31 **Abstract**

32 In steep wildfire-burned terrains, intense rainfall can produce large volumes of runoff that can
33 trigger highly destructive debris flows. The ability to accurately characterize and forecast debris-
34 flow hazards in burned terrains, however, remains limited. Here, we augment the Weather
35 Research and Forecasting Hydrological modeling system (WRF-Hydro) to simulate both overland
36 and channelized flows and assess postfire debris-flow hazards over a regional domain. We perform
37 hindcast simulations using high-resolution weather radar-derived precipitation and reanalysis data
38 to drive non-burned baseline and burn scar sensitivity experiments. Our simulations focus on
39 January 2021 when an atmospheric river triggered numerous debris flows within a wildfire burn
40 scar in Big Sur – one of which destroyed California’s famous Highway 1. Compared to the
41 baseline, our burn scar simulation yields dramatic increases in total and peak discharge, and shorter
42 lags between rainfall onset and peak discharge. At Rat Creek, where Highway 1 was destroyed,
43 discharge volume increases eight-fold and peak discharge triples relative to the baseline. For all
44 catchments within the burn scar, we find that the median catchment-area normalized discharge
45 volume increases nine-fold after incorporating burn scar characteristics, while the 95th percentile
46 volume increases 13-fold. Catchments with anomalously high hazard levels correspond well with
47 post-event debris flow observations. Our results demonstrate that WRF-Hydro provides a
48 compelling new physics-based tool to investigate and potentially forecast postfire hydrologic
49 hazards at regional scales.

50

51 **Short Summary**

52 In January 2021 a storm triggered numerous debris flows in a wildfire burn scar in California. We
53 use a hydrologic model to assess debris flow hazards in pre-fire and postfire scenarios. Compared
54 to pre-fire conditions, the postfire simulation yields dramatic increases in total and peak discharge,
55 substantially increasing debris flow hazards. Our work demonstrates the utility of 3-D hydrologic
56 models for investigating and potentially forecasting postfire debris flow hazards at regional
57 scales.

58

59 **1 Introduction**

60 Following intense rainfall, areas with wildfire burn scars are more prone to flash flooding (Neary
61 et al., 2003; Bart & Hope 2010; Bart 2016) and runoff-generated debris flow hazards than
62 unburned areas (Moody et al., 2013; Ice et al., 2004; Shakesby & Doerr, 2006). After wildfire,
63 reduced tree canopy interception, decreased soil infiltration due to soil-sealing effects (Larsen et
64 al., 2009), and increased soil water repellency – especially in hyper-arid environments (Dekker
65 and Ritsema, 1994; Doerr and Thomas, 2000; MacDonald and Huffman, 2004) – increases excess
66 surface water, and on sloped terrains leads to overland flow (Shakesby & Doerr, 2006; Stoof et al.,

67 2012). As water moves down hillslopes and erosion adds sediment to water-dominated flows, clear
68 water floods can transition to turbulent and potentially destructive debris flows (Meyer & Wells,
69 1997; Cannon et al., 2001, 2003; Santi et al., 2008). In contrast to debris flows initiated by shallow
70 landslides, this rainfall-runoff process has been identified as the major cause for postfire debris
71 flows in the western U.S. (Cannon, 2001; Cannon et al., 2003, 2008; Kean et al., 2011; Nyman et
72 al., 2015; Parise & Cannon, 2012), and in other regions with Mediterranean climates (Mitsopoulos
73 & Mironidis, 2006; Bisson et al., 2005; Parise & Cannon, 2008, 2009; Rosso et al., 2007). In
74 California, because climate change is projected to increase the intensity and frequency of wet-
75 season precipitation (Swain et al., 2018; Polade et al., 2017), increase wildfire potential (Swain,
76 2021; Brown et al., 2021), and extend the wildfire season (Goss et al., 2020), occurrence and
77 intensity of postfire debris flows are likely to increase (Cannon et al., 2009; Kean & Staley, 2021;
78 Oakley, 2021).

79 To assess postfire debris flow hazards, statistical approaches including empirical models and
80 machine-learning techniques are commonly used in both research and operational settings
81 (Gardner et al., 2014; Cannon et al., 2010; Staley et al., 2016; Cui et al., 2019; Nikolopoulos et al.,
82 2018; Friedel 2011a, 2011b). Statistical approaches are useful for identifying and characterizing
83 relationships amongst contributing environmental factors and are helpful in operational settings
84 due to low computational costs and the potential for rapid assessment. For example, the U.S.
85 Geological Survey (USGS) currently employs a statistical approach in their Emergency
86 Assessment of Postfire Debris-flow Hazards that consists of a logistic regression model to predict
87 the likelihood of post-wildfire debris flows (e.g., Staley et al., 2016; Cannon et al., 2010), and a
88 multiple linear regression model to predict debris flow volumes (Gartner et al., 2014). Machine-
89 learning techniques have also been used to predict postfire debris flows in the western U.S.
90 (Nikolopoulos et al., 2018; Friedel 2011a, 2011b). For example, self-organizing maps and genetic
91 programming were used to predict postfire debris flow occurrence (Friedel 2011b) and volumes
92 (Friedel 2011a), respectively. Compared to the current USGS predictive models, genetic
93 programming was posited to be more useful in solving non-linear multivariate problems (Friedel
94 2011a), while a random forest algorithm demonstrated increased performance in predicting
95 postfire debris flow occurrence (Nikolopoulos et al., 2018). Despite the utility and advantages of
96 data-driven hazard prediction approaches, these techniques do not simulate the underlying physics,
97 which limits their utility in developing a better process-based understanding of debris flow
98 mechanics, limits their applicability in climatological and geographic settings different than their
99 training sites, and limits their use in non-stationary conditions (e.g., under changing climatic
100 conditions).

101 In contrast, physics-based models that simulate spatially-explicit hydrologic and mass wastage
102 processes are well-suited for mechanistic sensitivity analyses in diverse settings, but applications
103 of these models have tended to focus on landslide-induced debris flows (e.g., Iverson & George,
104 2014; George & Iverson, 2014), rather than runoff-generated debris flows which are more common
105 in postfire areas (Cannon et al., 2001, 2003; Santi et al., 2008). Studies that have investigated
106 postfire hydrologic responses using process-based models have largely focused on short-term

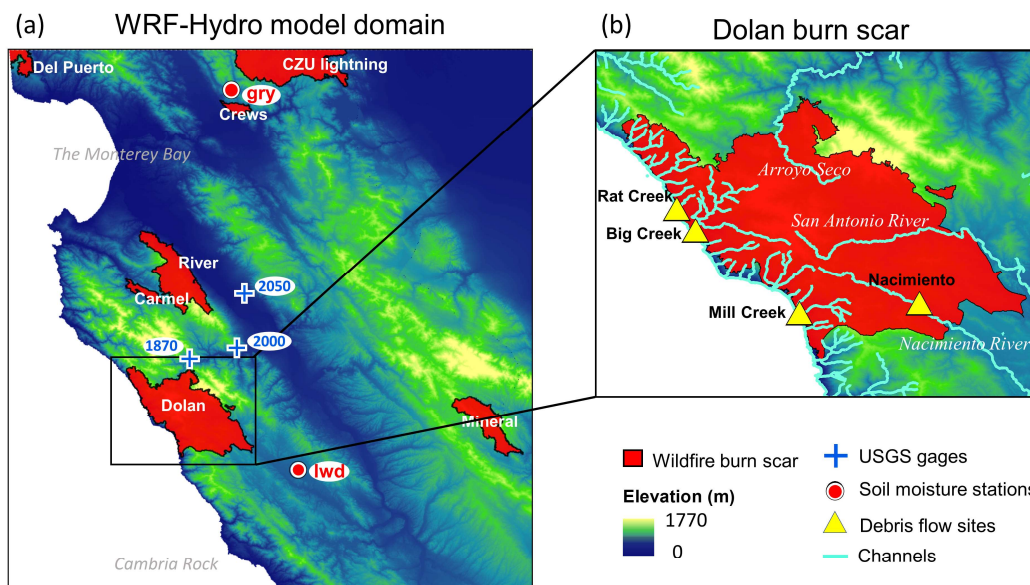

107 responses in individual catchments at high spatiotemporal resolutions (McGuire et al., 2016, 2017;
108 Rengers et al., 2016) or long-term runoff responses at coarse temporal resolutions (Rulli & Rosso,
109 2007; McMichael & Hope, 2007). For example, process-based models have employed shallow
110 water equations to understand the triggering and transport mechanisms of postfire debris flows in
111 single catchments (McGuire et al., 2016, 2017) and to investigate the timing of postfire debris
112 flows in three separate catchments (Rengers et al., 2016), the latter of which also assessed the
113 efficacy of a simplified kinematic wave approach. In addition to individual catchment applications,
114 process-based models often adopt simplifications that can limit effective prediction and hypothesis
115 testing to overcome computational limits. For example, the kinematic runoff and erosion model
116 (KINEROS2) simplifies drainage basins into 1-dimensional channels and hillslope patches
117 (Canfield & Goodrich, 2005; Goodrich et al., 2012; Sidman et al., 2015), and the Hydrologic
118 Modeling System (HEC-HMS) uses an empirically-based curve number method to estimate
119 saturation excess water (Cydzik et al., 2009), which cannot resolve infiltration excess overland
120 flow, a critical process in burn scars (Chen et al., 2013).

