199 and 157 m in cases A4, B4 and C4, respectively, with sed-on. Likewise, for all cases, in this section there was penetration of the sea into urban areas of Cartagena, reaching 52 (A4), 105 (B4) and 58 m (C4) as measured from the boundary street of the area.

295

Figure 6: Maximum flood reach (with sediment transport module on and off) and post-storm shorelines simulated by XBeach including additional effect of a +0.25 m high tide for Lenny 1999 (a), 2010 cold front succession (b), and 2017 cold front (c) with different SLR conditions. Map base images retrieved from © Google Earth and modified by the authors.

4 Discussion

315 The results of the XBeach numerical model simultaneously show the morphological changes and flooding that a dissipative beach with a microtidal regime such as Bocagrande Beach can experience, as caused by extreme wave events caused by cold fronts and hurricanes combined with rising mean sea levels. Evaluation of the scenarios was based on a rigorous post-storm hydrodynamic and morphodynamic calibration. As far as the authors know and checked, this methodological approach has not been followed for studying the simultaneous impact of erosion and flooding in a coastal area. This is because among the investigations reviewed and analyzed, the numerical models used lacked respective hydrodynamic and morphodynamic calibrations specific to the area studied (e.g., Annette et al., 2020). Following these ideas, the methods used in our study provide a better approximation of the real conditions of a dissipative beach with microtidal regime such as that of Bocagrande. This is because the flood studies of this beach did not consider the effects of erosion (Orejarena et al., 2019; Andrade et al., 2013).

320

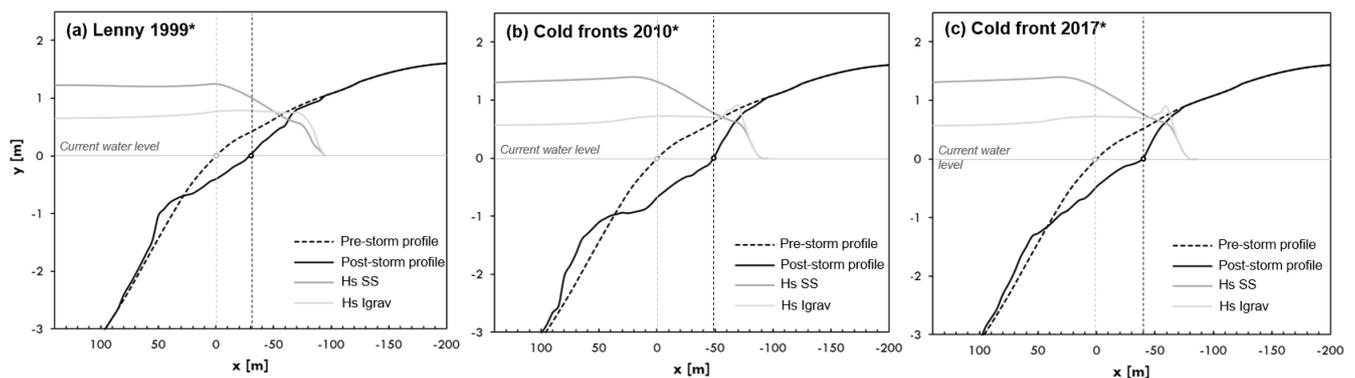

The erosion and flood processes cannot be decoupled because omitting erosion underestimates coastal flooding, as shown by the results of the present study and others (e.g., Alireza et al., 2020).

325

The extreme episode caused by successive cold fronts represents the most critical condition of coastal erosion, as occurred in 2010 (Bernal et al., 2016). This succession of extreme events generated a progressive erosion toward the coast because of a slow recovery of the beach profile. The extreme events proved efficient in substantially altering the morphology of that profile, resulting in a larger area of onshore erosion and a smaller area of offshore accretion (Figure 8), whose imbalance in cross-shore sedimentary balance was caused by sediment transport longitudinal to the coast. In this sense, the post-storm profile was a consequence of the partial migration of sediments from the beachfront toward the submerged beach, forming a longitudinal bar that modified the hydrodynamic conditions of the study area.

