Abstract

Displacement monitoring is a critical control for risks associated with potentially sudden slope failures. Instrument measurements are, however, obscured by the presence of scatter. Data filtering methods aim to reduce the scatter and therefore enhance the performance of early warning systems (EWSs). The effectiveness of EWSs depends on the lag time between the onset of acceleration and its detection by the monitoring system, such that a timely warning is issued for the implementation of consequence mitigation strategies. This paper evaluates the performance of three filtering methods (simple moving average, Gaussian-weighted moving average, and Savitzky-Golay), and considers their comparative advantages and disadvantages. The evaluation utilized six levels of randomly generated scatter on synthetic data as well as high-frequency global navigation satellite system (GNSS) displacement measurements at the Ten-mile landslide in British Columbia, Canada. The simple moving average method exhibited significant disadvantages compared to the Gaussian-weighted moving average and Savitzky-Golay approaches. This paper presents a framework to evaluate the adequacy of different algorithms for minimizing monitoring data scatter.

Keywords: Landslide; Early Warning System; Scatter; Filter; Gaussian-Weighted Moving Average, Savitzky-Golay

26 **1. Introduction**

27 Landslides are associated with significant losses in terms of mortality and financial consequences
28 in countries all over the world. In Canada, landslides have cost Canadians approximately \$10
29 billion since 1841 (Guthrie, 2013) and more than \$200 million annually (Clague and Bobrowsky,
30 2010). Essential infrastructure, such as railways and roads that play vital roles in the Canadian
31 economy, can be exposed to damage if it transverses landslide-prone areas. Attempting to
32 completely prevent landslides is typically infeasible, as stabilizing options and realignment may
33 be cost-prohibitive or lead to environmental damage. This accentuates the significance of
34 adopting strategies that require constant monitoring to mitigate the consequences of sudden
35 landslide collapses (Vaziri et al., 2010; Macciotta and Hendry, 2021).

36 In recent years, detailed studies have addressed the use of early warning systems (EWSs) as a
37 robust approach to landslide risk management (Intrieri et al., 2012; Thiebes et al., 2014; Atzeni et
38 al., 2015; Hongtao, 2020). The United Nations defines an EWS as “a chain of capacities to provide
39 adequate warning of imminent failure, such that the community and authorities can act
40 accordingly to minimize the consequences associated with failure” (UNISDR, 2009). Although an
41 EWS comprises various components acting interactively, the core of its performance relies on its
42 ability to detect the magnitude and rate of landslide displacement (Intrieri et al., 2012). Given that
43 the timely response of an EWS determines its effectiveness, an accurate sense of landslide
44 velocity and acceleration is necessary. Monitoring instruments able to provide real-time or near
45 real-time readings such as global navigation satellite systems (GNSSs) and some remote sensing
46 techniques are, satisfactory for this purpose (Yin et al., 2010; Tofani et al., 2013; Benoit et al.,
47 2015; Macciotta et al., 2016; Casagli et al., 2017; Chae et al., 2017; Rodriguez et al., 2017, 2018,
48 2020; Huntley et al., 2017; Intrieri et al., 2018; Journault et al., 2018; Carlà et al., 2019; Deane,
49 2020; Woods et al., 2020, 2021). These instruments can record the displacement of locations at
50 the surface of the landslide with a high temporal resolution, which allows the monitoring system
51 to track movements on the order of a few millimeters per year. In practice, the results are usually

52 obscured by the presence of scatter, also known as noise, and outliers that affect the quality of
53 observations. These unfavorable interferences do not reflect the true behavior of the ground
54 motion and stem from sources such as the external environment and the quality of the
55 communication signals and wave propagation in the case of remote sensing techniques (Wang,
56 2011; Carlà et al., 2017b).

57 Scatter can be defined as measurement data that are distributed around the “true” displacement
58 trend, such that the average difference between the scatter and the displacement trend is zero
59 and has a finite standard deviation. Scatter in displacement measurements can significantly
60 impact the evaluation of slope movements performed on unfiltered data and decrease the
61 reliability of an EWS. This can lead to false warnings of slope acceleration or unacceptable time
62 lags between the onset of slope failure and its identification, and therefore a loss of credibility for
63 an EWS (Lacasse and Nadim, 2009). As a result, scatter should be reduced as much as possible
64 without removing the true slope displacement trends. The application of algorithms that work as
65 filters aims to minimize the amplitude of measured scatter around the displacement trend.

66 Several approaches have been proposed to filter displacement measurements based on either
67 the frequency or time domain. Fourier and wavelet transformations aim to find the frequency
68 characteristics of the data, then attenuate or amplify certain frequencies. These approaches are
69 discussed in Karl (1989), who suggests they are generally unsuitable for non-stationary data such
70 as monitoring data time series. Filters that work on the time domain can be classified as recursive,
71 kernel, or regression filters. Recursive filters, such as the exponential filtering function, calculate
72 the filtered value at a given time based on the previous filtered value. Kernel filters, which include
73 simple moving average (SMA) and Gaussian-weighted moving average (GWMA), calculate the
74 filtered values as the weighted average of neighboring measurements. Of these two kernel filters,
75 SMA is frequently used in the literature largely due to its simplicity (Dick et al., 2015; Macciotta et
76 al., 2016, 2017b; Carlà et al., 2017a,b, 2018, 2019; Bozzano et al., 2018; Intrieri et al., 2018;
77 Kothari and Momayez, 2018; Chen and Jiang, 2020; Zhou et al., 2020; Deng et al., 2021; Desrues

78 et al., 2021; Grebby et al., 2021; Zhang et al., 2021a,b). Regression filters calculate the filtered
79 values by means of regression analysis on unfiltered values (e.g., Savitzky-Golay, or S-G)
80 (Savitzky and Golay, 1964; William, 1979; Cleveland, 1981; Cleveland and Devlin, 1988; Reid et
81 al., 2021). Carlà et al., (2017b) studied both SMA and exponential filtering on multiple failed
82 landslide cases and concluded the latter is inferior in terms of accuracy of failure time prediction.
83 On the other hand, Carri et al. (2021) cautioned the designers and users of EWSs against the use
84 of SMA when rapid movements are expected. However, published applications of filters other
85 than SMA for landslide monitoring are scarce, and studies dedicated to comparing the
86 functionality of other filters to that of SMA are limited.

87 This paper presents an approach to detect and remove outliers, evaluates the performance of
88 three filters (SMA, GWMA, and S-G), and assesses their suitability to be utilized in an EWS. We
89 evaluated three filters against the following criteria: 1) scatter is minimized, 2) true underlying
90 displacement trends are kept with as little modification as possible, and 3) filtered displacement
91 trends detect acceleration episodes in a timely manner. Moreover, the paper investigates the
92 significance of the time lag between a landslide acceleration event and its identification by a
93 monitoring system for the three filters evaluated.

94 **2. Methodology**

95 **2.1. Synthetic Data Generation**

96 A numerical analysis on a synthetic dataset approach was adopted, which consists of synthetic
97 dataset scenarios generated to resemble typical landslide displacement measurements, including
98 acceleration and deceleration periods. These scenarios are idealizations based on observations
99 of typical landslide displacements published in the literature (Leroueil, 2001; Intrieri et al., 2012;
100 Macciotta et al., 2016; Schafer, 2016; Carlà et al., 2017a; Scoppettuolo et al., 2020). A total of 12
101 dimensionless scenarios were built, with all data between the coordinates $x=0, y=0$ and $x=1, y=1$.
102 The x value represents time, and normalization between 0 and 1 allows for extrapolation of the

103 findings for variable displacement measurement frequencies (e.g., the full range of x could
104 represent a week, a month, a year). The analysis of synthetic data focuses on the ability of
105 different algorithms to minimize scatter and identify changes in measured trends; therefore, y
106 represents any of the displacement measurement metrics of interest, e.g., displacement,
107 cumulative displacement, velocity, inverse velocity, etc. Mathematical equations and graphical
108 illustrations of the 12 scenarios are shown in Fig. 1.

109 Nine of the scenarios are referred to as harmonic scenarios, which are characterized by gradual
110 changes in the trend of parameter y . The remaining three scenarios show sudden variations at or
111 near $x=0.5$, and are referred to as instantaneous scenarios. Considering the discrete nature of
112 instrument measurements, and to account for different ranges in measurement frequencies, each
113 scenario was generated several times, each time with a different number of points (Table 1).

