17 **Abstract.** Geoelectric time series (TS) has long been studied for its potential for probabilistic earthquake  
18 forecasting, and a recent model (GEMSTIP) directly used the skewness and kurtosis of geoelectric TS to  
19 provide Time of Increased Probabilities (TIPs) for earthquakes in several months in future. We followed  
20 up on this work by applying the Hidden Markov Model (HMM) on the correlation, variance, skewness,  
21 and kurtosis TSs to identify two Hidden States (HSs) with different distributions of these statistical  
22 indexes. More importantly, we tested whether these HSs could separate time periods into times of  
23 higher/lower earthquake probabilities. Using 0.5-Hz geoelectric TS data from 20 stations across Taiwan  
24 over 7 years, we first computed the statistical index TSs, and then applied the Baum-Welch Algorithm  
25 with multiple random initializations to obtain a well-converged HMM and its HS TS for each station.  
26 We then divided the map of Taiwan into a 16-by-16 grid map and quantified the forecasting skill, i.e.,  
27 how well the HS TS could separate times of higher/lower earthquake probabilities in each cell in terms  
28 of a *discrimination power* measure that we defined. Next, we compare the *discrimination power* of  
29 empirical HS TSs against those of 400 simulated HS TSs, then organized the statistical significance  
30 values from these cellular-level hypothesis testing of the forecasting skill obtained into grid maps of  
31 *discrimination reliability*. Having found such significance values to be high for many grid cells for all  
32 stations, we proceeded with a statistical hypothesis test of the forecasting skill at the global level, to find  
33 high statistical significance across large parts of the hyperparameter spaces of most stations. We therefore  
34 concluded that geoelectric TSs indeed contain earthquake-related information, and the HMM approach  
35 to be capable at extracting this information for earthquake forecasting.

## 1 Introduction

Earthquakes (EQs) are one of the most destructive natural hazards that can befall us, with the potential to take many human lives and deal serious damages to economies and environments. It is imperative for us to work towards better forecasting/prediction capabilities against EQs, to inform pre-EQ evacuation, post-EQ relief, as well as expediting critical reinforcement works for selected buildings and infrastructures. To achieve this goal, the scientific community has done much work discovering precursors and models that are useful for the forecasting/prediction of EQs.

First, let us clarify that in the seismological community, the terms “prediction” and “forecast” are often used interchangeably (Kagan, 1997; Ismail-Zadeh, 2013). When they are distinguished, the term “prediction” emphasizes the issuing of an *alarm* with high accuracy and reliability indicating the time, location, and magnitude of the next large EQ (Geller et al., 1997), whereas the term “forecast” is a statement about the probability of EQ(s) within the specified spatial-temporal window (Ismail-Zadeh, 2013). Till this day, it is extremely difficult to make accurate and specific EQ predictions (Geller et al., 1997). However, the forecasting of EQs is a far more tractable task: a method that performs better than random guesses (the null hypothesis) is recognized as having *predictive power* or *predictive skill* (“prediction” and “forecast” used as synonym here) (Kagan, 1997). In this paper, we will also use the two terms interchangeably.

If we categorize EQ forecasting methods according to their time scales, we can organize them into three categories: long-term (decades ahead), intermediate-term (a few years ahead), and short-term (days or a few months ahead) (Peresan et al., 2005; Kanamori, 2003). EQ forecasting at different time scales serve different purposes. For a region of interest, a long-term EQ forecasting aims to estimate the probabilities of large EQs in the next decades or more. In most past studies, the primary input data was the historical EQ catalog, which allowed statistical modellings of the occurrence times of large and medium sized EQs (Kagan and Jackson, 1994; Sykes, 1996; Papazachos et al., 1987; Papadimitriou, 1993; Papazachos et al., 1997), assuming that EQs’ occurrences in the same spatial area follow a Poisson process of relatively constant rate. One such example is the probabilistic seismic hazard assessment (PSHA) first established by Cornell in 1968 (Cornell, 1968). This became a popular method for long-term seismic hazard assessment implemented in many countries (Tavakoli and Ghafory-Ashtiany, 1999; Petersen, 1996; Meletti et al., 2008; Vilanova and Fonseca, 2007; Nath and Thingbaijam, 2012; Wang et al., 2016). In this method, we take into account both historical EQ catalog information, as well as ground motion characteristics for the modelling of energy attenuation over spatial distances, thus providing a map of seismic hazard rates that varies across location for the next 50 years. Long-term EQ forecasting such as PSHA can be valuable for location-specific seismic risk evaluation, thereby providing guidelines or criteria for local construction projects. For example, a building that is expected to last 100 years must be able to withstand 10 large EQs of the magnitude that occurs once every 10 years locally. What long-term EQ forecasting does not do, would be to tell people how to do things differently at any time.

For intermediate-term EQ forecasting, the aim is to detect deviations of EQ rates from their long-time values, to assess increased probabilities of EQs within the next one to ten years. For example, if a region usually has a magnitude-6 EQ every 10 years, and 15 years have passed without one, the region would be in a state of increased probability. A famous example for the intermediate-term EQ forecasting is the

86 M8 algorithm (Kossobokov et al., 2002; Peresan et al., 2005; Keilis-Borok, 1996), developed by Healy  
87 et al. (1992). The M8 algorithm used the EQ catalog as input, and returned as output the Time of  
88 Increased Probability (TIP) for EQs of magnitude 7.5 and above for the next one year. Another example  
89 is the CN algorithm (Peresan et al., 2005; Keilis-Borok, 1996) developed by Keilis-Borok and Rotwain  
90 (1990), that also took the EQ catalog as input to produce as output TIP for strong EQs (defined  
91 specifically for different regions) within the next half to a few years. In the literature, we also found the  
92 self-organizing spinodal (SOS) model (Chen, 2003; Rundle et al., 2000), which used the increased  
93 activity of medium-sized EQs as precursors to large EQs that could occur within the next several years  
94 or decades. Finally, one of the more successful methods at this time scale is pattern informatics (Nanjo  
95 et al., 2006), which was demonstrated to be effective at predicting  $M \geq 5$  EQs in Japan between 2000  
96 and 2009. Intermediate-term EQ forecasting can, for example, help local authorities prioritize inspections  
97 and reinforcements of old buildings over the construction of new ones.