121 Given the current state of debris flow hazard assessment and prediction in previously burned
122 terrains, in addition to the growing influence of anthropogenic climate change on wildfire and
123 extreme precipitation, development of physics-based hazard assessment tools that can be used in
124 both hindcast investigations and forecasting applications is needed. Furthermore, due to the diverse
125 morphology of precipitation events and their interaction with geographically distributed wildfire
126 burn scars, development of tools that can assess hazards over regional domains, particularly in
127 operational forecasting applications, is critical. Here to advance the field of burn scar debris flow
128 hazard assessment, we explore the use of the physics-based and fully-distributed Weather Research
129 and Forecasting Hydrological modeling system version 5.1.1 (WRF-Hydro). WRF-Hydro is an
130 open-source community model developed by the National Center for Atmospheric Research
131 (NCAR). It is the core of National Oceanic and Atmospheric Administration's (NOAA) National
132 Water Model forecasting system, and has been used extensively to study channelized flows (e.g.,
133 Lahmers et al., 2020; Wang et al., 2019). Here, we modify WRF-Hydro to output high temporal
134 resolution fine-scale (100 m) debris flow-relevant overland flow; a process computed using a fully
135 unsteady, explicit, finite difference diffusive wave formulation. Previous efforts, employing
136 shallow water equations, diffusive, kinematic, and diffusive-kinematic wave models, have
137 demonstrated that water-only models can provide critical insights on runoff-driven debris flow
138 behavior (Arattano & Savage, 1994; McGuire & Youberg, 2020; Arratano & Franzi, 2010; Di
139 Cristo et al., 2021), even in burned watersheds (Rengers et al., 2016).

140 To test and demonstrate the utility of WRF-Hydro in debris flow studies, we investigate the
141 January 2021 debris flow events within the Dolan burn scar on the Big Sur coast of central
142 California (Fig. 1a–b). We first identify multiple debris flow sites using optical and radar remote
143 sensing data and field investigations. We then calibrate WRF-Hydro against ground-based soil
144 moisture and streamflow observations and use it to study the effects of burn scars on debris flow
145 hydrology and changes in hazard potential. The paper is organized as follows. Section 2 describes
146 our debris flow identification approach and historical context. Section 3 presents a description of

147 WRF-Hydro. Section 4 describes the simulation, calibration, and validation of WRF-Hydro.
148 Section 5 presents the results. Section 6 discusses the results and Sect. 7 provides a conclusion.

149

151 topography, 2020 wildfire season burn scars, and PSL soil moisture and USGS stream gage
152 observing sites. The black rectangle outlines (b) the Dolan burn scar inset, in which debris flow
153 locations and major streams are marked and labeled.

154

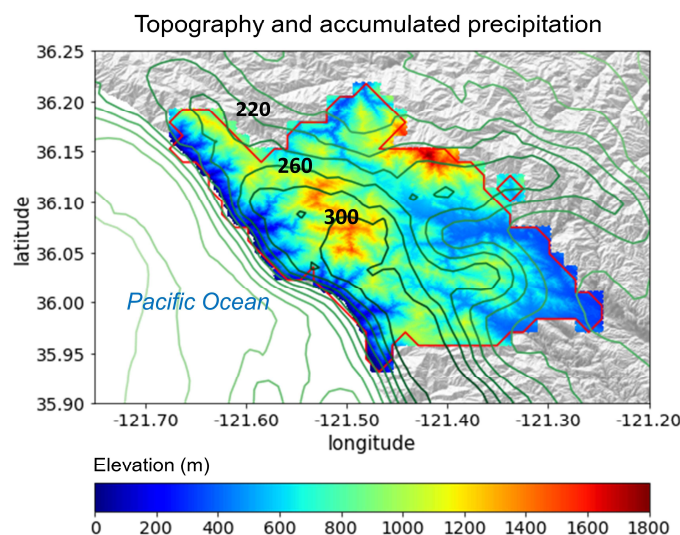

155

156 2 Study domain and debris flow identification methodology

157 The Dolan wildfire burned from August 18th till December 31st, 2020. 55% of areas within the fire
158 perimeter were burned at moderate-to-high severity (Burned Area Emergency Response, 2020).
159 After the fire, USGS Emergency Assessment of Postfire Debris-flow Hazards produced a debris
160 flow hazard assessment using a design storm based statistical model (USGS, 2020). On January
161 27–29, 2021, an atmospheric river (AR) made landfall on the Big Sur coast, bringing more than
162 300 mm of rainfall to California's Coast Ranges (Fig. 2), with a peak rainfall rate of 24 mm h⁻¹.
163 During the AR event, a section of California State Highway 1 (CA1) at Rat Creek was destroyed
164 by a debris flow. CA1 was subsequently closed for three months and rebuilt at a cost of ~\$11.5M
165 (Los Angeles Times, 2021).

166

167

168 **Fig. 2** | The topography (shading; m) and MRMS accumulated precipitation (contour lines; mm)
 169 during the AR event from January 27th 00:00 to 29th 23:00 in the Dolan burn scar. Contour line
 170 interval for accumulated precipitation is 20 mm, and lines of 220, 260, and 300 mm are labeled.
 171 The red polygon outlines the perimeter of the Dolan burn scar.

172

173

174 2.1 Debris flow identification from remote sensing and field work

175 In addition to the Rat Creek debris flow, which made national news (Los Angeles Times, 2021),
 176 we identified three other debris flows using a combination of field investigation, and open access
 177 satellite optical and synthetic aperture radar (SAR) images (Fig. 3 and Fig. B1). We examined
 178 relative differences in normalized difference vegetation index (rdNDVI) defined by (Scheip &
 179 Wegmann, 2021):

$$180 \quad rdNDVI = \frac{NDVI_{post} - NDVI_{pre}}{\sqrt{NDVI_{pre} + NDVI_{post}}} \times 100 \quad (1)$$

181 where $NDVI_{pre}$ and $NDVI_{post}$ are the pre- and post-event normalized difference vegetation index
 182 (NDVI) images computed following:

$$183 \quad NDVI = \frac{NIR - R}{NIR + Red} \quad (2)$$

184 where NIR is the near-infrared response and Red is the visible red response. rdNDVI was calculated
 185 from Sentinel-2 satellite data using the HazMapper v1.0 Google Earth Engine application (Scheip
 186 & Wegmann, 2021). HazMapper requires selection of an event date, pre-event window (months),

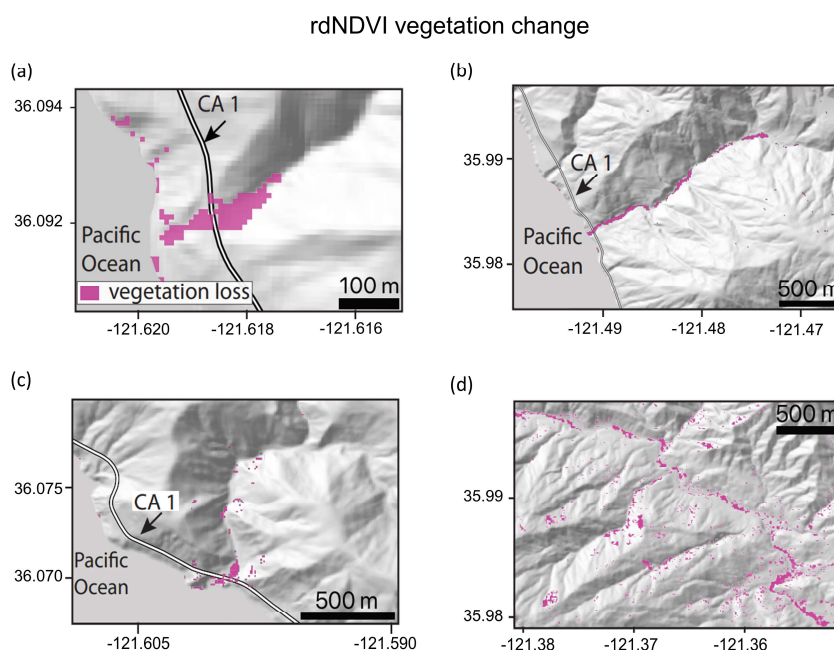

187 post-event window (months), max cloud cover (%) and slope threshold (°). These input
188 requirements filter the number of images used to calculate the rdNDVI. We set the event date to
189 27 January 2021 and used a 3 month pre- and post-event window with 0% max cloud cover and a
190 0° slope threshold to identify vegetation loss associated with the debris flows. We then created a
191 binary map to highlight debris flows (and other vegetation loss) pixels above a rdNDVI vegetation
192 loss threshold. We removed all pixels with rdNDVI > -10.

193 Lastly, we searched for debris flows (and other ground surface deformation) by examining SAR
194 backscatter change with data acquired by the Copernicus Sentinel-1 (S1) satellites (see full
195 description in Handwerger et al., in review). We measured the change in SAR backscatter by using
196 the log ratio approach, defined as

$$197 \quad I_{ratio} = 10 \times \log_{10} \left(\frac{\sigma_{pre}^0}{\sigma_{post}^0} \right) \quad (3)$$

198 where σ_{pre}^0 is a pre-event image stack (defined as the temporal median) of SAR backscatter and
199 σ_{post}^0 is a post-event image stack. Similar to the HazMapper method, our approach requires
200 selection of an event date, pre-event window (months), post-event window (months) and slope
201 threshold (°). No cloud-cover threshold is needed since SAR penetrates clouds. We used a 3 month
202 pre- and post-event window and 0° slope threshold to identify ground surface changes associated
203 with the debris flows. We then created a binary map to highlight debris flows by removing all
204 pixels with $I_{ratio} < 99$ th percentile value.

205 Identified debris flow source areas and deposition sites were confirmed by field investigation (N.J.
206 Finnegan) and named after the locations where they deposited (i.e., Big Creek, Mill Creek, and
207 Nacimiento). We note that there were likely more debris flows triggered during the AR event.
208 However, given the primary goal of this study – to demonstrate the utility of WRF-Hydro – a
209 comprehensive cataloging of debris flows is beyond this study’s scope.