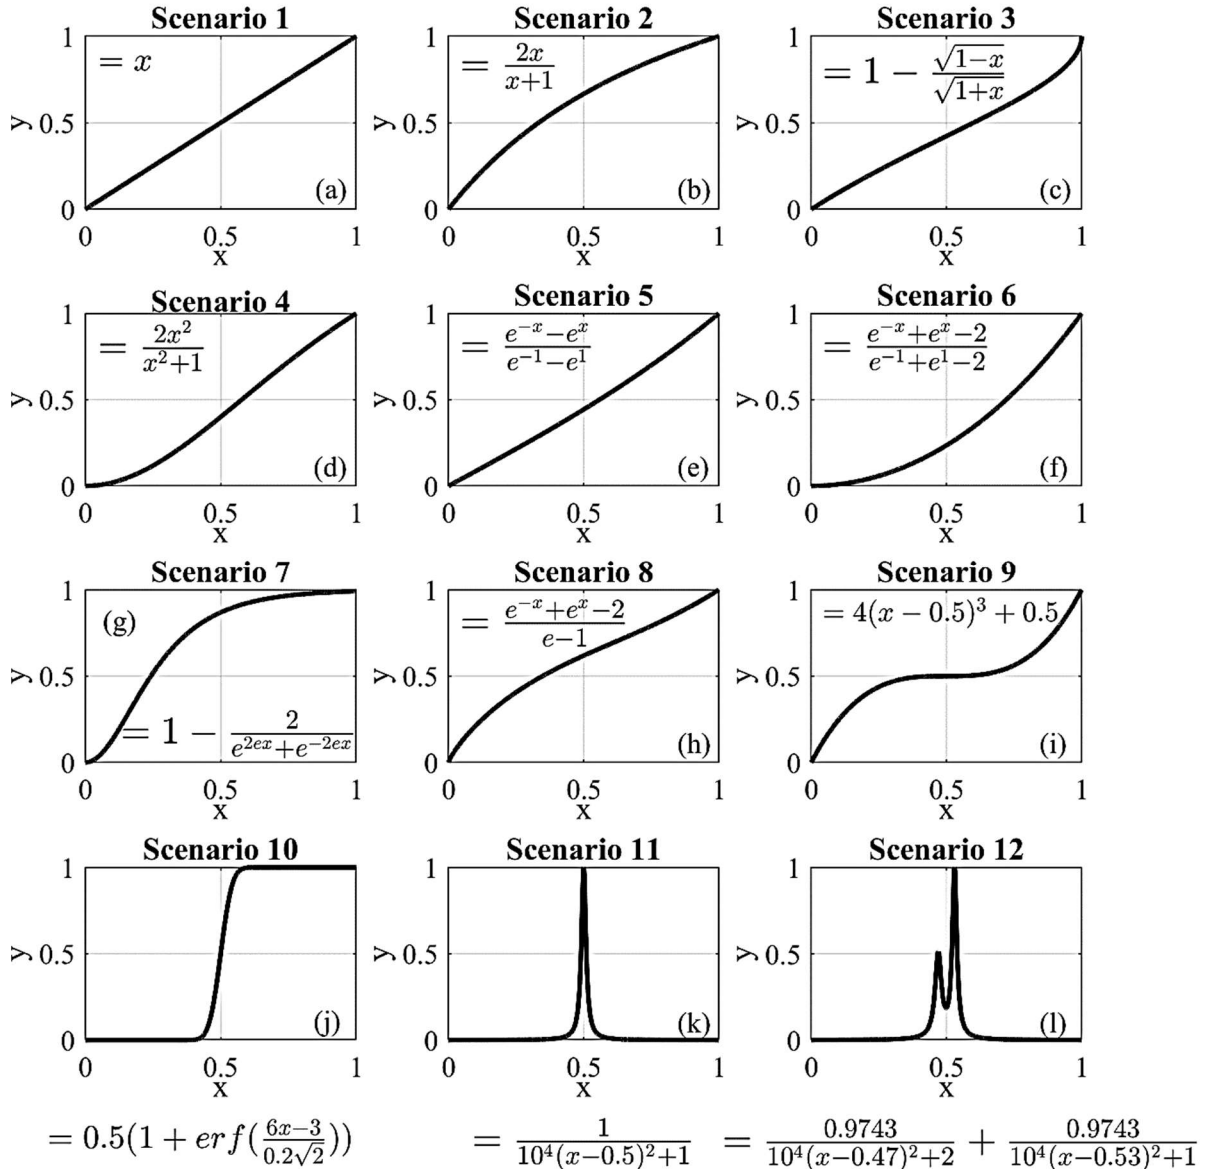

Fig. 1 Configuration of all synthetically generated scenarios

115
116

117 **Table 1** Number of points used to generate scenarios and examples of their corresponding time spans
118 represented by the range of x from 0 to 1 if the measurement frequency is known (1-h and 1-m readings
119 for illustrative purposes).

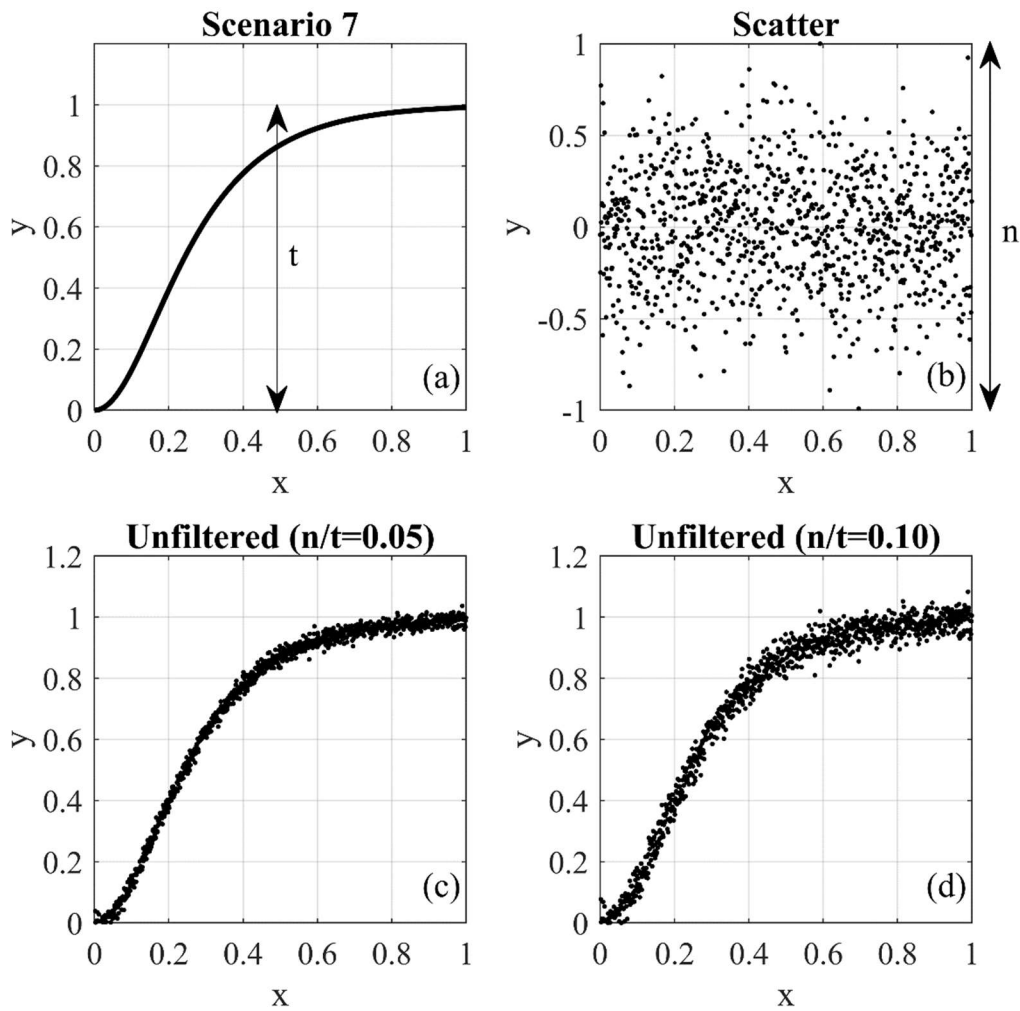

Number of points	Example monitoring frequency			
	1-h readings		1-m readings	
1000	41.7	Days	16.7	Hours
3000	4.1	Months	2.1	Days
9000	1.0	Years	6.3	Days

20000	2.3	Years	2.0	Weeks
40000	4.6	Years	4.0	Weeks
86000	9.8	Years	2.0	Months
250000			5.8	Months
500000			0.9	Year
750000			1.4	Years
1.00E+6			1.9	Years

120

121 The next step was adding random scatter to the scenarios to represent unfiltered displacement
122 measurements. Macciotta et al. (2016) show the scatter in displacement monitoring for a GNSS
123 used in their analyses fitted a Gaussian distribution. We validated the scatter distribution fit
124 approximates a Gaussian distribution for the displacement data scatter of the case study in this
125 paper. This assumption, however, has an underpinning theoretical base established by the central
126 limit theorem in probability theory. It states that the mathematical summation of independent
127 variables (such as scatter) goes toward a Gaussian distribution (Smith, 2013). As a result, the
128 scatter was randomly produced from a normal distribution centered at zero, with extreme values
129 truncated between -1 and 1 and a standard deviation of 0.20 . Random generation of the scatter
130 followed the techniques outlined in Clifford (1994) known as the acceptance-rejection method,
131 which generates scatter values through a series of iterations until the algorithm generates the
132 initial normal distribution. The amplitude of the scatter around the trend in parameter y was defined
133 for each scenario by scaling the randomly generated scatter. This allowed for the investigation of
134 the effect of different scatter magnitudes on the performance of the filters. Scaling was done by
135 defining the ratio n/t , which is the ratio of scatter amplitude (maximum deviation around the trend,
136 termed n) to the range of values of the trend (t) in each scenario. Six levels of n/t (0.001 , 0.005 ,
137 0.010 , 0.050 , 0.100 , and 0.150) were considered when performing the analysis to cover a range
138 of possible levels of scatter in unfiltered measurements. Fig. 2 shows two samples of synthetic

139 unfiltered scenarios that are the result of superimposing scatter with n/t values of 0.05 and 0.10,
140 respectively, on scenario No. 7.