98

99 Short-term EQ forecasting use a variety of methods to forecast the time, place, and magnitude of a  
100 specific large EQ. Here we commonly find methods using the EQ catalog as input data, and apply  
101 machine learning approaches (Asim et al., 2017; Reyes et al., 2013), as well as Hidden Markov Model  
102 (HMM) approaches (Yip et al., 2018; Chambers et al., 2012). For example, in (Chambers et al., 2012) an  
103 HMM was trained to track the waiting time between EQs with magnitudes above 4 in southern California  
104 and western Nevada (Yip et al., 2018), giving EQ forecasts for up to ten days in the future. Apart from  
105 using EQ catalog data, there is an increased variety of methods using other data inputs, such as the widely  
106 used Seismic Electric Signals (SEs) (Uyeda et al., 2000; Varotsos et al., 2013; Varotsos et al., 2002;  
107 Varotsos et al., 2017; Varotsos and Lazaridou, 1991; Varotsos et al., 1993), to look for EQ precursors in  
108 the form of abnormal changes to the geoelectric potential. In addition to looking for specific SES-type  
109 precursors, we also found papers using methods such as artificial neural networks (ANNs) (Moustra et al.,  
110 2011), Fisher Information (Telesca et al., 2005a; Telesca et al., 2009), and multi-fractal analysis  
111 (Telesca et al., 2005b) directly on geoelectric time series (TSs) data to make short-term EQ forecasting.  
112 Other data that can be used include the combination of geoelectric and magnetic data (Kamiyama et al.,  
113 2016; Sarlis, 2018), GPS crustal movements (Kamiyama et al., 2016; Wang and Bebbington, 2013),  
114 electromagnetics of the atmosphere (Hayakawa and Hobara, 2010), and lithosphere dynamics (Shebalin  
115 et al., 2006). Short-term EQ forecasting can guide emergency responses such as evacuations and pre-  
116 mptive relief efforts, although they are usually not reliable enough based on our current level of  
117 understandings.

118

119 Among all these precursors, our recent research interest was on the potential use of geoelectric TSs for  
120 EQ forecasting (Chen and Chen, 2016; Chen et al., 2020; Jiang et al., 2020; Telesca et al., 2014; Chen et  
121 al., 2017). In 2016 and 2017, Chen and his colleagues (Chen and Chen, 2016; Chen et al., 2017) analyzed  
122 the data of 20 geoelectric stations in Taiwan (Fig. 1) and studied the association between skewness and  
123 kurtosis of the geoelectric data and  $M_L \geq 5$  EQs, where  $M_L$  is the Richter magnitude scale. Through  
124 statistical analyses, they found significant correlations between geoelectric anomalies and these large  
125 EQs. They then developed an EQ forecasting algorithm named GEMSTIP to extract TIPs for future EQs.  
126 TIPs were identified through differences in the distributions of skewness and kurtosis with those found  
127 during normal periods. Moreover, Jiang et al. (2020) investigated the geoelectric signals before, during,  
128 and after EQs by the shifting correlation method, and found that the lateral and vertical electrical  
129 resistivity variation and subsurface conductors might amplify SEs, which agreed with the findings by

130 Sarlis (Sarlis et al., 1999) and Huang (Huang and Lin, 2010).

131

132

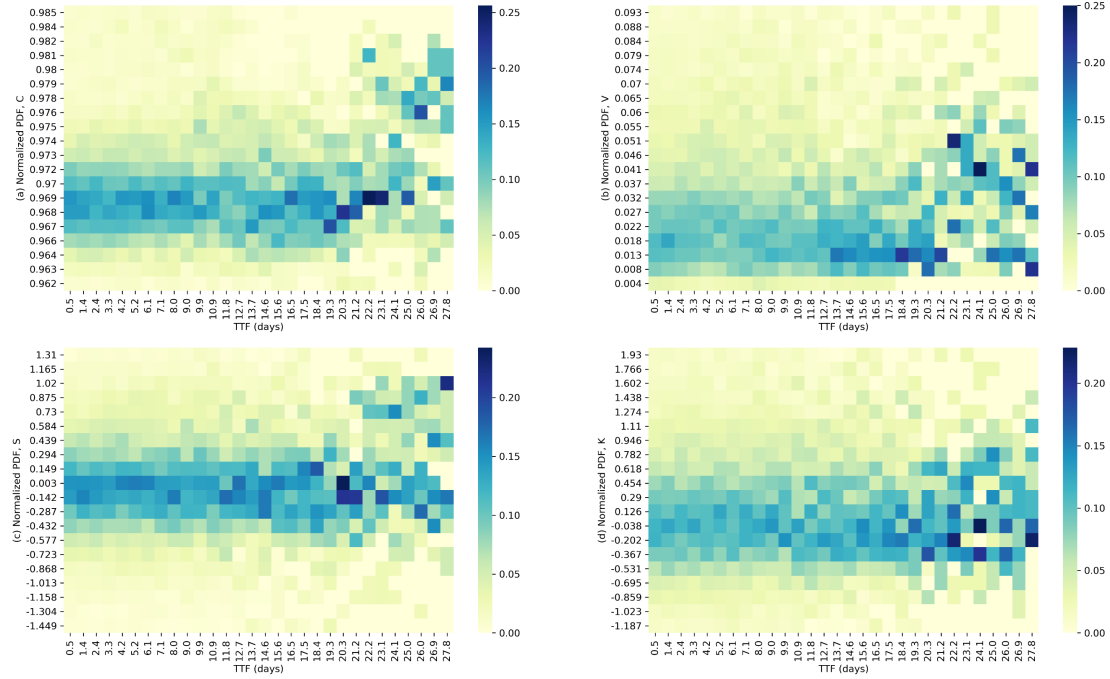

133 **Figure 1: Map of the spatial distributions of seismicity and geoelectric stations (green triangles) in Taiwan. In**  
134 **this figure, past EQs with  $M_L \geq 3$  are shown as light blue dots while past EQs with  $M_L \geq 6$  are shown as**  
135 **red stars.**

136

137 Inspired by these findings, in this paper we wanted to take a closer look at the relationship between the  
138 EQ times and statistical indexes of geoelectric TSs, namely correlation ( $C$ ), variance ( $V$ ), skewness ( $S$ ),  
139 and kurtosis ( $K$ ). During initial explorations, we computed the TSs of these indexes (see Sect. 2.2 for  
140 computation details) on geoelectric TSs given by the 20 stations over the 7-year period of Jan. 2012 –  
141 Dec. 2018 (see Sect. 2.1 for data details). We then aggregated the distribution of the indexes' values  
142 within different times-to-failure (TTFs, i.e., time remaining to the next EQ) intervals. In Fig. 2, we show  
143 the normalized frequency distributions of  $C$ ,  $V$ ,  $S$ ,  $K$  computed from KAOH station at different TTFs  
144 (using 0.9-day intervals) for  $M_L \geq 4$  EQs within 2 degrees longitude-latitude of KAOH station. In this  
145 figure, we see bands of darker-colored pixels across the TTFs. Specifically, for  $C$ ,  $V$ , and  $S$ , there are  
146 sudden shifts in the average position of the bands, suggesting that there are two regimes (short TTFs and  
147 long TTFs) where the geoelectric fields show qualitatively different behaviors. For all statistical indexes,  
148 we find the darkest pixels concentrated in the long-TTF regime, whereas in the short-TTF regime, the  
149 pixels show a lower variability in their intensities. We suspect that this second phenomenon is the result  
150 of fewer samples at longer TTFs.