210

211 **Fig. 3|** Identified debris flow sites using rdNDVI vegetation change within the Dolan burn scar.
212 We convert the rdNDVI data into a binary map by setting a threshold value, which yield only the
213 likely debris flow locations. (a)–(d) Sentinel-2 rdNDVI vegetation change at (a) Rat Creek, (b)
214 Mill Creek, (c) Big Creek, and (d) the Nacimientto River.

215

216 3 WRF-Hydro

217 3.1 Model description

218 WRF-Hydro is an open-source physics-based community model that simulates land surface
219 hydrologic processes. It includes the Noah-Multiparameterization (Noah-MP) land surface model
220 (LSM; Niu et al., 2011), terrain routing module, channel routing module, and a conceptual
221 baseflow bucket model. The Noah-MP LSM is a 1-dimensional column model that calculates
222 vertical energy fluxes (i.e., sensible and latent heat, net radiation), moisture (i.e., canopy
223 interception, infiltration, infiltration excess, deep percolation), and soil thermal and moisture states
224 on the LSM grid (1 km in our application). The infiltration excess, ponded water depth, and soil
225 moisture are then disaggregated using a time-step weighted method (Gochis & Chen, 2003) and
226 sent to the terrain routing module which simulates subsurface and overland flows on a finer terrain
227 routing grid (100 m in our application). According to the mass balance, local infiltration excess,

228 overland flow, and exfiltration from baseflow contribute to the surface head which flows into river
229 channels if defined retention depth is exceeded. The channel routing module then calculates
230 channelized flows assuming a trapezoidal channel shape (Fig. B2). Parameters related to the
231 trapezoidal channel, such as channel bottom width (B_w), Manning's roughness coefficient (n), and
232 channel side slope (z) are functions of channel stream order (Fig. B3 and Table B1). Computed
233 streamflow is then output on the 100 m grid. Equations used to compute infiltration excess,
234 overland flow, and channelized flow are provided in Sect. 3.3 and 3.4.

235 By default, WRF-Hydro uses Moderate Resolution Imaging Spectroradiometer (MODIS)
236 Modified International Geosphere-Biosphere Program (IGBP) 20-category land cover product as
237 land cover (Fig. B4) and 1-km Natural Resources Conservation Service State Soil Geographic
238 (STATSGO) database for soil type classification (Fig. B5; Miller & White, 1998). Land surface
239 properties including canopy height (HVT), maximum carboxylation rate (VCMX25), and overland
240 flow roughness (OV_ROUGH2D) are functions of land cover type (Table B2 & Fig. B4). Default
241 soil hydraulic parameters in WRF-Hydro (i.e., soil porosity, grain size distribution index, and
242 saturated hydraulic conductivity) are based on Cosby et al.'s (1984) soil analysis (Table B3) and
243 are used to map onto the STATSGO 16 soil texture types (Fig. B5).

244

245 **3.2 Meteorological forcing files**

246 WRF-Hydro is used in standalone mode (i.e., it is not interactively coupled with the atmospheric
247 component of WRF), but rather is forced with a combination of Phase 2 North American Land
248 Data Assimilation System (NLDAS-2) meteorological data and Multi-Radar/Multi-Sensor System
249 (MRMS) radar-only quantitative precipitation (Zhang et al., 2011, 2014, 2016). A description of
250 the MRMS dataset and uncertainties therein can be found in Appendix A. NLDAS-2 provides
251 hourly forcing data including incoming shortwave and longwave radiation, 2-m specific humidity
252 and air temperature, surface pressure, and 10-m wind speed at 1/8-degree spatial resolution.
253 MRMS provides hourly precipitation rate at 1-km resolution.

254

255 **3.3 Overland flow routing and output**

256 The Noah-MP LSM calculates rate of infiltration excess following Chen & Dudhia (2001):

257

$$258 \quad \frac{\partial h}{\partial t} = \frac{\partial P_d}{\partial t} \left\{ 1 - \frac{[\sum_{i=1}^4 \Delta D_i (\theta_s - \theta_i)] [1 - \exp(-k \frac{K_s}{K_{ref}} \delta_t)]}{P_d + [\sum_{i=1}^4 \Delta D_i (\theta_s - \theta_i)] [1 - \exp(-k \frac{K_s}{K_{ref}} \delta_t)]} \right\} \quad (4)$$

259

260 where h (m) is the surface water depth and t is the time. P_d (m) is the precipitation not intercepted
261 by the canopy; ΔD_i (m) is the depth of soil layer i ; θ_i is the soil moisture in soil layer i ; θ_s is the

262 soil porosity; K_s (m s^{-1}) is the saturated hydraulic conductivity; K_{ref} is $2 \times 10^{-6} \text{ m s}^{-1}$ which
263 represents the saturated hydraulic conductivity of the silty-clay-loam soil texture chosen as a
264 reference; δ_t (s) is the model time step; and k which is equal to 3.0 is the runoff-infiltration
265 partitioning parameter [the same as kdt_{ref} in Chen & Dudhia (2001)].

266

267 Noah-MP passes excess water to the terrain routing module, which simulates overland flow using
268 a 2-dimensional fully-unsteady, explicit, finite-difference diffusive wave equation adapted from
269 Julien et al. (1995) and Ogden (1997). It is considered superior to the traditionally used kinematic
270 wave formulation in that it accounts for backwater effects and flow over adverse slopes. The
271 diffusive wave formulation is the simplified form of the Saint Venant equations, i.e., continuity
272 and momentum equations for a shallow water wave. The 2-dimensional continuity equation for a
273 flood wave is:

$$274 \quad \frac{\partial h}{\partial t} + \frac{\partial q_x}{\partial x} + \frac{\partial q_y}{\partial y} = i_e \quad (5)$$

275 where h is the surface flow depth, q_x and q_y are the unit discharges in the x- and y-directions,
276 respectively, and i_e is the infiltration excess. Manning's equation which considers momentum loss
277 is used to calculate q . In the x-direction:

$$278 \quad q_x = \alpha_x h^\beta \quad (6)$$

279 Where β is a unit dependent coefficient equal to $\frac{5}{3}$, and

$$280 \quad \alpha_x = \frac{S_{fx}^{1/2}}{n_{ov}} \quad (7)$$

281 where n_{ov} is the tunable overland flow roughness coefficient. The momentum equation in the x-
282 direction is given by:

$$283 \quad S_{fx} = S_{ox} - \frac{\partial h}{\partial x} \quad (8)$$

284 where S_{fx} is the friction slope, S_{ox} is the terrain slope, and $\frac{\partial h}{\partial x}$ is the change in surface flow depth
285 in the x-direction.

286 Off-the-shelf, WRF-Hydro does not output overland flow at terrain routing grids (100 m), however
287 it is computed in the background to determine channelized streamflow. One key advance made in
288 this work is that we modified WRF-Hydro source code to output overland flow. Overland flow
289 depth (m) was converted to overland discharge ($\text{m}^3 \text{ s}^{-1}$) by multiplying flow depth by grid cell area
290 ($10,000 \text{ m}^2$) and dividing by the LSM time step (1 h).

291

292 3.4 Channel routing

293 If overland flow intersects grid cells identified as channel grids [2nd Strahler stream order and
294 above; pre-defined by the hydrologically conditioned USGS National Elevation Dataset 30-m
295 digital elevation model (DEM)], the channel routing module routes the water as channelized
296 streamflow using a 1-dimensional, explicit, variable time-stepping diffusive wave formulation.
297 Similarly, the continuity equation for channel routing is given as:

$$298 \quad \frac{\partial A}{\partial t} + \frac{\partial Q}{\partial s} = q_l \quad (9)$$

299 and the momentum equation is given as:

$$300 \quad \frac{\partial Q}{\partial t} + \frac{\partial(\frac{\gamma Q^2}{A})}{\partial s} + gA \frac{\partial H}{\partial s} = -gAS_f \quad (10)$$

301 where s is the streamwise coordinate, H is water surface elevation, A is the flow cross-sectional
302 area calculated as $(B_w + H z)H$ (Fig. B2), q_l is the lateral inflow rate into the channel grid, Q is
303 the flow rate, γ is a momentum correction factor, g is acceleration due to gravity, and S_f is the
304 friction slope computed as:

$$305 \quad S_f = \left(\frac{Q}{K}\right)^2 \quad (11)$$

306 where K is the conveyance computed from the Manning's equation:

$$307 \quad K = \frac{C_m}{n} AR^{2/3} \quad (12)$$

308 where n is the Manning's roughness coefficient, A is the channel cross-sectional area, R is the
309 hydraulic radius (A/P), P is the wetted perimeter, and C_m is a dimensional constant (1.486 for
310 English units or 1.0 for SI units).

311

312 4 Model simulation, calibration, and validation

313 4.1 Model domain

314 The WRF-Hydro model domain spans regions in California including the Coast Ranges, Monterey
315 Bay, and the Central Valley, and covers several burn scars from the 2020 wildfire season (Fig. 1a).
316 Here we focus our analysis on the Dolan burn scar where the hazardous debris flows occurred (Fig.
317 1b). According to the USGS 30-m DEM, the Rat Creek debris flow site sits at the base of a 1st
318 order catchment with a drainage area of 2.23 km². Mill Creek, Big Creek, and Nacimiento debris
319 flows were initiated within extremely steep, intensely burned, 1st order catchments, but were
320 deposited in 2nd, 3rd, and 3rd Strahler stream order channels, respectively.

321 To calibrate and validate WRF-Hydro output, we use soil moisture observations from two Physical
322 Sciences Laboratory (PSL) monitoring stations [i.e., Lockwood (lwd) and Gilroy (gry)] (Fig. 1a).