141
142 **Fig. 2** The procedure of generating a scenario with scatter: (a) generated scenario trend, (b) randomly
143 generated scatter, and two scenarios with scatter based on n/t values of (c) 0.05 and (d) 0.10

144 2.2 Data Processing Approaches

145 2.2.1. Simple moving average

146 SMA is a well-known method for scatter reduction that attempts to reduce scatter by calculating
147 the arithmetic mean of neighboring points' values. A constant-length interval (window or
148 bandwidth) is used for the calculation for each point; this is also termed a "running" average.
149 Equation 1 is the formulation of this method, which was used by Macciotta et al. (2016) to analyze
150 GNSS data scatter:

151

$$\hat{y}_i = \frac{\sum_{i-\frac{p-1}{2}}^{i+\frac{p-1}{2}} y_j}{p}, \quad (1)$$

152

153

154

155

156

where \hat{y}_i is the filtered value, y_j is the unfiltered value, and p is the window length. The window length is constant across the dataset except for regions near the boundaries where fewer points are available. Accordingly, p will be adjusted to the number of available points that are indeed less than the value set by the user. This will cause variation in the effectiveness of the method at the extremes, which needs to be considered when evaluating the results of this approach.

157

2.2.2. Gaussian-weighted moving average

158

159

160

161

162

Varying the weights of the measurements within the calculation window in SMA can be used to develop different filtering methods. The largest weight can be given to the measurement at the time for which the calculation is being done, with weights decreasing for measurements farther away in time. One simple weighting function that can be adopted is the Gaussian (normal) distribution. Eq. 2 is the formulation of the Gaussian-weighted moving average (GWMA):

163

$$\hat{y}_i = \sum_{i-\frac{p-1}{2}}^{i+\frac{p-1}{2}} w_j y_j, \quad (2)$$

164

165

where w_j is the weight coefficient based on the Gaussian distribution and the other terms follow the same definition as per SMA.

166

2.2.3. Savitzky-Golay

167

168

169

170

171

172

S-G fits a low-degree polynomial equation to the unfiltered measurements within a window and defines the filtered measurements using the fitted curve (Schafer, 2011). Although this procedure seems dissimilar from the weighted averaging as discussed for GWMA, its function can be transformed into a kernel concept using the least-squares method if the data points are evenly spaced. The detailed procedure is presented in Appendix A. Fig. 3 shows the weight kernel over a window of seven points attained by fitting a quadratic polynomial. An immediate observation is

173 that some points are given negative weights. If points are not evenly spaced, the weighting kernel
174 cannot be used, and local regression analysis should be periodically conducted for each point.
175 Such filtering is known as locally estimated scatterplot smoothing (LOESS). This decreases the
176 computational efficiency of filter performance and exponentially increases the execution time.

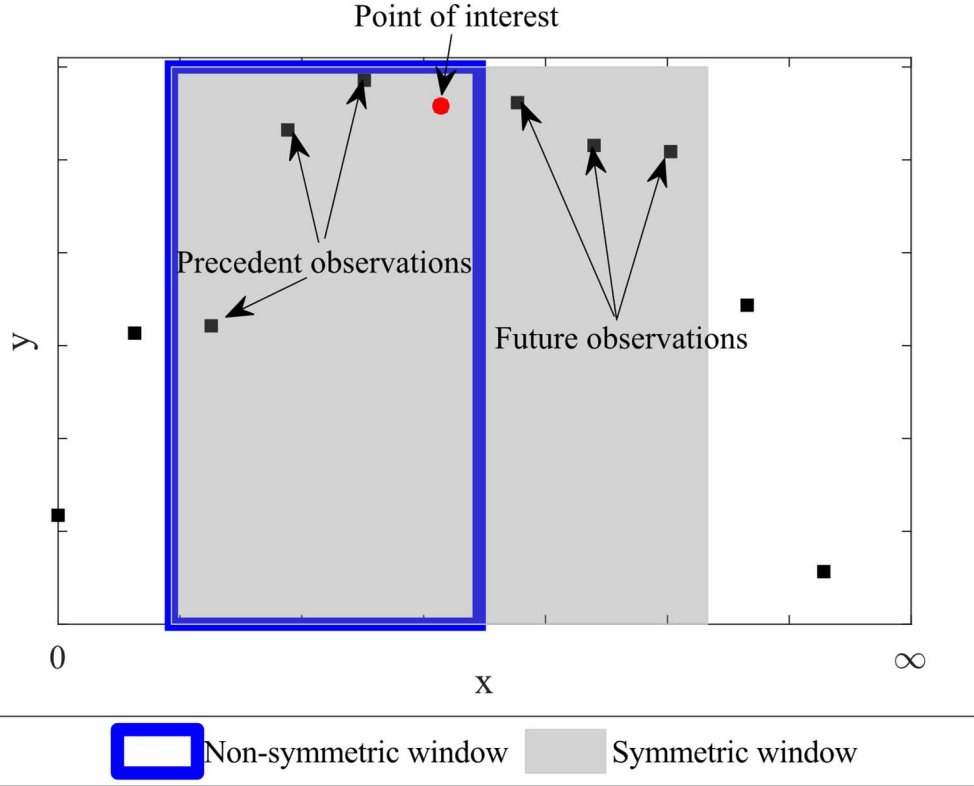

177

178

Fig. 3 The weighting kernel of the Savitzky-Golay filter for seven points

179 **2.3 Evaluation of Processing Algorithms**

180 The synthetic monitoring data and data from the case studies were filtered using SMA, GWMA,
181 and S-G techniques. The filters were applied with different lengths of moving windows, from 0.01
182 (1%) to 0.1 (10%) of all monitoring points, referred to as the bandwidth ratio. These limits for the
183 bandwidth ratio were selected based on literature reports for SMA. In the filtration process, we
184 only used the points prior to the time for which the calculation is being made (point of interest,
185 Fig. 4). This is to reflect the reality of displacement monitoring information as applied to EWSs.
186 To this end, filters used the first half of their kernels, but the weights were multiplied by 2 in
187 comparison to a symmetric window in order to keep the sum of weights equal to 1.

188
189 **Fig. 4.** Concept of symmetric and non-symmetric window types in the filtration process

190 All of these filters require the definition of the bandwidth. A roughness factor was defined to aid
191 in the evaluation of the effect of bandwidth in reducing scatter. This factor is defined as:

$$J_2 = \frac{\int (\hat{y}'')^2 dx}{R_a}, \quad (3)$$

$$R_a = \int (y'')^2 dx, \quad (4)$$

192 where J_2 is the roughness factor, \hat{y}'' is the second derivative of filtered measurements, R_a is the
193 absolute roughness computed by Eq. 4, and y'' is the second derivative of unfiltered
194 measurements. The second derivative measures how much the slope of the line connecting two
195 consecutive points changes, which itself is an indication of fluctuation. The greater this second
196 derivative, the greater the variation. J_2 was normalized to the overall curvature of the unfiltered
197 scenario to determine the relative scatter reduction after the application of a filter, eliminating any
198 roughness associated with the real trend in the scenario. In limit states, a value of 1 means that
199 fluctuations are similar to the unfiltered dataset, and therefore no improvement has been
200 achieved; a value of 0 suggests the slope of a scenario remains unchanged and indicates a linear

201 trend. Because all the scenarios, except the first, include trends showing concavity or convexity,
202 a residual value for the roughness factor would be expected in the lowest limit state, meaning that
203 a value of 0 is not necessarily a goal. J_2 was used to infer the minimum value of bandwidth ratio
204 after which no significant change in the fluctuation of results is achieved. Considering the second
205 power in the formulation of J_2 , all observations are valid if the scenarios are mirrored (when they
206 vary from 1 to 0, instead of 0 to 1).

207 The filters are not expected to remove all scatter, and the error attributed to the residual scatter
208 can be calculated using the root mean square error (RMSE). Given that velocity values are usually
209 used as thresholds in an EWS, one concern is whether the filter should be applied to displacement
210 values or velocity values derived from unfiltered displacements. To address this issue, two
211 different approaches to filtering were investigated: direct and indirect. As a result, two different
212 approaches using the RMSE were also utilized here.

213 *2.3.1. Direct scatter filtration*

214 Direct filtration means the filter is applied to the diagram of interest. If the filtered displacement
215 values are the goal, and the filter is applied to unfiltered displacement values, then the filtering
216 process is called direct filtration. The same concept applies when velocity values are derived
217 using unfiltered displacements and the filters are then directly applied to the velocity values. In
218 this approach, the RMSE follows Eq. 5:

$$219 \quad RMSEd = \sqrt{\frac{1}{m} \sum_{i=1}^m (\hat{y}_i - y_i)^2}, \quad (5)$$

220 where $RMSEd$ is the measurement of error in direct filtration, y_i is the value of the true trend (for
221 the synthetic scenario), \hat{y}_i is the filtered value, and m is the total number of points. This approach
222 is often used in the literature (e.g., Macciotta et al., 2016; Carlà et al., 2017a,b, 2018, 2019; Intrieri
223 et al., 2018).

224 *2.3.2. Indirect scatter filtration*

225 Some EWSs can apply the filter to the displacements but use velocity trends as the metric for
226 evaluation. In this case, the filtered velocity values will be computed using the filtered
227 displacements. Indirect filtration indicates the diagram of interest is the first derivative of the
228 diagram to which the filter is applied. The RMSE, in this case, is defined as:

$$229 \quad RMSE_i = \sqrt{\frac{1}{m} \sum_{i=1}^m (\hat{y}_i' - y_i')^2}, \quad (6)$$

230 where $RMSE_i$ is the measurement of error in indirect filtration, y_i' is the first derivative of the true
231 trend, \hat{y}_i' is the first derivative of filtered data (derived velocity after the filter is applied to the
232 displacements), and m is the total number of points. Similar to J_2 , all observations are valid for
233 the mirrored scenarios of those presented in Fig. 1. This is a consequence of using the second
234 power in the definition of $RMSE_i$ and $RMSE_d$.