151

152

153 **Figure 2: Heatmaps of normalized probability density functions of  $C$ ,  $V$ ,  $S$ ,  $K$  at different times-to-failure**  
 154 **(TTFs), for the east-west component of the geoelectric TS. The TTFs are computed using  $M_L \geq 4$  EQs within**  
 155 **2 degrees longitude-latitude from station KAOH.**

156

157 To overcome this problem, which is created by superimposing the index TSs of different lengths between  
 158 EQs, we decided to discover such regimes directly from the geoelectric TSs by using HMMs. The HMM  
 159 is well known for being data-driven, enabling us to search and use more general statistical features  
 160 beyond limited templates that we currently know (Beyreuther and Wassermann, 2008). Additionally, its  
 161 explicit incorporation of the time dimension into the model is a distinct advantage for providing holistic  
 162 and time-sensitive representations, especially in the application of EQ forecasting (Beyreuther and  
 163 Wassermann, 2008). In our HMM, we defined two hidden states (HSs) as the high-level representations  
 164 of geoelectricity, featuring unique distributions of  $C$ ,  $V$ ,  $S$ ,  $K$ . Here we chose to use only two, instead  
 165 of more HSs, because 2-state HMM have already been successfully applied to model regimes with  
 166 different EQ frequencies using EQ catalogs as the only inputs (Yip et al., 2018; Chambers et al., 2012).  
 167 Thereafter, for each monitoring station, we obtained the TS of posterior HS probability, or HS TS, using  
 168 the TSs of  $C$ ,  $V$ ,  $S$ ,  $K$  and the Baum-Welch Algorithm (BWA). We then partitioned the time periods  
 169 under study according to the HS TSs, and investigated whether these HS TSs that are obtained purely  
 170 from geoelectric data can separate time periods of high versus low EQ ( $M_L \geq 3$ ) probabilities, with high  
 171 statistical confidence.

172

173 The goal of this investigation is to decide whether the HMM-modelling of geoelectric TS could provide  
 174 features (i.e., HS TSs) of true forecasting skill for intermediate-term EQ forecasting. Therefore, we are  
 175 more concerned with statistical significance, than with evaluating the exact forecasting accuracy, or the  
 176 forecasting of specific EQs. In this regard, we also note that the same HMM approach described in this  
 177 paper can be applied to many other geophysical high-frequency time series data, such as geomagnetic or  
 178 GPS ground movement data, even though we only used geoelectric data as the input of the HMM, to  
 179 show that the underlying seismic dynamics is indeed clearly separable into distinct regimes of higher

180 versus lower seismic activities (as supported by (Yip et al., 2018; Chambers et al., 2012)).

181

182 For the sake of our readers, we organize our Data and Methods in Sect. 2, Results and Discussions in  
183 Sect. 3, and Conclusions in Sect. 4. In Sect. 2, we provide information on the EQ catalog, the geoelectric  
184 TSs, how we pre-processed the latter, and subsequently computed the index TSs of  $C$ ,  $V$ ,  $S$ ,  $K$  from  
185 them. We then explain how an HMM and the Baum-Welch Algorithm works, before applying them to  
186 our problem. We also explain why we did not estimate individual HMMs from the index TSs of  $C$ ,  $V$ ,  
187  $S$ ,  $K$ , but one HMM for each station from an observation TS aggregating  $C$ ,  $V$ ,  $S$ ,  $K$  through k-means  
188 clustering. At the end of this section, we present our procedures to quantify how informative the HSs are  
189 against EQ activities, by defining and analyzing EQ Grid Maps, EQ Frequencies, and EQ Frequency  
190 Ratios ( $R_F$ ). In Sect. 3, we first used the  $R_F$  grid map of one of the 20 stations to illustrate how we can  
191 compare a Discrimination Power ( $D$ ) grid map against 400 simulated grid maps of  $D$ , to obtain the  
192 Discrimination Reliability ( $R_D$ ) grid map, which are cellular-level statistical significances that the HSs  
193 are useful for EQ forecasting. We then performed significance tests to verify that the HSs' forecasting  
194 power are also significant at the global level, using a metric of Global Confidence Level ( $GCL$ ) that we  
195 defined. To end Sect. 3, we explored how robust the  $GCL$  values are across the hyperparameter space  
196 and clarified how we chose the optimal hyperparameters for each station. Finally, we conclude in Sect.  
197 4.

198

199

## 200 **2 Data and Methods**

201

### 202 **2.1 Data Description**

203

204 The 1-Hz geoelectric TSs data used in this paper was provided by the 20 monitoring stations located  
205 across Taiwan (see Fig. 1), which are collectively named Geoelectric Monitoring System (GEMS). The  
206 spacings among stations are generally 50 km. The geoelectric data here is the self-potential data, which  
207 is the natural electric potential differences in the earth, measured by dipoles placed 1–4 km apart within  
208 each station. Each station can output two sets of high-frequency geoelectric TSs, measuring along the  
209 NS direction and the EW direction. Depending on the spatial constraints of some stations, the azimuths  
210 of the dipoles might deviate from the exact NS or EW directions by 10–40°. For the purpose of this study,  
211 we used the geoelectric TSs provided by the GEMS with the same time span as the EQ catalog data,  
212 which is from January 2012 to December 2018. We down sampled the data to 0.5 Hz, and used these in  
213 subsequent analyses.