323 Due to the Mediterranean climate of California, many USGS stream gages experience low or
324 flow during the dry season. In addition, many gages are under manual regulation to mitigate wet-
325 season flood risks and better distribute water resources. As such, it can be challenging to obtain
326 natural streamflow observations for model calibration. Here, three USGS stream gages [i.e.,
327 Arroyo Seco NR Greenfield, CA (ID 11151870), Arroyo Seco NR Soledad, CA (ID 11152000),
328 and Arroyo Seco BL Reliz C NR Soledad, CA (ID 11152050)] (Fig. 1a) on streams that have
329 measurable flows during our study period and are free of human regulation are used. These gages
330 are located downstream of the Dolan burn scar and hence are useful in calibrating the parameters
331 associated with burn scar effects. The PSL soil moisture observations were recorded at 2-minute
332 intervals and USGS streamflow gage data were recorded at 15-minute intervals, but we perform
333 all observation-model comparisons at hourly-mean resolution.

334

335

336 **4.2 Baseline simulation and soil moisture calibration**

337 WRF-Hydro was run from January 1–31 of 2021. We performed the baseline simulation by
338 modifying WRF-Hydro default parameters (Table B3) based on a calibration using soil moisture
339 observations from stations lwd and gry. Neither PSL station is located in a burn scar. Since the
340 baseline simulation includes no postfire characteristics, it can also be regarded as the “pre-fire”
341 scenario. Soil moisture at 10 cm below ground in the baseline simulation was calibrated by
342 performing a domain-wide adjustment of soil porosity and grain size distribution index at the
343 simulation start (Table B3). We then allowed the model to spin up from January 1–10 before using
344 January 11–31 for validation. Using a relatively short spin-up period is justified because prior to
345 the AR event, little rain fell on the Dolan burn scar (i.e., ~400 mm of rainfall fell from June to
346 December 2020). As such, in the months preceding the debris flow events, soil moisture
347 observations indicate already dry condition prior to our 10 day spin up.

348

349 After calibration, the simulated soil moisture closely mimics ground-based PSL observations (Fig.
350 4). Both the observed magnitude and variability are well captured, with the simulated ± 1 standard
351 deviation envelope largely encompassing PSL observations during the AR. Model performance
352 was evaluated using four quantitative metrics, i.e., correlation coefficient, root mean square error,
353 mean bias, and Kling-Gupta efficiency (KGE; Gupta et al., 2009; Kling et al., 2012). KGE has
354 previously been used in soil moisture calibration applications (e.g., Lahmers et al., 2019;
355 Vergopolan et al., 2020) and is computed as follows:

356

$$357 \quad KGE = 1 - \sqrt{(r - 1)^2 + (\alpha - 1)^2 + (\beta - 1)^2} \quad (13)$$

358

359 where r is the correlation coefficient between the observation and simulation, α is the ratio of the
360 standard deviation of simulation to the standard deviation of observation, and β is the ratio of the

361 mean of simulation to the mean of observation. KGEs close to 1 indicate a high-level consistency
362 between the simulation and observation, while negative KGEs indicate poor model performance
363 (Schönfelder et al., 2017; Andersson et al., 2017).

364

365 The model's ability to simulate soil moisture substantially improves after calibration (Fig. 4; Table
366 1). KGE values approach 1 (0.72 at lwd and 0.88 at gry), indicating that WRF-Hydro adequately
367 simulates the hydrologic environment and its response to meteorological change.

368

374 volumetric soil moisture 10 cm below ground in the baseline simulation (purple dashed line) at
375 PSL sites (a) Lockwood (lwd) and (b) Gilroy (gry). Envelope of purple shading depicts ± 1 standard
376 deviation of model simulated soil moisture. KGE scores are provided at top left for each station.

377

378

379

380 *Table 1*
 381 *Evaluation metrics of simulated soil moisture and streamflow*
 382

Soil moisture (Default / Baseline)				
Station	<i>r</i>	RMSE	Bias	KGE
lwd	0.97 / <u>0.98</u>	7.06 / <u>4.32</u>	5.21 / <u>4.16</u>	0.10 / <u>0.72</u>
gry	0.94 / 0.94	5.19 / <u>2.53</u>	-4.79 / <u>-1.66</u>	0.80 / <u>0.88</u>
Streamflow (Baseline / Burn scar)				
Station	<i>r</i>	RMSE	Bias	NSE
1870	0.28 / <u>0.93</u>	39.29 / <u>14.69</u>	1.65 / 3.36	-0.17 / <u>0.84</u>
2000	0.26 / <u>0.86</u>	51.22 / <u>24.92</u>	2.47 / 4.81	-0.15 / <u>0.73</u>
2050	0.25 / <u>0.81</u>	49.96 / <u>27.43</u>	5.70 / 8.24	-0.38 / <u>0.53</u>

383
 384 **Table 1** | Quantitative evaluation metrics for the simulated soil moisture and streamflow when
 385 compared against observations. The metrics include the Pearson correlation coefficient (*r*), root
 386 mean square error (RMSE), and mean bias (Bias). In addition, the comprehensive metrics Kling-
 387 Gupta efficiency (KGE) and Nash-Sutcliffe efficiency (NSE) are used to evaluate model-simulated
 388 soil moisture and streamflow, respectively. For soil moisture, the numbers in front of “/” are
 389 calculated between the default run (i.e., uncalibrated run) and the observations, whereas the
 390 numbers following “/” are the corresponding values in the baseline simulation (the purple dashed
 391 line in Fig. 4). For streamflow, the numbers in front of “/” are computed between the baseline run
 392 (purple dashed line in Fig. 6) and the observations, while the numbers behind “/” are for burn scar
 393 simulation (red line in Fig. 6). If the model performance regarding a certain metric is enhanced in
 394 the burn scar simulation, the number after “/” is underlined.

395

396 **4.3 Burn scar simulation and streamflow calibration**

397 To simulate effects of wildfire burn scars on hydrologic processes and debris flow hazards, we
 398 made two modifications to the baseline simulation soil moisture calibrated model configuration.
 399 First, we changed the land cover type within the burn scar perimeter to its nearest LSM analogue,
 400 i.e., “barren and sparsely vegetated”. The switch to barren land causes: (1) height of the canopy
 401 (HVT) to decrease to 0.5 m; (2) maximum rate of carboxylation at 25°C (VCMX25) to decrease
 402 to 0 $\mu\text{mol CO}_2/(\text{m}^2 \cdot \text{s})$; and (3) overland flow roughness coefficient (OV_ROUGH2D) to decrease
 403 to 0.035 (Fig. 5a–c) from default values (Fig. B4 and Table B2).

404

405 The second adjustment was to decrease soil infiltration rates within the burn scar perimeter,
 406 achieved by reducing soil saturated hydraulic conductivity (DKSAT; Fig. 5d; Scott & van Wyk,

1990; Cerdà, 1998; Robichaud, 2000; Martin & Moody, 2001) from default values (Table B3). Consistent with the hydrophobicity of burned soils, we calibrate the burn scar simulation by systematically exploring a range of burn scar area saturated hydraulic conductivities (0 to 3×10^{-7} m s^{-1} with a 5×10^{-8} m s^{-1} increment), with the goal of reproducing streamflow behavior similar to USGS gage observations. We found that a value of 1.5×10^{-7} m s^{-1} gives the highest Nash-Sutcliffe efficiency (NSE; Nash & Sutcliffe, 1970) across all three USGS stream gages (Table 1). NSE and KGE are the two most widely used metrics for calibration and evaluation of hydrologic models. The NSE has previously been used in streamflow calibration applications (e.g., Xia et al., 2012; Bitew & Gebremichael, 2011), and it is calculated as follows:

416

$$NSE = 1 - \frac{\sum_{t=1}^{t=T} (Q_{sim}(t) - Q_{obs}(t))^2}{\sum_{t=1}^{t=T} (Q_{obs}(t) - \overline{Q_{obs}})^2} \quad (14)$$

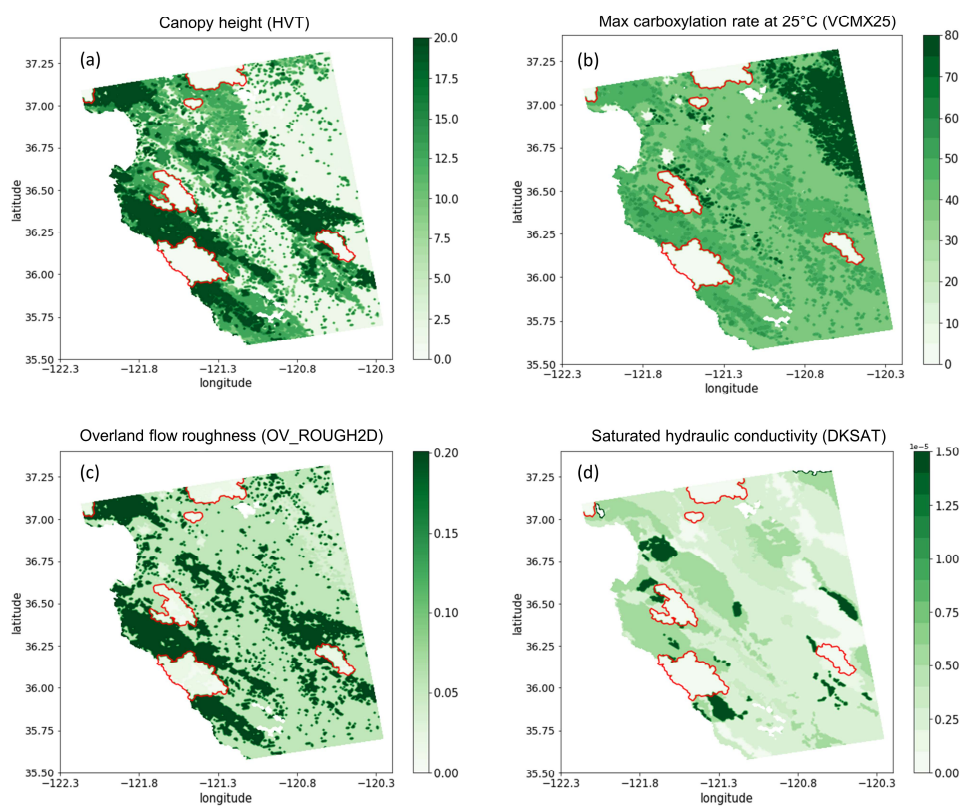

418

where T is the length of the time series, $Q_{sim}(t)$ and $Q_{obs}(t)$ are the simulated and observed discharge at time t , respectively, and $\overline{Q_{obs}}$ is the mean observed discharge. By definition, NSEs of 1 indicate perfect correspondence between the simulated and observed streamflow. Positive NSEs mean that the model streamflow has a greater explanatory power than the mean of the observations, whereas negative NSEs represent poor model performance (e.g., Moriasi et al., 2007; Schaepli & Gupta, 2007). When burn scar characteristics are included, NSEs increase from negative values in the baseline to greater than 0.5, and the NSEs at gages 1870 and 2000 reach 0.84 and 0.73, respectively. Higher NSE scores indicate the abovementioned burn scar parameter changes improve the model's ability to simulate streamflow observations downstream of the burn scar (Table 1).