235 **2.4 Lag Quantification**

236 Only antecedent measurements are fed into the filters, which is expected to result in a lag between
237 the true trend and its identification by the filters. This lag means the calculated value of velocity
238 or displacement occurred sometime in the past. Consequently, reducing this lag means less time
239 is lost with respect to providing an early warning. To quantify the induced lag, the filtered diagrams
240 of all scenarios at all n/t ratios and bandwidth ratio values were shifted backwards a number of
241 points equivalent to 0.001 (0.1%) to 0.1 (10%) of all generated points. We refer to this as the shift
242 ratio in the rest of this paper. This shift of filtered diagrams is expected to increase their similarity
243 with the true trend until the best correlation is achieved. The R^2 test was used to determine how
244 well the shifted and filtered results replicate the underlying trend.

245 **2.5. Geocubes Differential GNSS System**

246 A Geocubes system is a network of differential global navigation satellite system (GNSS) units
247 that work with a single frequency (1572.42 MHz), making it cost-effective (Dorberstein, 2011;

248 Benoit et al., 2014; Rodriguez et al., 2018). Geocubes communicate with each other through radio
249 frequency, and a reference unit outside the boundaries of the landslide is assumed as static for
250 differential correction to increase the poor accuracy associated with single frequency GNSSs
251 (Benoit et al., 2014; Rodriguez et al., 2018). The ability of this system to achieve real-time
252 positioning, remote data collection, and processing makes it a suitable candidate for incorporation
253 into an EWS. As a result, Geocube data are used in this study to evaluate the performance of the
254 three mentioned filters.

255 **2.6. Outlier Detection**

256 Outliers are defined herein as abnormal inconsistencies (e.g., displacement directions,
257 magnitudes) when compared to the majority of observations in a random sampling of data (Zimek
258 and Filzmoser, 2018). Techniques for outlier detection have been proposed based on the
259 statistical characteristics of datasets. One common example is the Z-score method, which
260 calculates the mean and standard deviation of data within a defined interval and identifies outlier
261 data as those beyond three standard deviations from the mean (Rousseeuw and Hubert, 2011).
262 A limitation of this kind of approach is the sensitivity of the mean and standard deviation to the
263 outlier data points, which has led to the development of other methods that use other indices such
264 as the median (Salgado et al., 2016). One such technique that was adopted in this study is the
265 Hampel filter (Hampel, 1971). In this method, the median of the displacement measurements
266 within a running bandwidth is calculated and data outside a defined threshold from the median
267 are identified as outliers. The threshold is defined as a constant (threshold factor) multiplied by
268 the median absolute deviation. An asymmetric window with a bandwidth ratio of 0.004 (0.4%) and
269 a threshold factor of three were adopted following previous studies (Davies and Gather, 1993;
270 Pearson, 2002; Liu et al., 2004; Yao et al., 2019). The data identified as outliers were then
271 removed from the dataset.

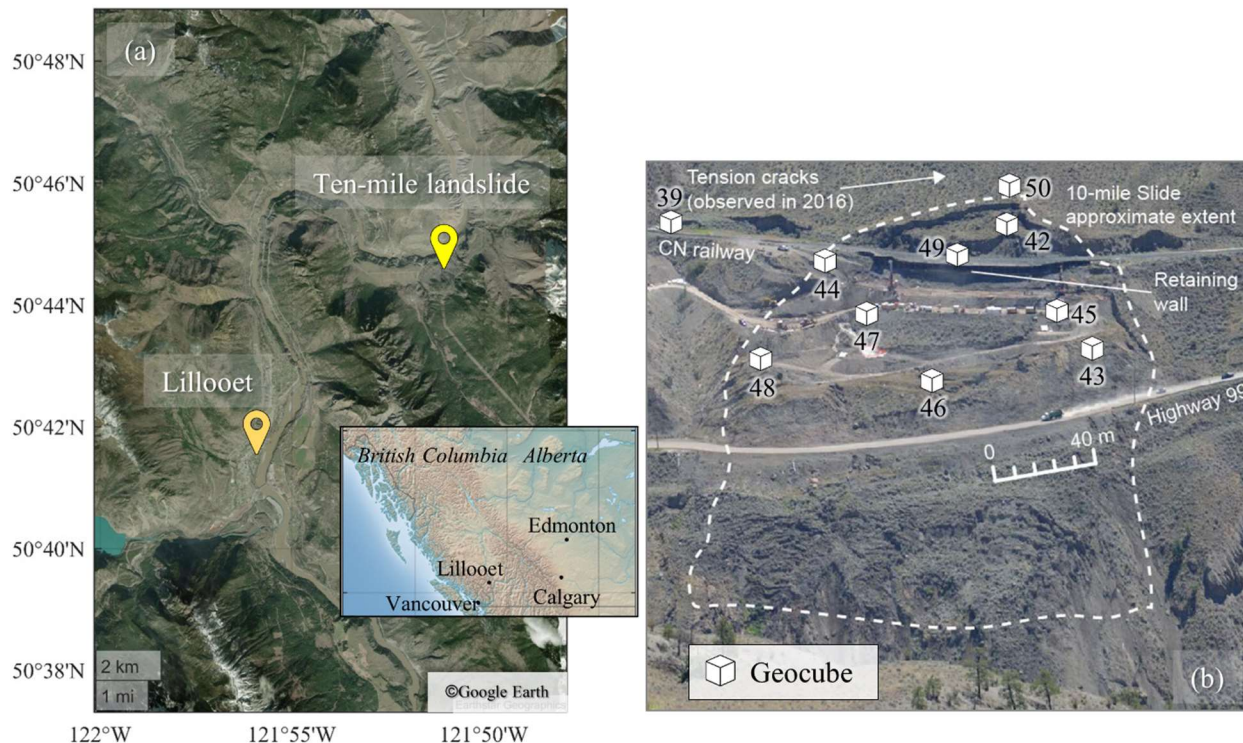

272 **3. Study Site – Ten-mile Landslide**

273 The Ten-mile landslide is located in southwestern British Columbia (BC), in the Fraser River
274 Valley north of Lillooet (Fig. 5a). It is a reactivated portion of a post-glacial earthflow (Bovis, 1985)
275 that was first recognized in the 1970s. The landslide velocity has increased from an average of 1
276 mm/day in 2006 to 6 mm/day in 2016, with a maximum measured velocity of 10 mm/day (Gaib et
277 al., 2012; BGC Engineering Inc., 2016). The movement of this landslide impacts the integrity of
278 BC Highway 99 and a section of railway operated by Canadian National Railway (CN) (Carlà et
279 al., 2018), with most movement limited to the volume downslope from the railway due to the
280 installation of a retaining wall (Macciotta et al., 2017a). Despite the stabilization work done to date,
281 the uppermost tension crack has retrogressed approximately 200 m in 45 years and is now
282 situated 60 m upslope of the railway track (Macciotta et al., 2017b). The landslide lateral extents
283 have not expanded since 1981 according to the aerial photographs Macciotta et al., 2017b). The
284 Ten-mile landslide is currently approximately 200 m wide, 140 m high, and has a volume of 0.75
285 to 1 million m³, moving towards the Fraser River on a continuous rupture surface with a dip of
286 about 22 to 24°, which is sub-parallel to the ground surface (Rodriguez et al., 2017; Donati et al.,
287 2020). The elevation of the shear surface and mechanism of the landslide have been inferred
288 from the readings of multiple slope inclinometers installed in 2015 (BGC Engineering Inc., 2015).

289 The bedrock in this region consists of volcanic rocks, such as andesite, dacite, and basalt, and is
290 overlain by Quaternary deposits (Donati et al., 2020; Carlà et al., 2018; Macciotta et al., 2017a).
291 The thickness of the landslide varies between 20 and 40 m and the ground profile from the surface
292 to depth comprises medium to high plastic clays and silts overlying colluvium material and glacial
293 deposits, overlying bedrock (BGC Engineering Inc., 2015). The stratigraphy of the sedimented
294 soils in the landslide area notably varies from one borehole to another and reflects the complex
295 stratigraphy of the earthflow.

296 A total of 11 Geocubes were installed at the Ten-mile landslide in 2016. Fig. 5b is a front view of
297 the landslide showing the locations of the Geocube units. Units 44 and 50 are installed near the
298 uppermost tension crack identified as the current landslide backscarp, unit 69 is 30 m above the

299 backscarp, and unit 39 is used as the reference point. Please note that unit 69 is used as the fixed
 300 Geocube, and is not shown in Fig. 5b. The other units are located within the boundaries of the
 301 landslide, with a maximum distance between units of 310 m (Rodriguez et al., 2018). The time
 302 step between every two consecutive measurements is 60 s. Fig. 6 shows the displacements of
 303 units 46 and 47, which were the largest in comparison to other Geocubes.

304

309 **4. Results**

310 **4.1. Synthetic Analysis**

311 Fig. 7 shows the roughness value (J_2) of scenario 6 for SMA, GWMA, and S-G on a semi-
 312 logarithmic scale. This figure illustrates how, regardless of the n/t ratio, J_2 substantially decreases
 313 as the bandwidth ratio increases to 0.01 and then asymptotically approaches a final value. This
 314 means that increasing the bandwidth ratio drastically reduces scatter; however, its effectiveness
 315 is restricted as the bandwidth ratio increases above 0.01. This observation was consistent for
 316 other scenarios. J_2 values (including scenario 6 in Fig. 7) indicate that J_2 approaches its minimum
 317 at bandwidth ratio values of 0.03 to 0.04, regardless of the filter selected.