214

215 The HMMs that we will show in Sect. 3 partitioned the 20 geoelectric TSs into two HSs, distinguished  
216 by the local statistics of their geoelectric fields. We believe these HSs can also exhibit different  
217 seismicities within their time durations. To check this, we used EQ catalog data compiled by the Central  
218 Weather Bureau (CWB), in charge of monitoring EQs in the region of Taiwan (Shin et al., 2013). The  
219 CWB seismic network is highly dense and provides an abundant set of waveform data. Due to  
220 considerable EQs recorded, the seismotectonics of Taiwan is well depicted, showing the complicated  
221 subduction between the Philippine Sea plate and Eurasian plate (Kuo-Chen et al., 2012; Yi-Ben, 1986).  
222 Despite the dense seismic network, the EQ catalog was shown to be incomplete at small magnitudes due  
223 to the detection threshold of seismic instruments and the coverage of networks (Fischer and Bachura,

224 2014; Nanjo et al., 2010; Rydelek and Sacks, 1989). The completeness magnitude ( $M_c$ ), defined as the  
 225 lowest magnitude above which all EQs are reliably detected, in Taiwan is approximately between 2 and  
 226 3 (Chen et al., 2012; Mignan et al., 2011). Chen et al. (2012) showed the temporal variation of  $M_c$ , while  
 227 Mignan et al. (2011) provided the spatial information of that. In this study, for the conservative estimate,  
 228 we took the completeness magnitude of 3 and analyzed EQs with  $M_L \geq 3$ , during the period from  
 229 January 2012 to December 2018 in the area of 119.5–122.5° E and 21.5–25.5° N, as shown in Fig. 1, in  
 230 which the locations of strong events with  $M_L \geq 6$  are marked. Some of these events were destructive.  
 231 For instance, at 03:57 on 6 February 2016 (UTC+8), an  $M_L$ -6.6 EQ occurred in the southern part of  
 232 Taiwan (120.54° E, 22.92° N). This event struck at a depth of around 14.6 km (Chen et al., 2017; Lee et  
 233 al., 2016; Pan et al., 2019). Such a comparatively shallow depth caused more intensities on the surface,  
 234 and resulted in wide-spread damage which included 117 deaths and over 500 wounded.

235

236 In the latest update of the GEMSTIP model, Chen et al. (2021) found out that by applying a specific  
 237 bandpass filter on the geoelectric TS, the model became better at anticipating EQs using the skewness  
 238 and kurtosis TSs. The filter they used is the order-3 Butterworth bandpass filter with lower and higher  
 239 cut-off frequencies of  $f_1 = 10^{-4.0}$  Hz and  $f_2 = 10^{-1.75}$  Hz respectively. These lower and upper cut-  
 240 off frequencies were determined to give the optimal signal-to-noise ratio by Chen et al. (2021).

241

242 Similar to the GEMSTIP model, our HMM modelling also searched for EQ-related information in  
 243 skewness and kurtosis TSs computed from the geoelectric TS, we conveniently utilized the insight from  
 244 Chen et al. (2021), and applied the same Butterworth filter on our geoelectric TS data before computing  
 245 the index TSs. This filter was applied using *scipy.signal (v1.4.1)* package in *Python (v3.6.5)*, with  
 246 instructions from (Scipy-Cookbook, 2012), which also demonstrated a clear working example of the  
 247 Butterworth bandpass filter that readers can refer to.

248

## 249 **2.2 Computation of Index TSs of $C, V, S, K$**

250

251 For each station, there are two geoelectric TSs (NS and EW) of frequency 0.5-Hz. Each geoelectric TS  
 252 will produce four statistical index TSs ( $C, V, S, K$ ). For each station, we therefore obtained up to 8 index  
 253 TSs, 4 for each direction (NS and EW). Starting from the 0.5-Hz geoelectric TS, we computed one index  
 254 point for every non-overlapping time window of length  $L_w$  geoelectric TS data points. Later in Sect.  
 255 3.5, we will discuss in detail how we chose the optimal  $L_w$  individually for each station in parameter  
 256 space that we tested: [0.02, 0.03, 0.04, 0.05, 0.1, 0.2, 0.25] (days). As can be noticed from Fig. 12, 11  
 257 out of 20 stations' optimal choice was  $L_w = 0.02$  or 0.03 days, which we suppose can be a good  
 258 compromise between timely monitoring of state shifts and updating at a comfortable frequency for the  
 259 human decision makers. Potential decisions that such an update frequency may enable includes the  
 260 forward deployment of relief materials such as back-up generators, portable water treatment units, tents,  
 261 medical supplies, refresher training of emergency response teams, as well as administrative prioritizing  
 262 of re-certification works for buildings and structures in regions where more EQs are expected soon.

263

264 Next, we present the definitions for each index. Within each time window, let us write the geoelectric  
 265 field as  $\{X_n\}_{n=1, \dots, L_w}$ . The correlation  $C$  that we used in this paper is the lag-1 Pearson autocorrelation  
 266 of  $\{D_n = X_{n+1} - X_n\}_{n=1, \dots, L_w-1}$ , which is the *difference sequence* of  $\{X_n\}_{n=1, \dots, L_w}$ . Mathematically,

267 
$$C(\{X_n\}) = AC1(\{D_n\}) = \frac{\mathbb{E}[(D_n - \mu_D)(D_{n+1} - \mu_D)]}{\sigma_D^2}, \quad (1)$$

268 where  $\mathbb{E}$  is the expectation,  $\mu_D$  is the mean of  $\{D_n\}_{n=1, \dots, L_w-1}$  and  $\sigma_D$  is the standard deviation of  
 269  $\{D_n\}_{n=1, \dots, L_w-1}$ . The range of  $C$  is  $[-1, 1]$ , and  $C$  measures how fast the TS relaxes back to the  
 270 equilibrium. If  $C$  is close to 1,  $X$  would tend to increase or decrease persistently; if  $C$  is around 0,  
 271  $X$  would be equivalent to random walks; and if  $C$  is close to  $-1$ , every increase in  $X$  would tend to  
 272 be followed by a similar decrease.

273

274 The variance  $V$  of  $\{X_n\}_{n=1, \dots, L_w}$  is the sequence's second standard central moment. It is a positive  
 275 number that measures how drastically the values in the sequence are different from each other, with  
 276 higher values indicating higher difference. It is defined as:

277 
$$V(\{X_n\}) = \mathbb{E}[(X_n - \mu_X)^2], \quad (2)$$

278 where  $\mu_X$  is the mean of  $\{X_n\}_{n=1, \dots, L_w}$ . Additionally, we observed astronomically extreme values in the  
 279  $V$  TSs for most stations, which were caused by unknown technical errors, and we therefore considered  
 280 them outliers that have to be removed for consistent data quality. We discuss how we removed them in  
 281 detail in Supporting Information Sect. A. From here onwards, the  $V$  TSs will always refer to those after  
 282 the outlier-removal process.