330

335 **Figure 8: Time-averaged SS and Igrav waves and beach profiles before and after the storm for the most critical SLR condition (cases No. 4). Vertical dotted lines represent beachfront before and after the storm.**

In all the cases, it is evident that the greatest impact on the coast from extreme events in terms of flooding and erosion was mainly attributable to the event duration. Although Lenny 1999 ($H_{s, \max} = 2.76$ m, two days) and the 2017 cold front ($H_{s, \max} = 3.53$ m, five days) had the most energetic waves, the successive cold fronts of 2010 with average $H_{s, \max} = 1.87$ m and duration 14 days produced more erosion and flooding.

340

The results show SS wave energy dissipation with approach to the coast and Igrav wave energy gain due to a nonlinear transfer of energy from high to low frequencies, with the Igrav waves dominating nearshore hydrodynamics, consistent with the results of Conde et al. (2017b) (Figure 8). This result highlights the importance of involving Igrav waves in studies related to erosion and flooding of the coast, because those waves increase the oscillation of the run-up, causing further erosion (de Vries et al., 2007; Kamphuis, 1996).

345

The erosion of dissipative beaches has been attributed mainly to the forcing of the Igrav regime, owing to its predominance. Many authors highlight the importance of Igrav waves in sediment transport (e.g., Holman & Bowen, 1982; Carter et al., 1973) because they have been shown efficient in suspending sediments in areas of surf and swash (Osborne & Rooker, 1999; Aagaard & Greenwood, 1994; Beach & Sternberg, 1991). In such areas, suspended sediments are transported by currents invigorating coastal erosion. These effects are expected to intensify during extreme wave conditions because of increased Igrav energy (Senechal et al., 2011; Ruggiero et al.; 2004; Ruessink, 1998). However, the results of Conde et al. (2017b) for this beach show a saturation of Igrav energy in the swash zone; therefore, this is also true for the run-up. It should be noted that the aforementioned studies did not consider hydrodynamic-morphodynamic interaction. Including this interaction would improve the understanding of the Igrav regime and its effects on beach erosion and flooding.

The present study also stresses the importance of sea level in erosion and flooding processes. It indicates greater flooding and retreat of the coastline as sea level increases. Historical extreme events evaluated with different SLR forecasts show the most critical situation for a greater SLR and successive extreme events. An increase in sea level allows the energy dissipation of SS waves to occur more onshore, promoting coastline retreat. This reflects the strong vulnerability of the coast of Cartagena to erosion and flooding by potential threats such as (i) extreme waves generated by cold fronts and hurricanes, and (ii) a progressive increase in sea level, whose effects on the coasts strengthen when extreme events coincide with high tides (Figure 9).