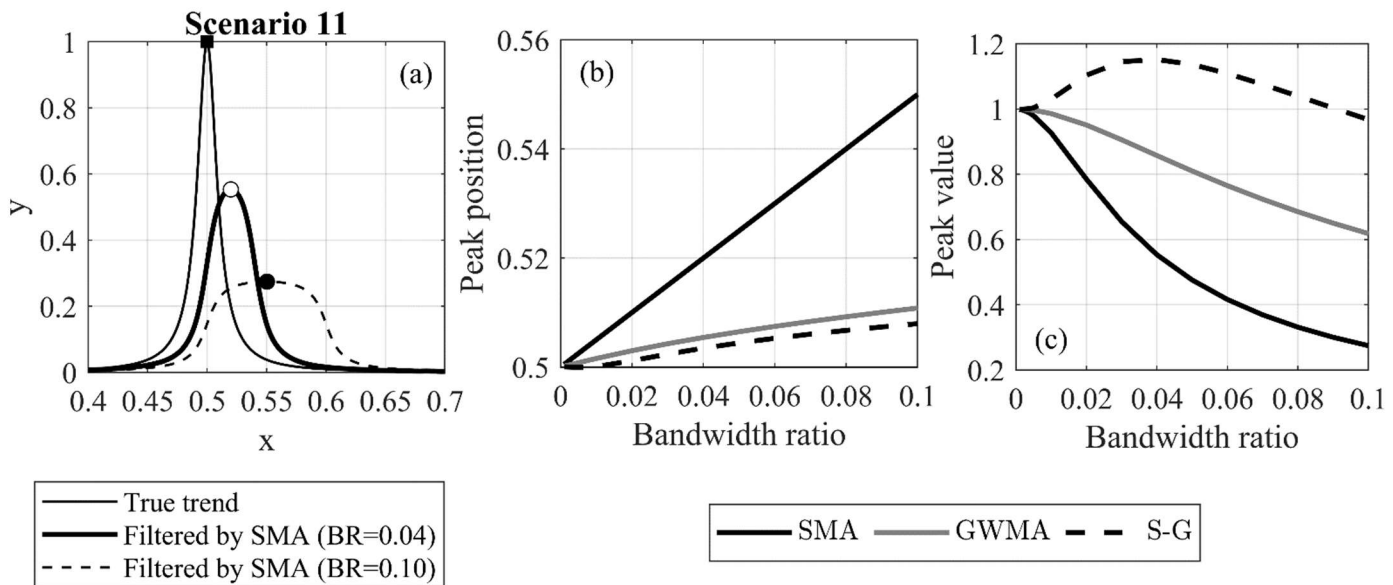

318

319 **Fig. 7** Variation of roughness factor for scenario 6 with respect to the applied filter on a semi-log scale

320 **4.1.1. Effect of filters on trend distortion**

321 Scenarios 11 and 12 were first analyzed to evaluate the degree to which the trend was preserved
 322 by these filters, as peaks made it easier for visualization. Fig. 8a shows the true trend of scenario
 323 11 along with two SMA-filtered scenarios at bandwidth ratios of 0.04 and 0.10, respectively. This
 324 figure shows that, as the SMA filter bandwidth increases, the peak in measurements is identified
 325 at a later time than the true trend ($x=0.5$) and the magnitude of the peak is reduced (more than
 326 70% reduction at a bandwidth ratio of 0.10). Furthermore, as the bandwidth ratio increases, the
 327 “instantaneous” nature of the peak is lost to a more transitional variation. This highlights a
 328 disadvantage of SMA when handling sudden changes in data trends. The calculated x value of
 329 the peak in scenario 11 is plotted for different bandwidth ratios and for all three filters in Fig. 8b.
 330 This figure shows the time at which the peak is identified lags as the bandwidth ratio increases
 331 for all filters; however, GWMA and S-G identify the peak with a much smaller lag, independent of
 332 the n/t ratio. As an example, for a year of monitoring data at a frequency of 30 s and bandwidth
 333 ratio of 0.10, SMA, GWMA, and S-G predict the peak point approximately 17, 3.5, and 2.7 days
 334 after the real peak, respectively. This lag can be attributed to the utilization of an asymmetric
 335 window, which leads to a lagged response of the filter. As more points are included in the filtering

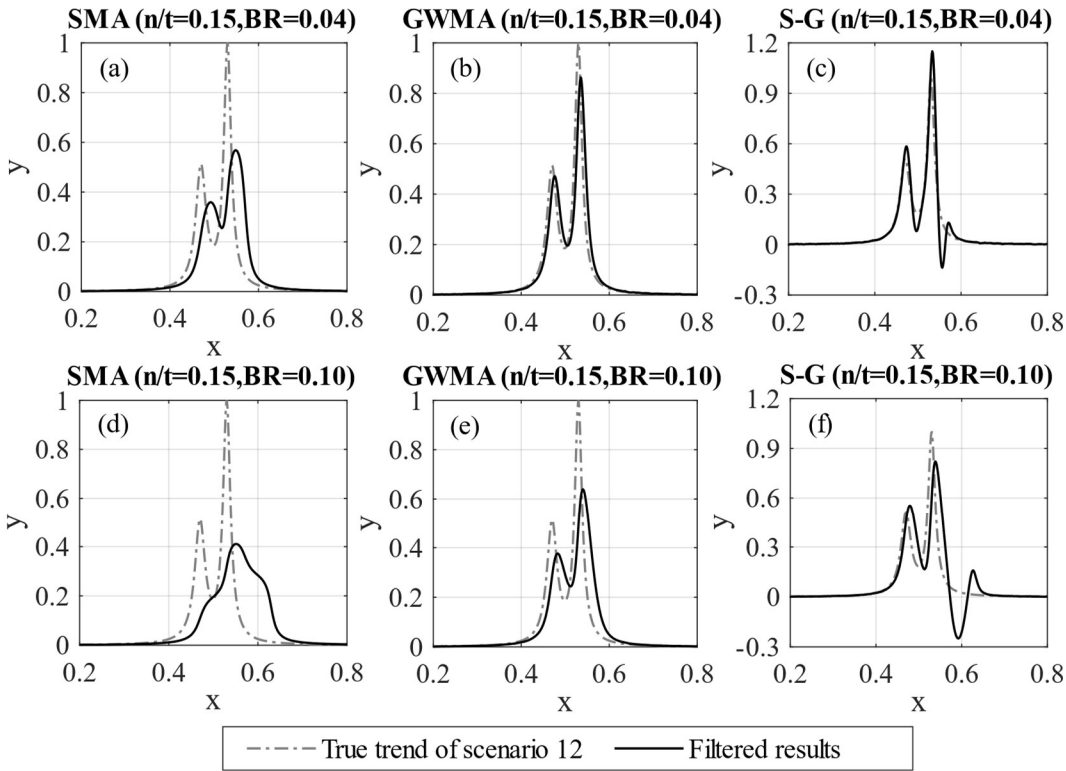

336 procedure (increasing bandwidth ratio), this lag increases because the averaging process is
 337 sensitive to window type. The degree of sensitivity, however, depends on the filter. Fig. 8c shows
 338 the variation of the peak magnitude with respect to the bandwidth ratio for all three filters. SMA
 339 and GWMA both underestimate the peak value, and the difference between the calculated peak
 340 and real peak increases as the bandwidth ratio increases. SMA calculations underestimate the
 341 peak more than twice as much as GWMA. On the contrary, S-G intensifies the peak up to a
 342 bandwidth ratio of 0.04, with the impact tending to diminish at larger bandwidth ratios; it predicts
 343 the true value at a bandwidth ratio value of almost 0.09.

344 **Fig. 8** (a) An example of peak displacement by applying SMA, and variation of (b) peak position and (c)
 345 peak value with respect to the filter and bandwidth ratio used (original peak at 0.5)
 346

347 Scenario 12 was used for a detailed evaluation of the ability of these filters to conserve the
 348 underlying original trend. **Error! Reference source not found.** Fig. 9 shows scenario 12 and the
 349 filtered results for all three filters and an n/t ratio of 0.15. This scenario and these specific
 350 parameters were selected for illustration purposes as they allow visual identification of differences
 351 for discussion. The SMA filter considerably underestimates the magnitude of the peak at a
 352 bandwidth ratio of 0.04, which should be the minimum bandwidth ratio according to Fig. 7. At a
 353 bandwidth ratio of 0.10, the filtered diagram is distorted in comparison to the true trend and the
 354 initial peak is not identified. GWMA at a bandwidth ratio of 0.04 shows less underestimation of

355 the peak magnitude, and a slight lag is visually observed at a bandwidth ratio of 0.10. This
 356 indicates the significantly better performance of GWMA over SMA. S-G results for both bandwidth
 357 ratios closely identify the time and magnitude of both peaks, indicating yet better performance.
 358 However, the peak is artificially intensified at a bandwidth ratio of 0.04, and a significant drop
 359 occurs well beyond the true trend immediately after the second peak for both bandwidth ratios
 360 (pulsating effect), which was also observed in scenario 11. Increasing the degree of the
 361 polynomial fitted as part of the S-G methodology was not completely effective at eliminating this
 362 effect. The pulsating effect was also observed when a symmetrical window was utilized and is
 363 attributed to the negative weights in the S-G kernel.