429

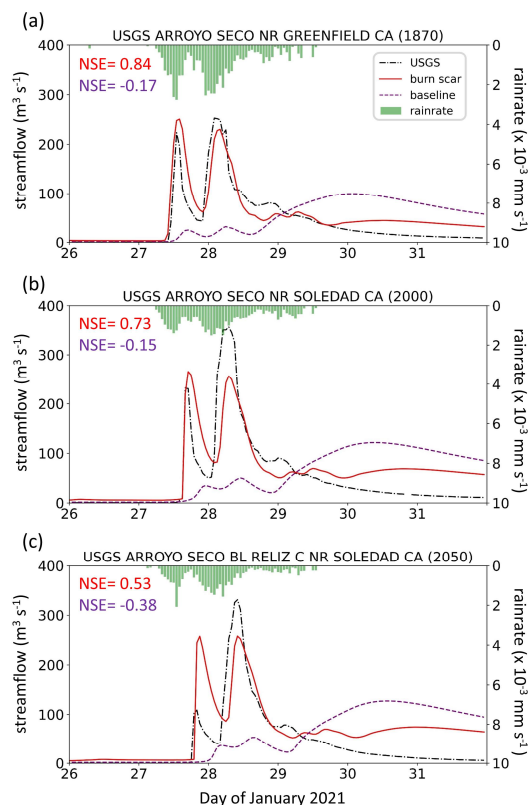

Parameter changes accounting for burn scar characteristics

430
431 **Fig. 5** | Parameter setting in the WRF-Hydro burn scar simulation. (a) The height of the canopy
432 (HVT; m; shading), (b) maximum rate of carboxylation at 25°C (VCMX25; $\mu\text{mol CO}_2/(\text{m}^2 \cdot \text{s})$;
433 shading), (c) overland flow roughness coefficient (OV_ROUGH2D; shading), and (d) saturated
434 hydraulic conductivity (DKSAT; m s^{-1} ; shading) in the burn scar simulation.

441 and (c) Arroyo Seco BL Reliz C NR Soledad, CA (ID 11152050). NSE scores for baseline (purple)
442 and burn scar simulations (red) are shown at top left.

443

444 5 Results

445 5.1 Hydrologic response due to burn scar incorporation

446 The pre-fire baseline simulation fails to capture the hydrologic behavior observed at the USGS
447 gages located within the burn scar (Fig. 6). Incorporation of burn scar characteristics substantially
448 alters the hydrologic response of the model and provides much higher fidelity streamflow

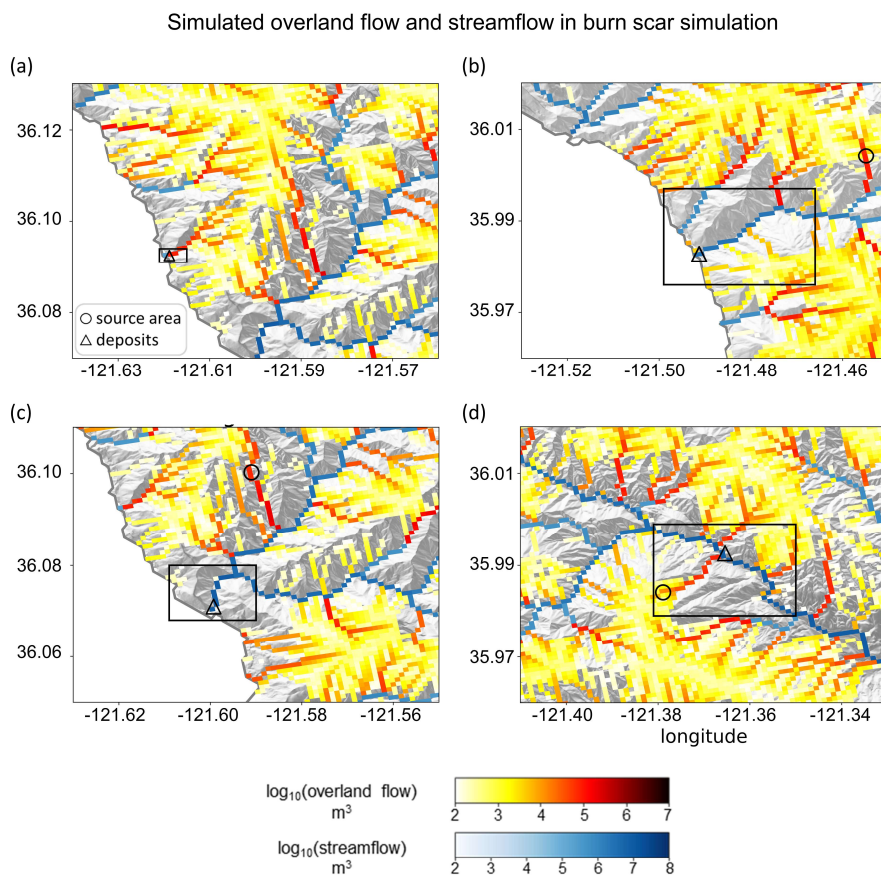

449 simulations (Fig. 6). Observed hydrographs are characterized by two early streamflow peaks
450 related to two precipitation bursts on January 27th and 28th. Our burn scar simulation captures this
451 behavior, while the baseline simulation streamflow peaks just once, with a lower magnitude and
452 an ~3-day lag after peak precipitation (Fig. 6). The steep rising limbs and high magnitude discharge
453 peaks of the burn scar hydrograph are indicative of flash flooding. Compared with the pre-fire
454 baseline scenario, the burn scar's barren land and low infiltration rate substantially accelerate
455 drainage rates and increase discharge volume into stream channels.
456

457 **5.2 Hydrologic response at four debris flow sites**

458 We identified locations and extent of four debris flows from remote sensing data and field work
459 (Fig. 3& Fig. B1). rdNDVI shows vegetation loss caused by debris flows. Mill Creek, Big Creek,
460 and Nacimiento were relatively large debris flows with runout lengths between ~2–5 km. Rat
461 Creek occurred in a smaller catchment and had a runout length of ~300 m. The difference in runout
462 length and debris flow size is primarily controlled by upstream catchment size. Due to its low
463 stream order (1st Strahler stream order), Rat Creek is the only debris flow site modeled entirely as
464 overland flow in our WRF-Hydro simulations.

465 At the four debris flow sites, we use three metrics to characterize hydrologic anomalies: (1)
466 accumulated runoff volume, (2) peak discharge, and (3) time to peak discharge. Fig. 7 depicts
467 accumulated channelized discharge volume (blue shading) and accumulated overland discharge
468 volume (yellow-red shading) from January 27th 00:00 to 28th 12:00 near the four debris flow sites
469 in the burn scar simulation. Accumulation time period is chosen such that it covers the first two
470 runoff surges in the simulated hydrographs which are likely associated with debris flows (Fig. 8)
471 given that nearly concurrent peak rainfall intensity and peak discharge is a signature characteristic
472 of debris flows (Kean et al., 2011). Runoff volume is on the order of 10^4 m³ at Rat Creek and 10^6
473 m³ at the other three sites.

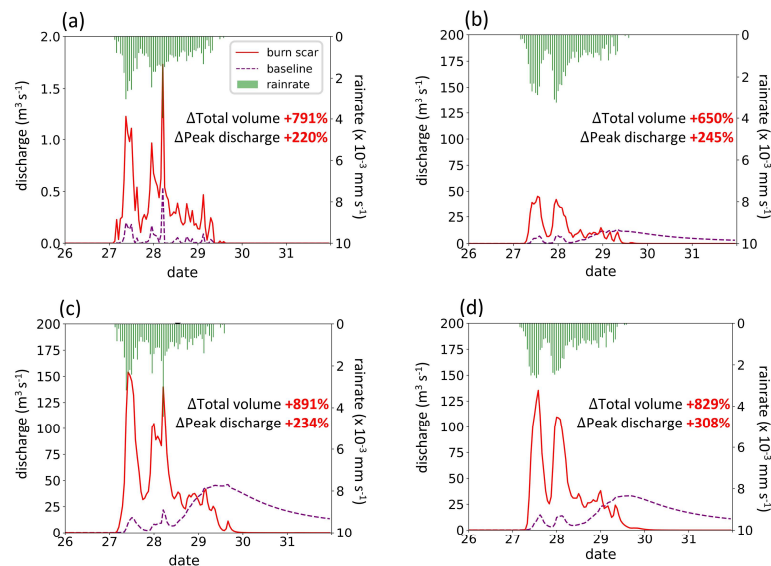

474
475 **Fig. 7** | WRF-Hydro simulated overland flow and streamflow in the burn scar simulation. (a)–(d)
476 Total volume of accumulated overland flow (yellow-red shading) and streamflow (blue shading)
477 on \log_{10} scale between January 27th 00:00 and 28th 12:00 at four debris flow sites. Black rectangles
478 correspond to domains in Fig. 3a–d. Black circles and triangles indicate debris flow source areas
479 and deposits, respectively.