283

284 The skewness  $S$  of  $\{X_n\}_{n=1, \dots, L_w}$ , or the sequence's third standard central moment, is defined as:

285 
$$S(\{X_n\}) = \mathbb{E} \left[ \left( \frac{X_n - \mu_X}{\sigma_X} \right)^3 \right], \quad (3)$$

286 where  $\sigma_X$  is the standard deviation of  $\{X_n\}_{n=1, \dots, L_w}$ . It is a real number measuring how asymmetric the  
 287 distribution of  $\{X_n\}_{n=1, \dots, L_w}$  is about the mean. For a perfectly symmetric distribution such as the normal  
 288 distribution, the skewness is 0. A positive skewness means the distribution has a longer tail to the right,  
 289 and a negative skewness means the distribution has a longer tail to the left.

290

291 The kurtosis  $K$  of  $\{X_n\}_{n=1, \dots, L_w}$ , or the sequence's fourth standard central moment, is defined as:

292 
$$K(\{X_n\}) = \mathbb{E} \left[ \left( \frac{X_n - \mu_X}{\sigma_X} \right)^4 \right]. \quad (4)$$

293 It is a real number measuring how frequently extreme values (values very far from the mean) appear in  
 294 the distribution. The higher the number, the more frequently extreme values can be found. As a reference,  
 295 the kurtosis of the normal distribution is  $K = 3$ . If  $K > 3$ , we say that the distribution is *leptokurtic*,  
 296 meaning the distribution has fatter tails and more frequent extreme values compared to the normal  
 297 distribution. If  $K < 3$ , the distribution is said to be *platykurtic*, meaning the distribution has thinner tails,  
 298 and extreme values appear less frequently compared to the normal distribution.

299

### 300 2.3 Estimation of HMM Using the Baum-Welch Algorithm

301

302 A Markov model is a stochastic model that can be used to describe a system whose future state  $s_{t+1}$  is  
 303 drawn from a set of  $L$  states  $\{S_l\}_{l=1, \dots, L}$  with probabilities  $p_{j \leftarrow i} = P(s_{t+1} = S_j | s_t = S_i)$  conditioned  
 304 by its current state  $s_t$ . The probabilities  $p_{j \leftarrow i}$  can be organized into a transition matrix  $\mathbf{A}$ , where  
 305  $A(i, j) = p_{j \leftarrow i}$ . The HMM is an extension of the Markov model, with the additional property that the  
 306 system state  $s_t$  is not explicitly known, hence the word "hidden" in the name. Instead, what can be  
 307 observed from an HMM at any time  $t$  is an observable  $o_t$  drawn from a size- $Q$  observable set

308  $\{O_q\}_{q=1,\dots,Q}$ . Just as in a Markov model, the future state  $s_{t+1}$  of an HMM is drawn from the set  
309  $\{S_l\}_{l=1,\dots,L}$  with probabilities  $p_{j \leftarrow i}$  (similarly conditioned by the current state  $s_t$ ) taken from the  
310 transition matrix  $\mathbf{A}$ . At time  $t$ , the observable  $o_t$  is emitted with a probability  $P(o_t = O_q | s_t = S_l)$   
311 that depends on which HS  $s_t = S_l$  the system is in. These probabilities can be organized into an  $L \times Q$   
312 emission matrix  $\mathbf{B}$ , where  $\mathbf{B}(l, k) = P(o_t = O_q | s_t = S_l)$ . Additionally, we call the HS probability  
313 distributions at the initial time as  $\boldsymbol{\pi}_0 = \{P(S_1), P(S_2), \dots, P(S_L)\}$ . With this, we have fully specified the  
314 HMM: the sets of HSs  $\{S_l\}_{l=1,\dots,L}$  and observations  $\{O_q\}_{q=1,\dots,Q}$  as well as the model parameters that  
315 are collectively called  $\lambda = (\mathbf{A}, \mathbf{B}, \boldsymbol{\pi}_0)$ .

316

317 In common real-world applications of HMM, the question is to estimate the probability distributions of  
318 the HS TS given the observation TS and the model parameter, namely  $P(s_t = S_l | \{o_t\}_{t=1,\dots,T}, \lambda)$ . More  
319 often than not, the model parameter  $\lambda$  is unknown and has to be simultaneously estimated as well. One  
320 of the most common ways to do this is the Baum-Welch Algorithm (BWA) (Zhang et al., 2014; Oudelha  
321 and Aïnon, 2010; Yang et al., 1995; Bilmes, 1998), which belongs to the family of Expectation  
322 Maximization methods (Bilmes, 1998). Starting from randomly initialized model parameters  $\lambda$ , the  
323 algorithm runs recursively to maximize the likelihood of the model given the observation TS. When the  
324 algorithm converges, we will obtain a set of estimated model parameters  $\tilde{\lambda} = (\tilde{\mathbf{A}}, \tilde{\mathbf{B}}, \tilde{\boldsymbol{\pi}}_0)$ , as well as a  
325 posterior probability  $P(s_t = S_l | \{o_t\}_{t=1,\dots,T}, \tilde{\lambda})$  TS. We include more details on the BWA in Sect. 2.5.  
326 Additionally, for readers who want an intuitive demonstration of how HMM and BWA works, we  
327 attached a simulation of a simple HMM and its BWA application in Supporting Information Sect. B.

328

329 HMMs are traditionally applied in fields such as speech recognition (Palaz et al., 2019; Novoa et al.,  
330 2018; Chavan and Sable, 2013; Abdel-Hamid and Jiang, 2013), bioinformatics, and anomaly detection  
331 (Qiao et al., 2002; Joshi and Phoha, 2005; Cho and Park, 2003). It has also been used for short-term EQ  
332 forecasting, using observations from EQ catalogs (Yip et al., 2018; Chambers et al., 2012; Ebel et al.,  
333 2007), as well as GPS measurements of ground deformations (Wang and Bebbington, 2013). To the best  
334 of our knowledge, there is no past HMM study on geoelectric TSs for EQ forecasting. In this paper, we  
335 argue that the HMM is an objective tool, because the HSs were estimated only from the geoelectric TSs,  
336 and thereafter validated against the EQ catalog. We believe this statistical procedure limits the bias that  
337 we could introduce into our prediction model when we optimized the model. This will be even clearer  
338 by the end of Sect. 2.5 where we summarize the entire procedure.