364
 365
 366 **Fig. 9** Filtered results of Scenario 12 with scatter using SMA (a,d), GWMA (b,e), and S-G (c,f) at
 367 bandwidth ratios (BRs) of 0.04 (a-c) and 0.10 (d-f)

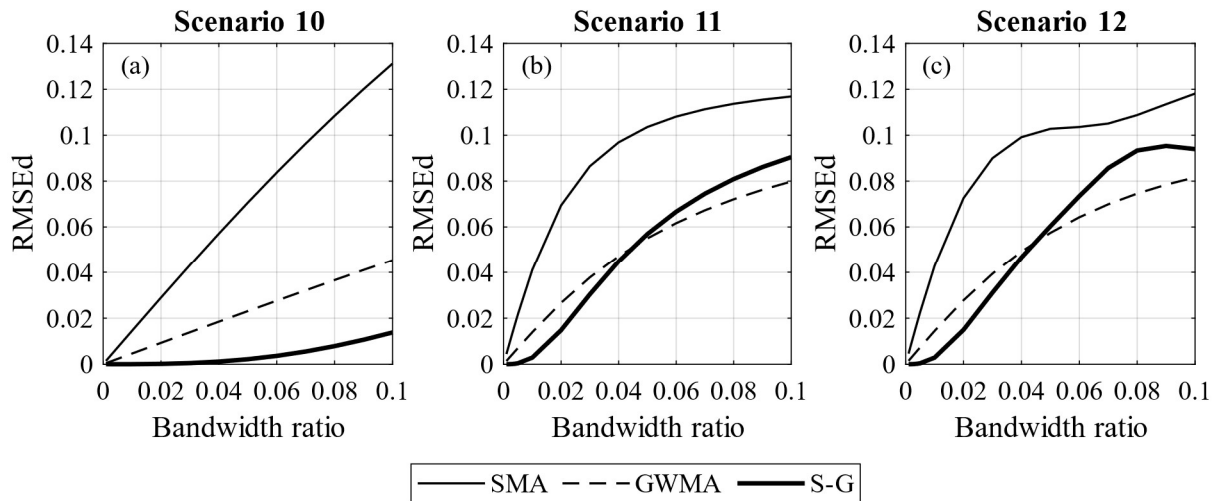

368 **4.1.2. Results of direct scatter filtration**

369 Fig. 10 shows the RMSEd of all three filters for all the harmonic synthetic scenarios. This figure
 370 shows that, for these numerical analyses on synthetic scenarios, the error depends linearly on

371 the bandwidth ratio for all of the filters and does not depend on the scenario or n/t ratio. SMA
 372 shows the greatest difference from the true trend, followed by GWMA (approximately 60% less
 373 difference than SMA). S-G, on the other hand, almost lies on the horizontal axis for all the
 374 bandwidth ratios, which means the filtered results yield near-zero error. Fig. 10 also shows how
 375 the error increases as the bandwidth ratio increases. This can be attributed to the utilization of an
 376 asymmetric window, which leads to a lagged response of the filter. As more points are included
 377 in the filtering procedure (increasing bandwidth ratio), this lag increases and, consequently,
 378 causes a larger error. The RMSEd of filters for the instantaneous synthetic scenarios are shown
 379 in Fig. 11. In scenario 10, the same behavior as noted for the harmonic scenarios can be seen
 380 for SMA and GWMA, whereas S-G is not as accurate. This is more noticeable in scenarios 11
 381 and 12 in which S-G becomes less accurate than GWMA at larger bandwidth ratios. This result
 382 shows that S-G cannot handle the instantaneous scenarios as satisfactorily as the harmonic ones.
 383 The errors related to SMA and GWMA for the instantaneous synthetic scenarios show non-linear
 384 behavior and are greater when compared to the harmonic scenarios. Fig. 11 clearly shows all
 385 filters are challenged by the instantaneous variations when compared to gradual ones in direct
 386 filtration.

387
388 **Fig. 10** RMSEd for the harmonic scenarios

389
390 **Fig. 11** RMSEd for the instantaneous scenarios

391 **4.1.3. Results of indirect scatter filtration**

392 Fig. 12 shows the RMSEi results for the harmonic scenarios (when performing indirect filtration)
 393 on a semi-logarithmic scale. We observed that the error considerably decreases as the bandwidth
 394 ratio increases to 0.02; however, to highlight the variation of error in the range of interest for the
 395 bandwidth ratio, only RMSEi values corresponding to bandwidth ratios greater than 0.04 are
 396 plotted in Fig. 12 and 13. In Fig. 12, the error for the GWMA is either equal to or slightly less than
 397 the error for the SMA, and S-G shows the least error for the harmonic scenarios. The RMSEi
 398 results for the instantaneous scenarios (Fig. 13) are similar to those for the harmonic scenarios
 399 for large n/t ratios (0.05, 0.10 and 0.15). For small n/t ratios, the GWMA is superior at bandwidth
 400 ratios above 0.06, and S-G has the worst performance.

401

403

404

Fig. 13 RMSE_i for the instantaneous scenarios

405 4.1.4. Lag quantification

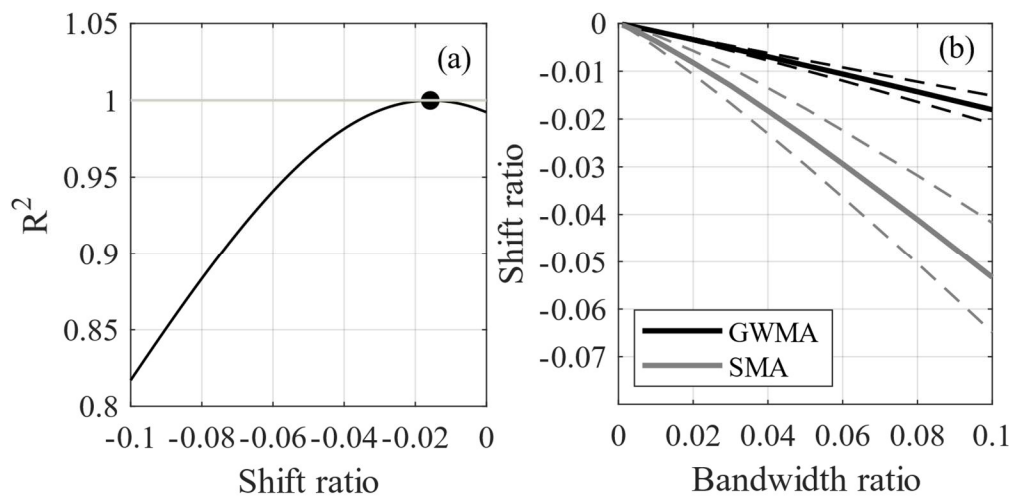

406 The non-symmetric inclusion of points causes the identification of a lag in the trend of filtered
407 data. Fig. 14 shows Scenario 10 with respect to the original trend, with scatter added (at an n/t
408 value of 0.15), and the results after filtering with each of the three methods at a bandwidth ratio
409 of 0.04. This figure clearly shows the lag between the results filtered by SMA and GWMA and the
410 true trend. S-G results do not have as severe a lag as that resulting from the other filters; we
411 attribute this to the negative weights in its kernel that anchor the filtered values and prevent a
412 lagged response. A minor pulsating effect can be observed in the S-G filtered data, decreasing
413 the calculated values at a much earlier time than the true trend. This suggests that S-G is robust
414 with respect to identifying initial changes in monitoring trends but overcorrects subsequent
415 changes; SMA grossly lags with respect to the identification of any change, and GWMA has a
416 reduced lag when compared to SMA.

417
418 **Fig. 14** Scenario 10 with and without scatter, and with scattered results filtered by SMA, GWMA, and S-G
419 for an n/t value of 0.15 and a bandwidth ratio of 0.04.

420 Fig. 15a shows an example of the R^2 correlation for scenario 7, comparing the original trend and
421 the results filtered by SMA at an n/t value of 0.01 and bandwidth ratio of 0.04. The shift ratio is

422 the shift of filtered trends (in the horizontal axis – parameter x) relative to the range of x values.
 423 R^2 calculations are shown for the filtered data (shift ratio of 0) and as the filtered trends are shifted
 424 backwards in time (negative shift ratio values). In this analysis, the peak R^2 value (largest
 425 correlation between the shifted filtered results and original trend) indicates the shift required to
 426 minimize the lag in identifying the original trend changes, therefore providing a quantitative
 427 approach to calculating the lag in parameter x . In the example in Fig. 15a, the lag corresponded
 428 to 0.018 (1.8%) of the total points.

429 **Fig. 15** (a) R^2 values for scenario 7 with filtered and shifted results at an n/t value of 0.01 and bandwidth
 430 ratio of 0.04 and (b) shift ratio at peak R^2 for all scenarios and n/t ratios, with the mean (solid line)
 431 bounded by one standard deviation (dashed lines)
 432

433 Peak R^2 values for all scenarios and n/t values are closely correlated with the bandwidth ratio.
 434 The lag, quantified by the shift ratio, is larger when the trend change is more pronounced;
 435 therefore, the correlation between the shift ratio and bandwidth ratio is different for different
 436 scenarios. Fig. 15b shows the mean correlation between the shift ratio and bandwidth ratio, for
 437 all scenarios and n/t values, bounded by one standard deviation, for GWMA and SMA. Table 2
 438 shows linear and quadratic regressions of this correlation and the strength of the correlation in
 439 terms of R^2 and RMSE. Fig. 15b quantitatively shows that GWMA lags less than SMA with respect
 440 to identifying changes in measurement trends. Moreover, the uncertainty associated with lag for
 441 SMA is greater than for GWMA because of the larger standard deviation. Fig. 15b quantifies how
 442 increasing the bandwidth ratio increases the lag with respect to identifying true measurement

443 trends and, although large bandwidth ratios decrease the scatter in data, the bandwidth ratio
 444 should carefully balance minimizing both scatter (J_2) and lag (shift ratio). S-G is not included in
 445 this analysis as the method resulted in no significant lag in identifying changes in measurement
 446 trends; however, it had the disadvantages previously noted including pulsating effects and
 447 overestimating peak values.