480
481
482 Dramatic hydrographic changes after inclusion of burn scar characteristics are simulated at debris
483 flow source areas (Fig. B6 and Table B4) and deposition sites (Fig. 8 and Table 2). WRF-Hydro
484 facilitates investigation of the hydrologic response at triggering and deposition locations and along
485 the runout path. Here, to emphasize the downstream hazards, our analysis is focused on debris
486 flow deposits. At Rat Creek, where a section of CA1 collapsed, the magnitude of discharge
487 substantially increases, and overland flow surges are concurrent with rainfall bursts (Fig. 8a). Total
488 discharge accumulated during the AR event increases approximately eight-fold (791%), and peak

489 discharge more than triples compared to the baseline simulation (Fig. 8a and Table 2). At Mill
490 Creek, Big Creek, and Nacimientto, baseline hydrographs are characterized by less variability,
491 muted responses to two early precipitation bursts, and a delayed third discharge peak that does not
492 occur until ~3 days after AR passage (Fig. 8b–d). Maximum discharge peaks in the baseline
493 hydrographs lag those in the burn scar simulation by ~2 days (Fig. 8b–d; Table 2). In the burn scar
494 simulation, total volume substantially increases at the three channelized sites – total volume
495 increases ~650% at Mill Creek, ~891% at Big Creek, and ~829% at Nacimientto (Fig. 8b–d and
496 Table 2), and the absolute increase in volume is on the order of 10^6 m³ (Table 2). Peak discharge
497 more than triples at Mill Creek and Big Creek and more than quadruples at Nacimientto.
498 Additionally, response times of the peak in discharge to the peak in precipitation decrease to less
499 than an hour, highlighting the simulated flashiness of the burned catchments.

512 *Table 2*

513 *The total runoff volume, peak discharge, and peak timing at debris-flow deposits*

Site name	Baseline simulation			Burn scar simulation			
	Total volume (m ³)	Peak discharge (m ³ s ⁻¹)	Highest peak timing	Total volume (m ³)	Peak discharge (m ³ s ⁻¹)	1 st Peak timing	2 nd Peak timing
Rat Creek	6,897	0.54	28 th 05:00	61,425 (+791%)	1.73 (+220%)	27 th 09:00	28 th 05:00
Mill Creek	312,925	13.10	29 th 08:00	2,347,457 (+650%)	45.21 (+245%)	27 th 13:00	27 th 23:00
Big Creek	842,808	46.10	29 th 16:00	8,354,095 (+891%)	154.10 (+234%)	27 th 10:00	28 th 05:00
Nacimiento	743,531	33.15	29 th 16:00	6,904,706 (+829%)	135.41 (+308%)	27 th 14:00	28 th 00:00

514

515 **Table 2**| The total runoff volume, peak discharge, and peak timing in the baseline and burn scar
 516 simulations from January 27th 00:00 to 31st 23:00 at deposition sites of Rat Creek, Mill Creek, Big
 517 Creek, and Nacimiento debris flows (black triangles in Fig. 7a–d). The peak timing shown in the
 518 baseline simulation is for the highest peak. The percent change of the total volume and peak
 519 discharge in the burn scar simulation relative to the baseline simulation are shown in parentheses.

520

521

522 **5.3 Debris flow hazard assessment for the Dolan burn scar**

523 Since high magnitude runoff is often the cause and precursor of runoff-generated debris flows in
 524 burned areas (Cannon et al., 2003, 2008; Rengers et al., 2016), we use simulated accumulated
 525 volume of overland flow and streamflow to assess runoff-generated debris flow hazard potential
 526 under pre-fire (i.e., baseline; Fig. 9a&d) and postfire (i.e., burn scar simulation; Fig. 9b&e)
 527 conditions. We assess changes at both stream and catchment levels and use the difference between
 528 burn scar and baseline simulations to assess added debris flow hazard potential (Fig. 9c&f).
 529 Consistent with the increasing erosive and entrainment power associated with increasing discharge,
 530 our debris flow hazard increases as the accumulated discharge volume increases. To reduce the
 531 effects of catchment size on the volume-based hazard levels, we normalize a catchment's discharge
 532 volume by the area of the catchment (Santi et al., 2012; Fig. 9d–f). Non-normalized catchment
 533 hazard maps are also provided (Fig. B7).

534

535 In the pre-fire baseline simulation, the AR-induced precipitation produces lower debris flow
 536 hazard over most of the domain, but elevated hazards along stream channels (Fig. 9a). We note no
 537 substantial differences between areas in or out of the burn scar. In the burn scar simulation, debris

538 flow hazard levels increase across the Dolan burn scar and along channels outside but downstream
539 of the burn scar (Fig. 9b–c). The discharge volume increases by an order of magnitude near Rat
540 Creek, Big Creek, Mill Creek, and Nacimiento. Within the burn scar, hazards along major stream
541 channels, such as the Nacimiento River and San Antonio River increase. Outside the burn scar,
542 hazard levels along river channels downstream of the burn scar, such as the Arroyo Seco River,
543 also increase (Fig. 9c).

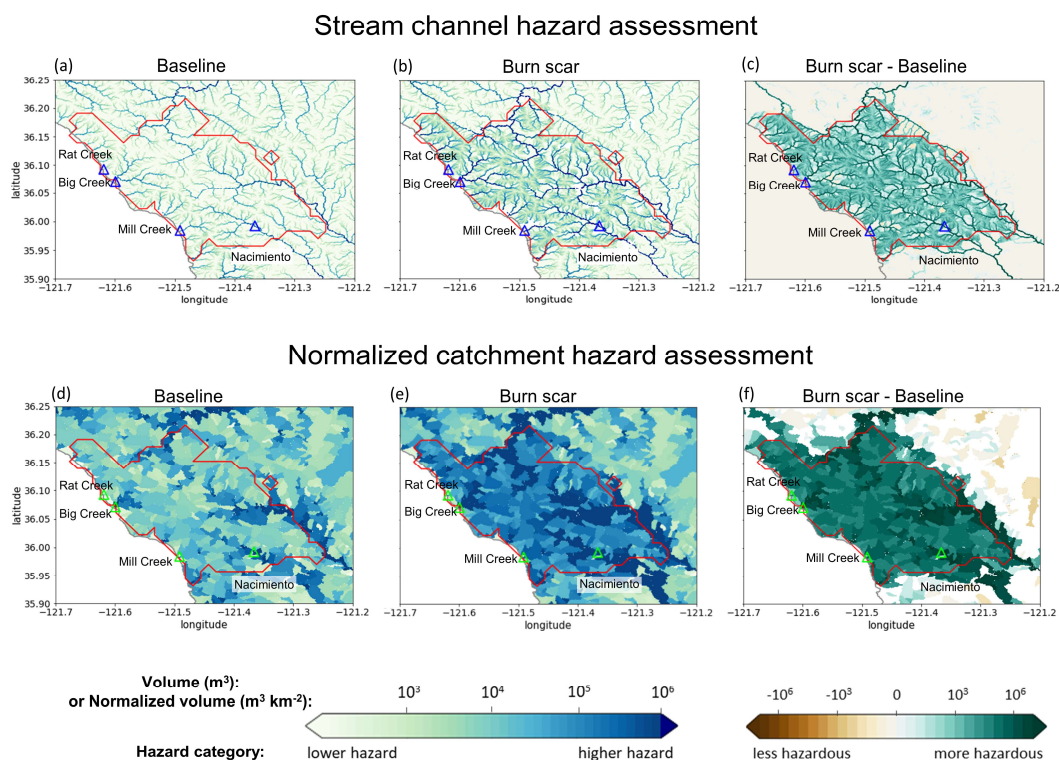

544

545 At the catchment level, debris flow hazards are assessed using accumulated discharge volumes
546 normalized by catchment areas (Fig. 9d–f). Accumulated discharge volumes are assessed at the
547 outlet of each catchment between January 27th 00:00 to 28th 12:00. In the baseline simulation, the
548 majority of catchments are subject to relatively low debris flow hazards compared to the burn scar
549 simulation with total normalized discharge volume less than $10^3 \text{ m}^3 \text{ km}^{-2}$ (Fig. 9d). In the burn scar
550 simulation, over half of catchments within the Dolan burn scar have normalized discharge volume
551 greater than $10^5 \text{ m}^3 \text{ km}^{-2}$, while over 1/4 of basins reach $10^6 \text{ m}^3 \text{ km}^{-2}$ (Fig. 9e). The additional
552 debris flow hazard brought about by the inclusion of wildfire burn scar characteristics is substantial
553 (Fig. 9f).