365

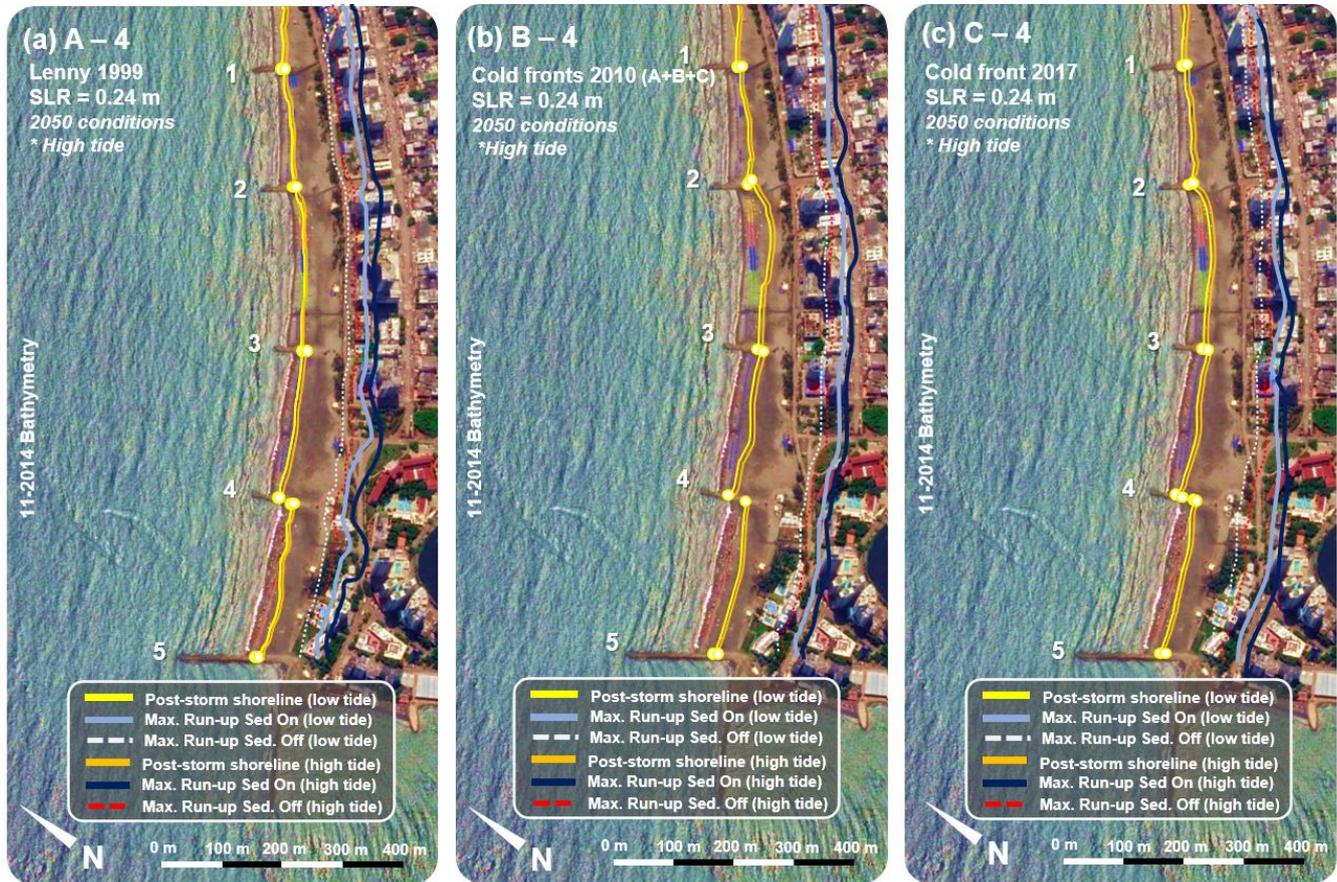

Figure 9: Maximum flood reach and post-storm shorelines simulated by XBeach at low and high tide. Map base images retrieved from © Google Earth and modified by the authors.

This research addresses the erosion and flooding that extreme wave events combined with SLR can cause on a dissipative microtidal beach. This type of beach is common in many parts of the world (e.g., on the coasts of the Caribbean and Mediterranean seas and Gulf of Mexico). The results indicate the worst-case scenario for successive extreme events. This demonstrates the importance of using this type of method, because typically only individual extreme events have been evaluated. Given that the present study examined real conditions of extreme events, each of which had specific characteristics (H_s , T_p , D_m and duration) that make it difficult to establish relationships between waves and flooding/erosion, we suggest an assessment of the influence of the various wave parameters (H_s , T_p and D_m) on flooding and erosion by varying (i) the water level and (ii) the duration of the extreme event.

5 Conclusions

The results of this research indicate that flooding on microtidal dissipative beaches under extreme wave conditions should be approached by considering morphodynamics, because ignoring them can underestimate flooding by ~15%.

380 A longer duration of extreme events causes greater erosion because of slow recovery of the beach profile, creating a post-storm profile with an erosion-accretion imbalance caused by the longitudinal transport of sediments toward the coast. The erosion and flood effects are intensified by SLR, resulting in the most unfavorable condition when extreme events are contemporaneous with high tides.

Individual extreme events are typically evaluated to establish the threat to coastal zones, but the results of the present study suggest the evaluation of successive extreme event scenarios, because they represent the worst erosion and flooding scenario.