448 **Table 2** Regression correlations between shift ratio (SR) and bandwidth ratio (BR) with the strength of the
 449 correlation in terms of R^2 and RMSE

	Linear regression		Quadratic regression	
SMA	SR=-0.5087(BR)	$R^2=0.9940$ RMSE=0.0014	SR=-1.323(BR ²)-0.4049(BR)	$R^2=0.9997$ RMSE=3.24E-4
GWMA	SR=-0.1783(BR)	$R^2=0.9996$ RMSE=1.2963E-4	SR=-0.1171(BR ²)-0.1691(BR)	$R^2=0.9999$ RMSE=3.5672E-5

450 **4.2. Results on the Ten-mile landslide**

451 Unfiltered results reported by Geocubes 46 and 47 installed on the Ten-mile landslide were
 452 processed by all three filters. To illustrate to the reader through visual inspection the difference
 453 between the performance of SMA, GWMA, and S-G, only a 200-day window of displacement data
 454 from Geocube 46 and filtered points produced by direct filtration are shown in Fig. 16. Fig. 16a
 455 also features an inset showing scaled scenario 4, which resembles the general trend of Geocube
 456 46 data for the period from day 200 to 400. Fig. 16 shows that increasing the bandwidth ratio
 457 reduces the scatter, but increases the lag in the filtered results, consistent with observations on
 458 the synthetic datasets. For bandwidth ratios larger than 0.04, SMA becomes insensitive to some
 459 short-scale (20- to 30-day) trends in the data (qualitative visual inspection). As an example, at a
 460 bandwidth ratio of 0.10, SMA suggests the displacement of Geocube 46 follows a bi-linear trend
 461 with an inflection point at day 240, while unfiltered points and other filters suggest other periods

462 of acceleration and deceleration. Importantly, S-G is sensitive to even subtle variation and does
 463 not show significant lag.

464
 465 **Fig. 16** Unfiltered displacement of Geocube 46 data vs. time and data filtered by SMA, GWMA, and S-G
 466 for bandwidth ratios (BRs) of (a) 0.04, (b) 0.07, and (c) 0.10.

467 Fig. 17 shows the filtered velocity values obtained by directly filtering the calculated velocities and
 468 by indirectly filtering the displacement values before calculating the velocity from Geocube 46

469 data. The direct and indirect filtering approaches demonstrated similar performance in terms of
470 scatter reduction for Geocube 46 data. As the bandwidth ratio increases, SMA tends to
471 significantly attenuate the local maximum and minimum points in comparison to results at smaller
472 bandwidth ratios, indicating a probable loss of information about the landslide behavior and
473 sensitivity of this filter to the bandwidth ratio, as also noted in Fig. 16 (curvature loss in SMA
474 results). Indirect filtration by SMA seems to be limited near the boundary at time zero, resulting in
475 a subdued replica of direct filtration. The length of this region is found to be governed by the
476 bandwidth ratio, as the necessary number of points for filtering in this portion has not been
477 provided to the filter. This is also observed in S-G results. This problem was not found in GWMA
478 results, as direct and indirect filtration both follow the same pattern. GWMA and S-G are both able
479 to preserve the velocity variation even at the most intense filtration (bandwidth ratio of 0.10);
480 however, variations between local maxima and minima are more extreme in S-G than GWMA
481 results. This is attributed to peak overestimation (Fig. 8 and 9) or a pulsating effect superimposing
482 on the peaks/troughs. Moreover, the S-G results still demonstrate relatively large fluctuations
483 even at the largest bandwidth ratio. This means that the application of S-G might still trigger false
484 alarms in an EWS if the landslide is moving at a faster rate or experiencing different episodes of
485 acceleration and deceleration. To avoid this, a larger bandwidth ratio should be used but this can
486 be problematic due to the higher computational effort required and issues that might follow, such
487 as the pulsating effect.

488 Results for Geocube 47 confirm the same observations made for Geocube 46 but also allow for
489 an evaluation of the significance of outliers on the filtered results. Fig. 18a displays the outliers
490 detected in the displacement diagram of Geocube 47 data along with the threshold established
491 by the Hampel algorithm using an asymmetric window, a bandwidth of 0.4% and a threshold factor
492 of 3. Fig. 18b-d shows a magnified portion of the displacement measurements for Geocube 47
493 filtered by each of the three filters at three different bandwidth ratios before the elimination of
494 outliers. This highlights the necessity of outlier elimination before the application of any scatter

495 filter. These plots show that detecting and removing outliers significantly impacts the performance
496 of S-G, as the presence of the outlier generates a peak that follows the outlier measurement and
497 is followed by a sudden decrease that drops well beyond the data trend. SMA tends to widen the
498 time range affected by the outlier more than GWMA but, for the most part, the SMA-filtered results
499 are almost parallel to the underlying trend. All filters appear to be significantly impacted by the
500 outlier value, suggesting a pre-processing filter is required to remove outliers regardless of the
501 use of SMA, GWMA, or S-G to reduce scatter. The outliers were successfully identified and
502 removed after the application of the Hampel algorithm, and the above-mentioned effects were no
503 longer observed in the filtered results.

511 *4.2.1. Lag minimization in filtered Geocube results*

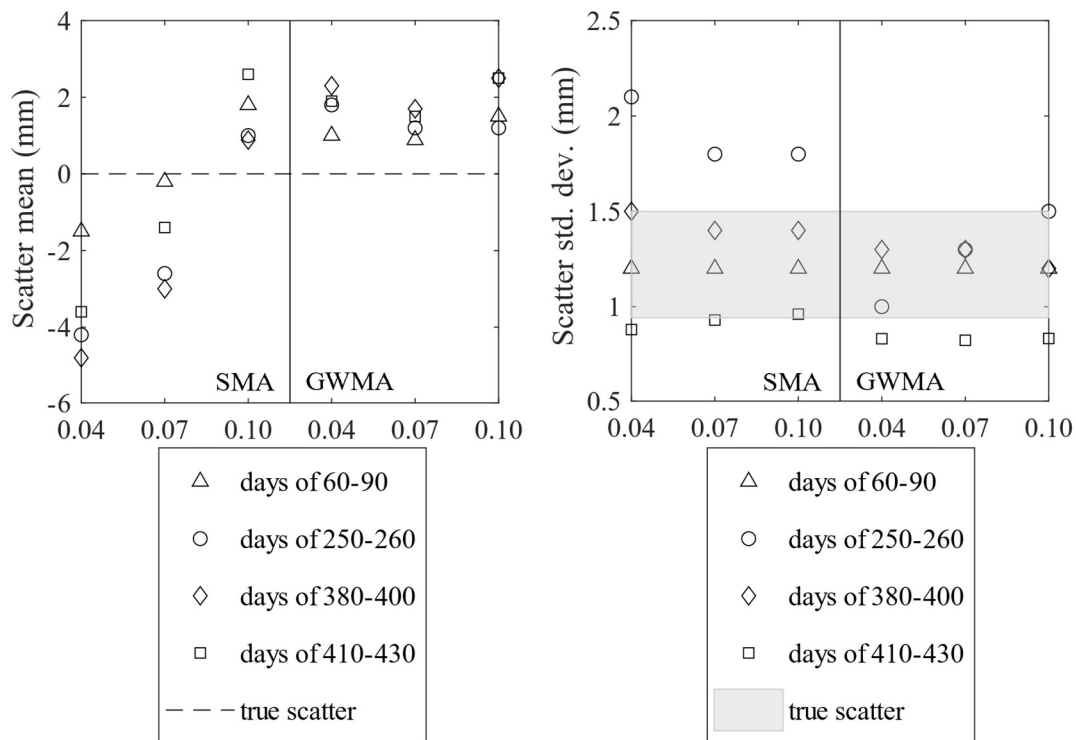

512 The lag between unfiltered and filtered data for Geocube 46 (Fig. 16) is consistent with the
 513 synthetic database results. The lag quantification results (Fig. 15b) were used to provide a
 514 correction value for the filtered Geocube results. The shift ratios used for this purpose with respect

515 to each filter and bandwidth ratio are tabulated in Table 3. To determine whether the results of
516 lag correction using the mean correlations derived from the synthetic scenarios (Table 2) were
517 acceptable, the filtered diagrams were shifted (using the mean line for GWMA and values
518 between the mean and lower boundary for SMA) and different portions of the displacement
519 diagrams for Geocubes 46 and 47 were examined. Some examples are shown in Fig. 19. The
520 mean and standard deviation of the scatter around the trend (error distribution) were calculated
521 by assuming a linear trend within the short periods of analysis (considered an approximation of
522 the true displacement trend for the short time interval). These were also calculated for the filtered
523 and shifted diagrams. The closer the mean and standard deviation of the filtered and shifted data
524 are to that obtained from the linear trend, the better the performance of the lag correction based
525 on the results from the synthetic scenarios. As an example, for the period from day 250 to 260,
526 the GWMA resulted in a standard deviation of 0.001 to 0.0015 for bandwidth ratios from 0.04 to
527 0.10, respectively; corresponding values for SMA to 0.0018 to 0.0021. This illustrates that shifted
528 GWMA results are closer to the true (scatter-free) displacements because the standard deviations
529 of scatter inferred by this filter are closer to the true scatter, although both have good agreement
530 with the true scatter. The means of inferred scatter by both filters are also close enough to the
531 mean of the true scatter (almost zero). The results show the statistical indices of scatter inferred
532 from the filtered shifted displacement measurements closely agree with that considered to be true
533 scatter, and therefore the filtered displacement measurements are corrected for lag. This
534 suggests the correlations stated in Fig. 15b and Table 2 based on the synthetic scenarios are
535 applicable to minimize the lag for the Geocube system at the Ten-mile landslide.