554 To summarize changes in debris flow hazards as a result of including burn scar characteristics in
555 WRF-Hydro simulations, we create distributions of pre-fire baseline and burn scar catchment-area
556 normalized discharge from the 404 catchments located within the Dolan burn scar perimeter (Fig.
557 10). After incorporating burn scar characteristics, the full distribution shifts to the right, indicating
558 increased hazard levels – a shift considered robust by a Student’s t-test (p value: $4.6\text{E-}45$). A
559 quantitative assessment of this shift indicates that the mean catchment area normalized discharge
560 volume increases by $\sim 1300\%$ (from $\sim 380\text{k}$ to $5.5\text{M} \text{ m}^3 \text{ km}^{-2}$) while the standard deviation increases
561 $\sim 1400\%$ (from $\sim 1.6\text{M}$ to $23.0\text{M} \text{ m}^3 \text{ km}^{-2}$). We also assess shifts at a range of distribution
562 percentiles: 5P: 148% ($\sim 0.6\text{k}$ to $\sim 1.5\text{k} \text{ m}^3 \text{ km}^{-2}$), 25P: 725% ($\sim 3.7\text{k}$ to $\sim 30.7\text{k} \text{ m}^3 \text{ km}^{-2}$), 50P: 924%
563 ($\sim 13\text{k}$ to $\sim 135\text{k} \text{ m}^3 \text{ km}^{-2}$), 75P: 980% ($\sim 120\text{k}$ to $\sim 1.3\text{M} \text{ m}^3 \text{ km}^{-2}$), and 95P: 1300% ($\sim 2.1\text{M}$ to
564 $\sim 29.1\text{M} \text{ m}^3 \text{ km}^{-2}$). In the burn scar simulation, more than half of catchments have normalized
565 volumes $> 10^5 \text{ m}^3 \text{ km}^{-2}$ and more than 1/4 of catchments have volumes $> 10^6 \text{ m}^3 \text{ km}^{-2}$ – values that
566 correspond to the 75P and 90P of the baseline simulation, respectively. Disproportionate shifting
567 of the right tail of the distribution suggests that extreme debris flow hazards increase non-linearly
568 under simulated burn scar conditions.

569 Our catchment-area normalized discharge volume-based hazard assessment also indicates that the
570 catchments containing Mill Creek, Big Creek, and Nacimiento had elevated hazard potential (Fig.
571 9d–f), consistent with our (limited) debris flow observations. Other areas with elevated hazards
572 include catchments containing the Arroyo Seco and San Antonio Rivers. Beyond the burn scar
573 perimeter, effects of fire expand to adjacent and downstream catchments, and the drainage basins
574 of the Arroyo Seco and Nacimiento Rivers are simulated to have potentially hazardous conditions,
575 i.e., normalized discharge volumes in excess of $10^6 \text{ m}^3 \text{ km}^{-2}$ (Fig. 9e&f).

576

577
578

579 **Fig. 9** | Discharge volume-based runoff-generated debris flow hazards. Debris flow hazards at
580 individual stream level for the (a) baseline, (b) burn scar, and (c) difference between burn scar and
581 baseline simulations. Hazard is estimated as total discharge volume from January 27th 00:00 to
582 28th 12:00. (d)–(f) Normalized debris flow hazards by catchment area at catchment level. For each
583 catchment, the hazard is determined by total discharge volume at the catchment outlet from
584 January 27th 00:00 to 28th 12:00 divided by catchment area.

585

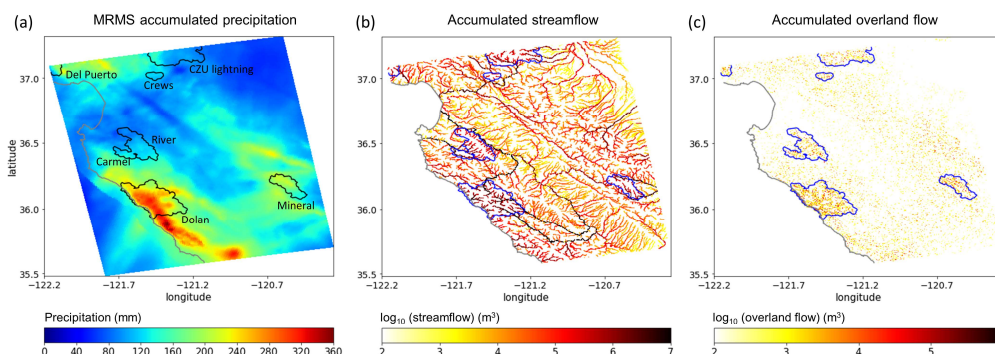

586 **Fig. 10** Distributions of accumulated discharge volumes at the outlet of the 404 catchments
587 normalized by upstream catchment areas within Dolan burn scar in the baseline simulation (purple
588 line) and in the burn scar simulation (red line). Dashed vertical lines indicate median values.

589 **5.4 Debris flow hazard assessment at regional scales**

590 While the results we present above primarily focus on hazards in the Dolan burn scar, our WRF-
591 Hydro domain includes a number of additional 2020 wildfire burn scar sites (Fig. 1a). Given the
592 long filament-like structure of western U.S. landfalling ARs, the heterogeneous nature of
593 landfalling trajectories, and the potential for systems to interact with diverse topographic terrains,
594 the development of tools capable of regional hazard assessments under high-gradient precipitation
595 events is crucial – particularly in a wildfire-prone region like California. To demonstrate the
596 potential utility of WRF-Hydro in regional applications, we assess hazards over our full domain
597 (Fig. 11). We find that hazard potential, from both channelized and overland flows, is greatest
598 within the burn scar sites, with maximum hazards found in the Dolan burn scar, consistent with
599 the location of elevated precipitation along the Coast Ranges – where more than 300 mm of rain
600 fell over three days (Fig. 11). Other high hazard-elevated precipitation regions within our domain
601 include the western edge of the Sierra Nevada and areas north of Monterey Bay, which collocate
602 with the Mineral and Del Puerto burn scars, respectively. Similar to our Dolan burn scar focused
603 analysis, areas within and downstream of these burn scar sites have elevated streamflow discharge
604 volumes compared to the non-burned areas (Fig. 11b). Likewise, areas of heightened accumulated

605 overland flow are elevated in burn scar regions, but also demonstrate a strong correspondence to
606 the spatial distribution of precipitation (Fig. 11a & c).

607

608 **Fig. 11|** MRMS accumulated precipitation and regional debris flow hazard assessment. (a) MRMS
609 accumulated precipitation during January 27th 00:00 to 29th 23:00 over the model domain
610 (shading; mm). Names of burn scars are labeled in black. (b) Accumulated streamflow (yellow-to-
611 red shading; m^3) and (c) accumulated overland flow from 27th 00:00 to 28th 12:00 over the model
612 domain (yellow-to-red shading; m^3). Wildfire perimeters of 2020 wildfire season are outlined in
613 black in (a), and in blue in (b) and (c). The coastline of California is in grey.

614

615 **6 Discussion**

616 Given the historic and growing frequency of wildfires in the western U.S. (Swain 2021; Williams
617 et al., 2019; Goss et al., 2020) and globally (Jolly et al., 2015; Flannigan et al., 2013), developing
618 tools to investigate, better understand, and potentially predict changes in burn scar hydrology and
619 natural hazards at regional scales is critical. Here, we demonstrate the first use of WRF-Hydro to
620 simulate the surface hydrologic response over a burn scar during a landfalling AR. We augmented
621 the default version of WRF-Hydro to output overland flow and to replicate burn scar behavior by
622 adjusting vegetation type and infiltration rate parameters. WRF-Hydro simulations were validated
623 against PSL soil moisture and USGS streamflow observations before we used simulated
624 streamflow and overland flow volumes to characterize debris flow hazard potential.

625

626 A comparison between baseline and burn scar simulations demonstrated that changes in hydraulic
627 properties of burned areas causes drastic changes in surface flows, including faster discharge
628 response times, greater discharge volumes, and overall flashier hydrologic behavior in surface
629 flows. As a result of including burn scar characteristics in WRF-Hydro simulations, median
630 catchment-area normalized discharge volume increases nine-fold, while 95P volume increases 13-

631 fold. The magnitude of our simulated changes is consistent with findings from previous postfire
632 hydrology studies (Anderson et al., 1976; Scott, 1993; Meixner & Wohlgemuth, 2003; Kinoshita
633 & Hogue, 2015; Kean et al., 2011). At Rat Creek, where a debris flow destroyed CA1, our model
634 simulation predicted an eight-fold increase in accumulated overland flow and a tripling in peak
635 discharge when compared to the baseline simulation. At Mill Creek, Big Creek, and Nacimiento,
636 the increase of runoff volume from the baseline to the burn scar simulation is on the order of 10^6
637 m^3 . Our hazard assessments based on catchment-area normalized discharge volumes indicated that
638 Mill Creek, Big Creek, and Nacimiento were under elevated debris flow hazards, corresponding
639 well with identified debris flow occurrences.

640

641 Despite methodological differences, our debris flow hazard assessment for this AR event is
642 generally consistent with the USGS' postfire, pre-AR, design-storm-based preliminary hazard
643 assessment (USGS, 2020). As described above, USGS preliminary hazard assessments use logistic
644 regression models to estimate the likelihood of debris flow occurrence and multivariate linear
645 regression models to estimate debris flow volumes. This empirical approach is trained on historical
646 western U.S. debris flow occurrence and magnitude data and incorporates estimated burn scar soil
647 erodibility and burn severity data (Cannon et al., 2010; Gartner et al., 2014; Staley et al., 2016).
648 For precipitation, the USGS assessment utilizes a design storm approach that assumes 1–5 year
649 return interval magnitude precipitation falls uniformly over a region/burn scar (USGS, 2020). For
650 the Dolan burn scar, both assessments find that large stream channels had relatively higher hazard
651 levels than small streams or overland areas. However, close comparison of hazard maps reveals
652 differences in spatial distribution of high-hazard catchments. In the USGS assessment, higher
653 hazard levels are predicted north and southeast of the burn scar, whereas in our assessment the
654 highest hazards occur along major stream channels. We hypothesize that USGS-assessed areas of
655 higher hazard potential are related to their use of design-storm precipitation (see Fig. 2 for MRMS
656 precipitation footprint) and burn severity data (Burned Area Emergency Response, 2020).
657 Comparison with the USGS assessment framework suggests room for improvement in WRF-
658 Hydro-based assessments (i.e., inclusion of burn severity and soil erodibility data), but also
659 highlights the potential utility of working with spatially-distributed and time-varying precipitation.
660 However, this also means the accuracy of WRF-Hydro predictions depends on the accuracy of
661 precipitation forcing, and in our hindcast application, MRMS precipitation data (Appendix A).
662 Accordingly, our WRF-Hydro-based hazard assessment could benefit from precipitation products
663 mosaiced from various sources to constrain precipitation-based uncertainties (e.g., gauge-
664 corrected and/or Mountain Mapper MRMS), although the long processing time of these datasets
665 inhibits timely post-event assessments.