339

#### 340 **2.4 HMM Modelling and Inputs to the BWA**

341

342 In the context of this study, we assume for simplicity two seismicity states of the earth crust beneath each  
343 station. These are our HSs  $\{S_1, S_2\}$ , since they cannot be directly observed. What we can observe directly  
344 are the geoelectric TSs for each station. Our goal is to reconstruct the HS TSs so that the distributions of  
345 indexes  $(C, V, S, K)$  of the geoelectric TSs in  $S_1$  and  $S_2$  are as different as possible. To do this, we  
346 computed 4 index TSs each for NS and EW geoelectric fields using the procedure described in Sect. 2.2,  
347 and organized them into a TS of 8-dimensional feature vectors  $\mathbf{F}_t =$   
348  $[C_{NS,t}, V_{NS,t}, S_{NS,t}, K_{NS,t}, C_{EW,t}, V_{EW,t}, S_{EW,t}, K_{EW,t}]$ . The values of each of the indexes are continuously  
349 distributed, but the standard BWA requires discrete observations  $\{O_q\}_{q=1,\dots,Q}$  as input. In this section,

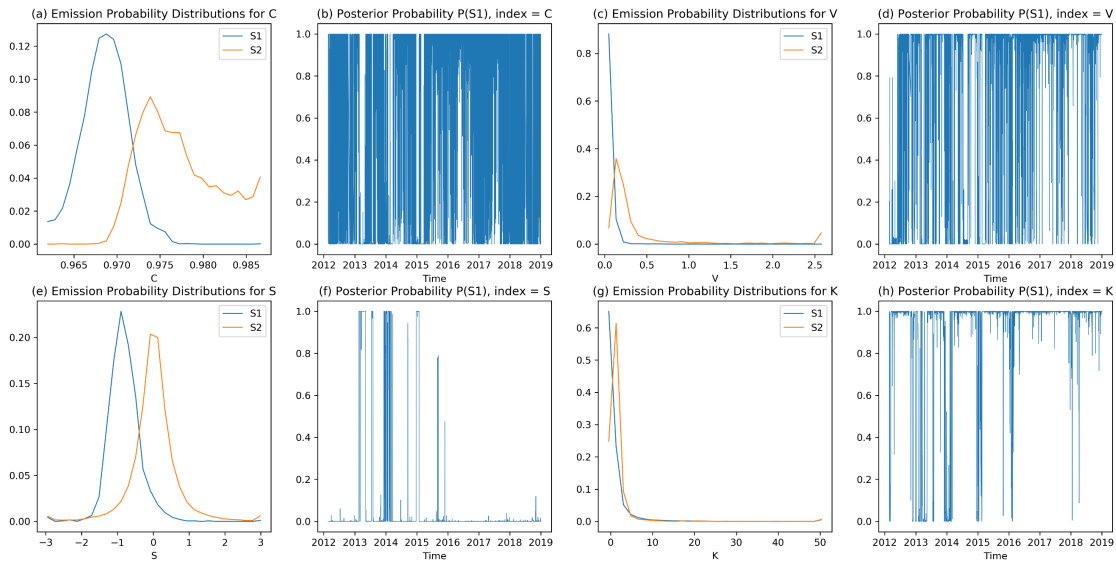

350 we discuss possible ways to convert  $\mathbf{F}_t$  into discrete observations for the BWA, and why we chose one  
 351 particular method for implementation.

352

353 One way to do so would be to model each component of  $\mathbf{F}_t$  as samples drawn from known distributions,  
 354 such as a normal distribution or a gamma distribution. Unfortunately, as we can see from Fig. 3  
 355 (introduced in the next paragraph), none of the known distributions fit the empirical data well.  
 356 Alternatively, we can discretize the components of  $\mathbf{F}_t$  by binning them. In other words, we represent  
 357 the distribution of each component with a histogram, with a specific choice of the number of bins (50  
 358 for example). This will effectively convert the continuous values of each component of  $\mathbf{F}_t$  into discrete  
 359 values, such as integer labels from 1 to 50 if we use 50 bins. Let us write the discretized  $\mathbf{F}_t$  as  $\bar{\mathbf{F}}_t =$   
 360  $[\bar{C}_{NS,t}, \bar{V}_{NS,t}, \bar{S}_{NS,t}, \bar{K}_{NS,t}, \bar{C}_{EW,t}, \bar{V}_{EW,t}, \bar{S}_{EW,t}, \bar{K}_{EW,t}]$ .

361

362 If we do this for the TSs of individual components, such as the TS of  $\bar{C}_{NS,t}$ , and use them as inputs for  
 363 the BWA, we will obtain one HS TSs for each of the 8 components. In Fig. 3, we show (A) the estimated  
 364 emission matrix  $\bar{\mathbf{B}}$  in Figs 3(a), (c), (e), (g), and (B) the posterior probability TSs in Figs 3(b), (d), (f),  
 365 (h) for 4 components:  $\bar{C}_{NS,t}, \bar{V}_{NS,t}, \bar{S}_{NS,t}, \bar{K}_{NS,t}$  of KAOH station. These posterior probability TSs are  
 366 different, which is not what we desire. Therefore, instead of this, we would like to use all 8 components  
 367 in  $\bar{\mathbf{F}}_t$  as a single input to the BWA, to obtain a single HS TS for each station.  
 368

369

370 **Figure 3: The output of BWA: the emission probability, or the probability mass functions, as well as their**  
 371 **posterior HS probability TSs, for  $\bar{C}_{NS,t}$  (a, b),  $\bar{V}_{NS,t}$  (c, d),  $\bar{S}_{NS,t}$  (e, f), and  $\bar{K}_{NS,t}$  (g, h), respectively, using**  
 372 **station KAOH's geoelectric TS data, with 50 bins.**

373

374 The BWA has no problem dealing with high-dimensional problems, provided the inputs are discrete.  
 375 However, this method would work well only if the overall number of possible observations is small. If  
 376 we use 50 bins for each of the eight indexes, there would be  $D = 50^8 \approx 3.91 \times 10^{13}$  possible  
 377 observations, meaning the emission matrix would be of dimension  $3.91 \times 10^{13}$ -by-2. Reducing the  
 378 number of bins to just 10 for each index, we still have  $D = 10^8$  possible observations. This latter space  
 379 is still too large for the BWA to search through exhaustively in a reasonable amount of time, even though  
 380 we feel 10 bins for each index may already be too coarse and likely to miss subtle details. Furthermore,

381 with so many possible observations, we expect the emission probabilities to be significantly different  
 382 from 0 only for a very small subset of the  $D$  possible observations.

383

384 We do not know *a priori* what the elements of this very small subset are. They may occur as isolated  
 385 points in the search space, or they may occur in groups of closely spaced points. In the continuous feature  
 386 space, each of these groups of observations represents a cluster of similar feature vectors. To determine  
 387 the number of such clusters, and where they occur in the 8-dimensional continuous feature space, we  
 388 mapped similar feature vectors to the same label using the k-means clustering algorithm (Gupta et al.,  
 389 2010; Wen et al., 2006; Dash et al., 2011), which is commonly used for discretizing continuous vectors  
 390 such as  $\mathbf{F}_t$ . We chose to use the k-means clustering for discretizing  $\mathbf{F}_t$  because of its low computational  
 391 cost as well as its reliability in grouping similar feature vectors in the feature space. In so doing, we  
 392 created a discrete feature space with reasonable size, as high-level labels of different geoelectric  
 393 dynamics. The mathematical details of k-means clustering can be found in Supporting Information Sect.  
 394 C.