536 **Table 3.** Shift ratios used for lag minimization of Geocube 46 displacements

Bandwidth ratio	Shift ratio	
	SMA	GWMA
0.04	-0.02	-0.007
0.07	-0.035	-0.012
0.10	-0.06	-0.018

541

542 **5. Discussion**

543 Previous studies dedicated to landslide monitoring consistently adopt SMA for scatter

544 minimization in displacement data. However, the adequacy of this filter and the effect of bandwidth

545 selection were not well understood. Analyzes conducted on synthetic databases in this study

546 using a roughness factor (J_2) demonstrate that at least 4% of the total observations should be fed
547 into the filter to ensure fluctuations are sufficiently reduced.

548 The results of this study show that SMA tends to considerably distort the underlying trend at a
549 bandwidth ratio of 0.10 (Fig. 8 and 9), and its lagged response with respect to real-time monitoring
550 is almost three times that of GWMA results. As a result, a bandwidth ratio between 0.04 and 0.07
551 is suggested. However, we caution that the bandwidth should be selected with complete
552 awareness that SMA is highly sensitive to bandwidth, and sensitivity analyses on bandwidth are
553 recommended when defining an EWS. Corresponding observations were made during the
554 analysis of displacement data from Geocubes installed on the Ten-mile landslide.

555 Error calculations show that GWMA and S-G outperform SMA in both direct and indirect filtration
556 and are more successful in preserving the true displacement trend. The near-zero lagged
557 response of S-G makes it a notable candidate for developing an EWS. Nonetheless, its intrinsic
558 shortcoming in handling peaks, leading to a pulsating effect, will pose challenges for its utilization.
559 The bandwidth range used for SMA is also suggested to be applied with the S-G filter.

560 GWMA results suggest a proper trade-off can be achieved between minimizing the lag time and
561 scatter and avoiding the pulsating effect. Compared to SMA and S-G, GWMA is less sensitive to
562 changes in the bandwidth. Analyses focused on the Geocube data also confirm that GWMA is
563 capable of constraining the fluctuations in the velocity diagram while not attenuating variations in
564 the displacement rate diagram. Moreover, the lag quantification chart proposed could reliably
565 capture the required shift with a greater degree of confidence in comparison to SMA even at the
566 largest bandwidth ratio studied here (0.10). The bandwidth for GWMA can therefore range from
567 0.04 to 0.10. Moreover, we observed consistency between direct and indirect filtration results
568 using GWMA but greater differences when using SMA or S-G results. This was especially the
569 case in the early parts of the datasets and at some locations where outlier elimination was likely
570 ineffective.

571 Filter and bandwidth selections should not be arbitrarily or purely empirical, as differences in
572 outcomes can be substantial. An automated surveillance system for landslides demands stability
573 in filter performance for a variety of circumstances, considering the ground can experience
574 irregular sequences of acceleration and deceleration. The results here suggest practice moves
575 away from the adoption of SMA due to the limitations discussed. S-G demonstrates some
576 inconsistent or erratic performance for certain displacement trends, which is detrimental although
577 overall the error is smaller than for SMA. On the balance of its strengths and limitations as
578 evaluated in this study, GWMA appears to be the more robust approach.

579 **6. Conclusions**

580 This study evaluated the suitability of SMA, GWMA, and S-G filters for scatter reduction of
581 datasets targeted for use in an EWS. A total of different 12 scenarios with harmonic and
582 instantaneous changes were synthetically generated and random variations with Gaussian
583 distribution were then added to produce unfiltered results. The three filters considered were then
584 each applied with different bandwidths and the error computed. These filters were also
585 successfully applied to the records from two Geocubes installed on the Ten-mile landslide. The
586 results led to the following conclusions:

- 587 • When used for direct filtration of harmonic scenarios, the error resulting from the GWMA
588 approach is approximately one-third that of the SMA approach. The S-G approach results
589 in near-zero error regardless of the values of the bandwidth ratio and n/t . When used for
590 direct filtration of instantaneous scenarios, the superiority of S-G is no longer unconditional
591 and depends on the bandwidth ratio; this reflects the fact that S-G cannot appropriately
592 handle peaks in the velocity diagram.
- 593 • When used for indirect filtration of harmonic scenarios, S-G again outperforms the other
594 methods. The error associated with GWMA is marginally less than for SMA. These

595 observations are not valid when the filters are applied to instantaneous scenarios, as
596 GWMA results in less error than S-G at bandwidth ratios above 0.03.

- 597 • Detailed investigations with scenarios 11 and 12 demonstrate that SMA distorts the
598 underlying trend by displacing and sometimes neglecting peak(s), while GWMA and S-G
599 tend to preserve them somewhat similarly.
- 600 • Due to the presence of negative weights in the S-G kernel, some artificial smaller troughs
601 and peaks are created after major peaks. This phenomenon, referred to herein as a
602 pulsating effect, results in an unfavorable performance of S-G on the velocity and
603 displacement diagrams, especially in the presence of outliers.
- 604 • Investigations on the roughness factor reveal the bandwidth ratio should be at least 0.04.
605 Taking this into account, GWMA seems to be the most reasonable option as the related
606 uncertainties are much smaller than for S-G and the error is acceptable and less than for
607 SMA.
- 608 • A consequence of using asymmetric windows in the filtering process is a lag in the SMA
609 and GWMA results that increases with increasing bandwidth ratio. Lag quantification
610 suggests a correlation between the needed shift and bandwidth ratio that can be used to
611 eliminate the lag. SMA requires approximately three times the shift of GWMA on average.
- 612 • Application of these filters to displacement data reported by Geocubes shows SMA and
613 S-G are unable to properly handle data points at the beginning of the dataset (i.e., near
614 the boundary) in indirect filtration of the velocity diagram. Moreover, SMA and S-G are
615 inclined to respectively underestimate and overestimate peaks and fluctuations in the
616 velocity diagram. Overall, GWMA provides the most reliable filtered values for velocity with
617 no distinct difference between direct and indirect filtration.

618 **Appendix A**

619 Consider a polynomial of degree k that is intended to be fitted over an odd number of points
 620 denoted as z . The weighting coefficients of the Savitzky-Golay filter can be extracted from the first
 621 row of matrix C (Eq. 7):

$$622 \quad C = (J^T J)^{-1} J^T, \quad (7)$$

623 where T operator is the transpose of a matrix and J is the Vandermonde matrix, with elements at
 624 the i th row and j th column ($1 \leq i \leq z$ and $1 \leq j \leq k+1$) that can be achieved as follows:

$$625 \quad J_{ij} = m_i^{j-1}, \quad (8)$$

626 where m is the local index of points ($-(z+1)/2 \leq m \leq (z+1)/2$). As an example, the kernel of an S-G
 627 filter that fits a quadratic polynomial ($k=2$) over seven points ($z=7$) is attained here. In the first
 628 step, J is set up as follows:

$$629 \quad J = \begin{bmatrix} 1 & (-3)^1 & (-3)^2 \\ 1 & (-2)^1 & (-2)^2 \\ 1 & (-1)^1 & (-1)^2 \\ 1 & (0)^1 & (0)^2 \\ 1 & (1)^1 & (1)^2 \\ 1 & (2)^1 & (2)^2 \\ 1 & (3)^1 & (3)^2 \end{bmatrix}. \quad (9)$$

630 Then, using Eq. 1, matrix C is computed as Eq. 10:

$$631 \quad C = \begin{bmatrix} -0.0952 & 0.1429 & 0.2857 & 0.3333 & 0.2857 & 0.1429 & -0.0952 \\ -0.1070 & -0.0714 & -0.0357 & 0 & 0.0357 & 0.0714 & 0.1071 \\ -0.0595 & 0 & -0.0357 & -0.0476 & -0.0357 & 0 & 0.0595 \end{bmatrix}. \quad (10)$$

632 The second and third rows of C are the coefficients to find the filtered values' first and second
 633 derivations at the point of interest, respectively.

634 **Data availability**

635 The synthetic database can be generated through the comprehensive steps provided here. The
 636 Geocube measurements of the Ten-mile landslide displacement are not publicly available.

638 Sohrab Sharifi: conceptualization, methodology, analysis, writing – draft preparation. Michael
639 Hendry: supervision, review, writing – review and editing, project administration. Renato
640 Macciotta: supervision, review, writing – review and editing. Trevor Evans: writing – review and
641 editing, validation, project administration.

642 **Competing interests**

643 The authors declare that they have no conflict of interest.

644 **Acknowledgment**

645 The authors thank Canadian National Railway (CN) for providing access to the Ten-mile site and
646 for purchasing the Geocube units. This research was conducted through the (Canadian) Railway
647 Ground Hazard Research Program, which is funded by the Natural Sciences and Engineering
648 Research Council of Canada (NSERC ALLRP 549684-19), Canadian Pacific Railway, CN, and
649 Transport Canada.