666

667 As a water-only model, WRF-Hydro is currently restricted to simulating the hydrologic ingredients
668 of debris flows. While water-only models have been widely used to investigate and better
669 understand debris flow dynamics (Arattano & Savage, 1994; Arattano & Franzi, 2010; Rengers et
670 al., 2016; McGuire & Youberg, 2020; Di Cristo et al., 2021), sediment supply, soil erodibility, and

671 other sedimentological factors also play important roles in determining the potential for and
672 severity of mass failure events (McGuire et al., 2017). Developing a debris flow model that couples
673 hydrologic and sediment erosion and transport processes would represent a significant advance
674 and be of great practical use (Banihabib et al., 2020; Shen et al., 2021). At a minimum, soil grain
675 size maps and domain-specific rainfall intensity-duration curves can provide guidance to define
676 transitions from water floods to debris flows if historical debris flow data is available in the study
677 domain (McGuire & Youberg, 2020; Tognacca et al., 2000; Gregoretti & Fontana, 2008; Cannon
678 et al., 2007).
679

680 **7 Conclusion**

681
682 Use of WRF-Hydro to simulate runoff-generated debris flow hazards in burn scar settings
683 represents a novel application. It is notable that in this application we have balanced the
684 computational cost of a regional domain with our choice of resolved spatial resolution for terrain
685 routing and overland flow calculations (100 m). However, WRF-Hydro has previously been
686 applied to smaller domains at higher terrain routing resolutions (~30 m). Future work could assess
687 the use of the model to study burn scar hydrology at finer spatial scales, should the application
688 warrant and should underlying data at sufficient resolution exist. Other potential applications of
689 our modified model framework include alpine areas and steep hillslopes with sparse vegetation
690 where runoff-generated debris flows dominate over landslide-initiated ones (Davies et al., 1992;
691 Coe et al., 2003, 2008).
692

693 Further, our burn scar parameter changes are performed to Noah-MP, which is the core land
694 surface component of the National Centers for Environmental Prediction Global Forecast System
695 (GFS) and Climate Forecast System (CFS), thus the findings presented herein, are likely to prove
696 useful in the broader worlds of forecast meteorology and climate science. In addition, here WRF-
697 Hydro is driven by historical precipitation and meteorological data, i.e., in hindcast mode. We see
698 no reason why this modeling framework could not also be employed to project hazards under
699 future climatic conditions (e.g., Huang et al., 2020), or given its relatively low computational
700 expense, in operational forecast mode. Indeed, modern ensemble-based meteorological forecasting
701 could provide high spatiotemporal forcing data with which disaster preparedness managers could
702 probabilistically assess debris flow hazard potential, and issue advanced life and property saving
703 warnings.
704
705
706

707 **Appendix A**

708 **Text A1. Multi-Radar/Multi-Sensor System (MRMS) radar-only precipitation estimate and**
709 **uncertainty**

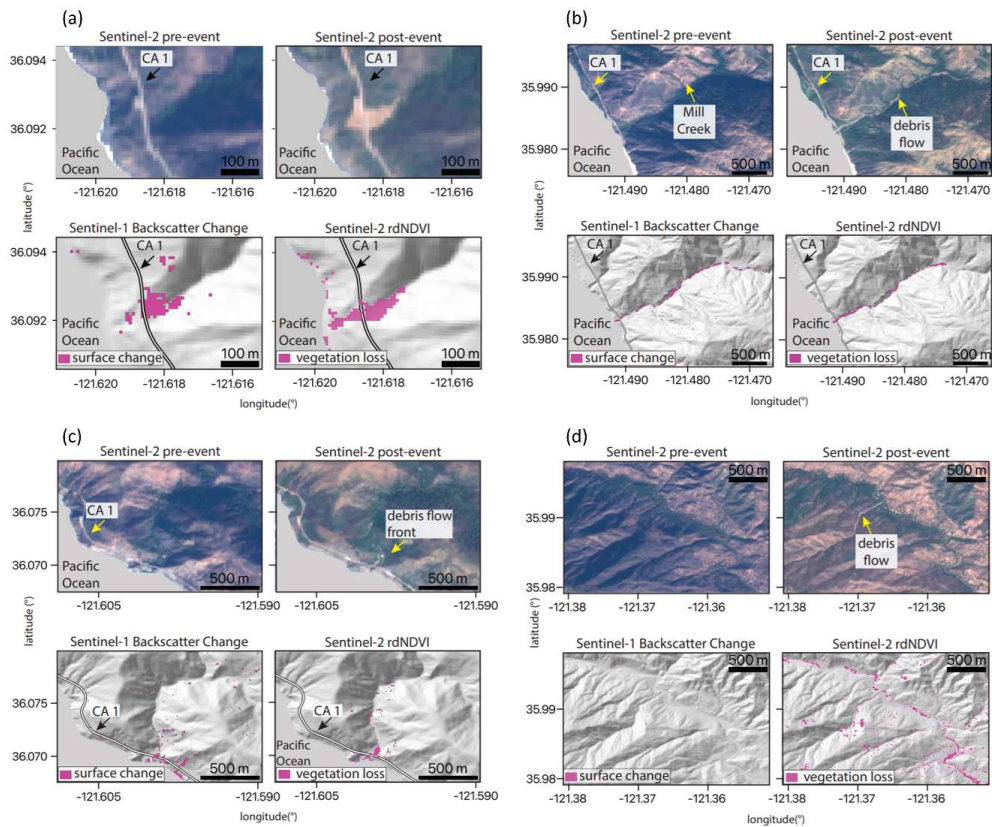

710 MRMS is a precipitation product that covers the contiguous United States (CONUS) on 1-km grids.
711 It combines precipitation estimates from sensors and observational networks (Zhang et al.,
712 2011, 2014, 2016), and is produced at the National Centers for Environmental Prediction (NCEP)
713 and distributed to National Weather Service forecast offices and other agencies. Input datasets
714 used to produce MRMS include the U.S. Weather Surveillance Radar-1988 Doppler (WSR-88D)
715 network and Canadian radar network, Parameter-elevation Regressions on Independent Slopes
716 Model (PRISM; Daly et al. 1994, 2017), Hydrometeorological Automated Data System (HADS)
717 gauge data with quality control (Qi et al., 2016), and outputs from numerical weather prediction
718 models. There are four different MRMS quantitative precipitation estimates (QPE) products
719 incorporating different input data or combinations: radar only, gauge only, gauge-adjusted radar,
720 and Mountain Mapper. For our study period (i.e., January 1–31, 2021), only the radar-only QPE
721 is currently available.

722

723 We acknowledge that precipitation data has uncertainties. Use of different precipitation products
724 may produce different results. A study comparing different gridded precipitation datasets including
725 satellite-based precipitation data, gauge dataset, and multi-sensor products revealed large
726 uncertainties in precipitation intensity (Bytheway et al., 2020). However, comparing different
727 precipitation datasets to characterize uncertainties is beyond the scope of this study. MRMS
728 provides gridded precipitation at high temporal (hourly) and spatial (1-km) resolutions, making it
729 a useful tool to demonstrate the utility of WRF-Hydro in post-wildfire debris flow hazard
730 assessments.

815

816 Data availability statement

817 The NLDAS-2 reanalysis forcing data is publicly available at NASA GES DISC:
818 <https://disc.gsfc.nasa.gov/datasets?keywords=NLDAS>. A detailed description can be found at
819 <https://ldas.gsfc.nasa.gov/nldas/v2/forcing>. The MRMS radar-only precipitation estimate is
820 publicly available at: <https://mtarchive.geol.iastate.edu/>. A description can be found at
821 <https://www.nssl.noaa.gov/projects/mrms/>. The PSL in-situ soil moisture data is publicly available
822 at: <https://psl.noaa.gov/data/obs/datadisplay/>. The USGS streamflow is publicly available at:
823 <https://waterdata.usgs.gov/nwis/>. The remote sensing data used in this manuscript were provided
824 by the European Space Agency (ESA) Copernicus program and accessed on Google Earth Engine
825 (<https://code.earthengine.google.com>). All processed data required to reproduce the results of this
826 study are archived on Zenodo at <http://doi.org/10.5281/zenodo.5544083>.

827 **Code availability statement**

828 The modified WRF-Hydro Fortran code and instructions to output the overland flow at terrain
829 routing grid can be downloaded at <https://github.com/NU-CCRG/Modified-WRF-Hydro>.

830 HazMapper v1.0 is available at <https://hazmapper.org/>. The SAR backscatter change method code
831 is available at https://github.com/MongHanHuang/GEE_SAR_landslide_detection.

832 **Author contribution**

833 Conceptualization: CL, ALH, & DEH; Simulation and model analysis: CL; JW & WY model
834 methodological development. Remote sensing analysis: ALH; Field Observations: NJF; GIS
835 assistance: YX; Funding acquisition: GB & DH; CL wrote the original draft and all authors
836 reviewed and edited the manuscript.