395

396 The indexes  $C_{NS,t}$ ,  $V_{NS,t}$ ,  $S_{NS,t}$ ,  $K_{NS,t}$  have highly disparate dynamic ranges, and should not be directly  
 397 combined into a feature vector. Therefore, before the clustering, we first standardized our indexes by  
 398 dividing them by their respective standard deviations. The purpose of this step is to ensure the weights  
 399 associated with each index during the k-means clustering are equal, so as not to bias our search for  
 400 features with high dynamic range. Mathematically, the feature vector of standardized indexes at time  
 401  $t$ ,  $\mathbf{F}'_t$  can be written as:

$$402 \quad \mathbf{F}'_t = \left[ \frac{C_{NS,t}}{\sigma(C_{NS,t})}, \frac{V_{NS,t}}{\sigma(V_{NS,t})}, \frac{S_{NS,t}}{\sigma(S_{NS,t})}, \frac{K_{NS,t}}{\sigma(K_{NS,t})}, \frac{C_{EW,t}}{\sigma(C_{EW,t})}, \frac{V_{EW,t}}{\sigma(V_{EW,t})}, \frac{S_{EW,t}}{\sigma(S_{EW,t})}, \frac{K_{EW,t}}{\sigma(K_{EW,t})} \right]. \quad (5)$$

403

404 We then implemented k-means clustering using the *Scikit-learn* package (v0.23.1) in *Python* (v3.6.5), on  
 405 the sequence of feature vectors  $\mathbf{F}'_t$  covering the time period from January 2012 to December 2018. The  
 406 choice of the *number of clusters*  $Q$  was determined as part of the hyperparameter optimization,  
 407 described in Sect. 3.5. In this way, we matched each  $\mathbf{F}'_t$  to a discrete label  $o_t \rightarrow O_q$  (where  $q$  is an  
 408 integer from 1 to  $Q$ ), to obtain the TS of discrete observations  $\{o_1, o_2, \dots, o_t, \dots, o_T\}$  for each station  
 409 as its input to the BWA.

410

## 411 2.5 Implementation of BWA

412

413 In this section, we describe how we implemented the BWA to obtain one HS TS for each station. We start  
 414 by describing how we initialized and iterated the BWA, as well as how we dealt with local optima in the  
 415 BWA results by using multiple initializations.

416

417 The first step of the BWA is to initialize the HMM model parameters  $(\mathbf{A}, \mathbf{B}, \boldsymbol{\pi})$ . Since we had no prior  
 418 knowledge on the model parameters, we initialized parameters  $(\mathbf{A}_0, \mathbf{B}_0, \boldsymbol{\pi}_0)$  randomly. After this, we  
 419 iterated BWA's expectation maximization steps 30 times, starting with iteration index  $i = 1$ . Each  
 420 iteration comprises of the forward procedure, the backward procedure, and the update. In Supporting  
 421 Information Sect. D, we present the mathematical details of how the forward procedure, the backward  
 422 procedure, and the update are done.

423

424 As the iteration goes, the BWA improves the likelihood of observing the input observation TS  
 425  $o_1, o_2, \dots, o_T$  given the model parameters  $(\mathbf{A}_i, \mathbf{B}_i, \boldsymbol{\pi}_i)$ , which converges when the improvements on the  
 426 posterior probability  $P(o_1, o_2, \dots, o_T | (\mathbf{A}_i, \mathbf{B}_i, \boldsymbol{\pi}_i))$  become minimal. In practice, we found that 30  
 427 iterations were long enough for most models to converge. We therefore obtained the estimated model  
 428 parameters  $(\tilde{\mathbf{A}}, \tilde{\mathbf{B}}, \tilde{\boldsymbol{\pi}}) = (\mathbf{A}_{30}, \mathbf{B}_{30}, \boldsymbol{\pi}_{30})$ , as well as the posterior probability TS of  $P(s_t =$   
 429  $S_t | o_1, o_2, \dots, o_T, \tilde{\mathbf{A}}, \tilde{\mathbf{B}}, \tilde{\boldsymbol{\pi}})$  for both HSs and all  $t$ , which we write in short form as:  $\mathbf{P}_1 =$   
 430  $(P(s_1 = S_1), P(s_2 = S_1), \dots, P(s_T = S_1))$  and  $\mathbf{P}_2 = (P(s_1 = S_2), P(s_2 = S_2), \dots, P(s_T = S_2))$ . Here,  
 431 we noted that BWA assigns the indexing of HSs randomly; therefore, the  $S_1$  of one station is not  
 432 guaranteed to be equivalent to the  $S_1$  of another station.

433

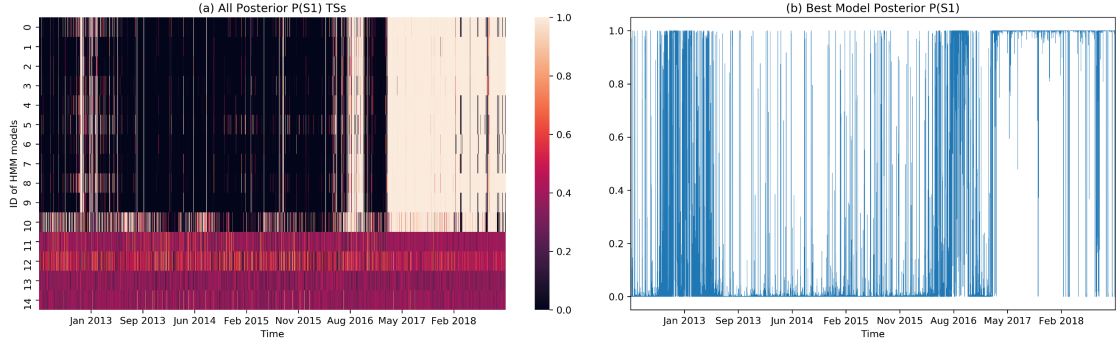

434 We cannot simply do the above BWA estimation once to get  $(\tilde{\mathbf{A}}, \tilde{\mathbf{B}}, \tilde{\boldsymbol{\pi}})$ , because the BWA converges to  
 435 local optima instead of the global optimum in the model parameter space (Bilmes, 1998; Yang et al.,  
 436 2017; Larue et al., 2011). Also, the initial parameters have a significant influence on the local optimum  
 437 where the BWA converges. In order to obtain a global optimum result within a reasonable computation  
 438 time, we ran 15 BWA estimations in parallel for each station, with different random initial parameters.  
 439 For each station, we then chose the model with the highest model score given by  
 440  $P(o_1, o_2, \dots, o_T | (\tilde{\mathbf{A}}, \tilde{\mathbf{B}}, \tilde{\boldsymbol{\pi}}))$  for subsequent analysis. Later in Fig. 4(a), we also show all 15 HMMs to  
 441 demonstrate how consistent the converged models are. We can write the posterior probability TS of this  
 442 model as  $\tilde{\mathbf{P}}_1 = (P(s_1 = S_1), P(s_2 = S_1), \dots, P(s_T = S_1) | o_1, o_2, \dots, o_T, (\tilde{\mathbf{A}}, \tilde{\mathbf{B}}, \tilde{\boldsymbol{\pi}}))$ .

443

444 For each initial condition, the BWA randomly assigns one HS to be  $S_1$ , and the other to be  $S_2$ . To show  
 445 all 15 HMMs simultaneously in Fig. 4(a), we need to standardize  $S_1$  and  $S_2$  across all HMMs. For this  
 446 purpose, we set  $\tilde{\mathbf{P}}_1$  as the “standard”. For the remaining 14 posterior probabilities  $\{\mathbf{P}_1^i\}_{i=2, \dots, 15}$ , we  
 447 checked their Expected Absolute Difference  $EAD = \text{mean}(|\tilde{\mathbf{P}}_1 - \mathbf{P}_1^i|)$  from  $\tilde{\mathbf{P}}_1$ , whose value ranges  
 448 from 0 and 1. If  $EAD > 0.5$ ,  $\mathbf{P}_1^i$  is more similar to  $\tilde{\mathbf{P}}_2$  than to  $\tilde{\mathbf{P}}_1$ , and we proceed to swap the HS  
 449 indexing for the  $i^{\text{th}}$  HMM by assigning  $\mathbf{P}_1^i(\text{new}) \equiv \mathbf{P}_2^i$  and  $\mathbf{P}_2^i(\text{new}) \equiv \mathbf{P}_1^i$ . Otherwise,  $\mathbf{P}_1^i$   
 450 corresponds to the same HS as  $\tilde{\mathbf{P}}_1$ , and we leave its HS indexing unchanged. In this way, we standardized  
 451 all 15 models so that their  $\mathbf{P}_1$  can be visualized together in Fig. 4(a), with the  $\tilde{\mathbf{P}}_1$  TSs sorted by their  
 452 model scores  $P(o_1, o_2, \dots, o_T | (\tilde{\mathbf{A}}, \tilde{\mathbf{B}}, \tilde{\boldsymbol{\pi}}))$ , and the optimal model at the first row. In Fig. 4(b), we show  
 453 the actual posterior probability TS of this optimal model. The figures of 15 HMMs for all 20 stations are  
 454 included in the Supporting Information Sect. E.

455

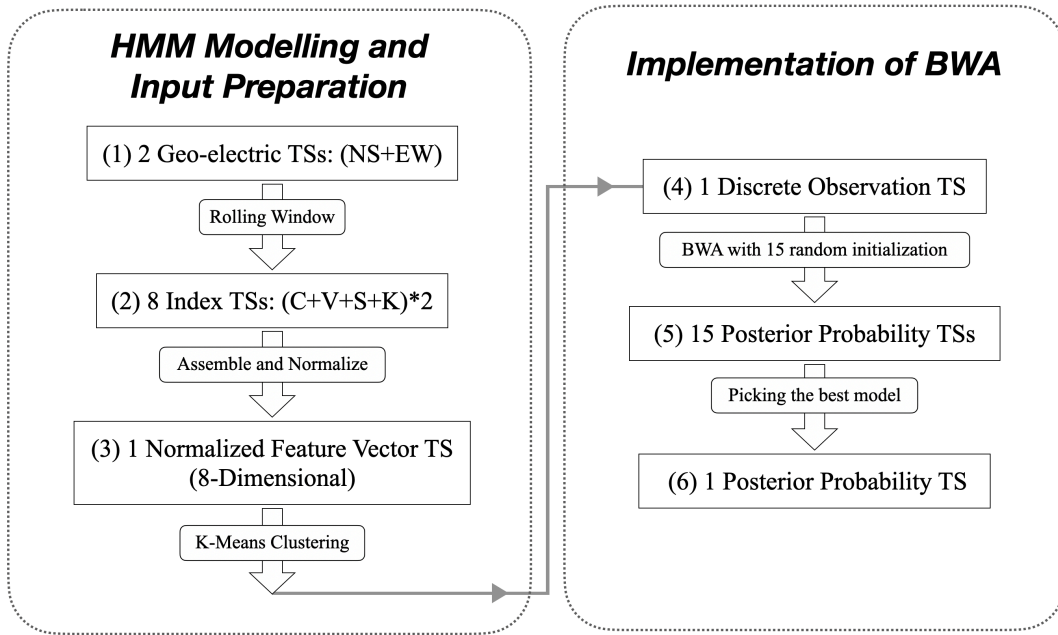

456

457 **Figure 4: The step-by-step data visualization for station CHCH, showing (a) a heatmap of the 15 HMM models’**  
 458 **posterior probability TSs for  $S_1$ , sorted by model score from highest to lowest. The posterior probabilities for**  
 459 **the last 4 HMMs are messy, because the BWA estimations do not converge; (b) the optimal model’s posterior**  
 460 **HS probability TS for  $S_1$ ,  $\tilde{P}_1$  (obtained using optimal hyperparameters:  $[L_w, Q] = [0.02 \text{ (day)}, 30]$ ).**

461

462 We summarize the procedures used to obtain  $\tilde{P}_1$ , starting from a pair of geoelectric TSs for each GEMS  
 463 station in the form of a flow chart in Fig. 5. It is noteworthy that the full procedure contains essentially  
 464 only 2 hyperparameters:  $Q$  and  $L_w$ . The figures shown in the results section will use the optimal  
 465 hyperparameters, whose identification procedure will be discussed in detail later in Sect. 3.5.  
 466 Additionally, for each station’s optimal HMM, we plotted the distribution of indexes  $(C, V, S, K)$  at both  
 467 HSs in Supporting Information Sect. F.

468

469

470 **Figure 5: Flow chart summarizing the procedures of obtaining the optimal posterior probability TS  $\tilde{P}_1$  from**  
 471 **the data of one GEMS station.**

472

473

## 474 2.6 EQ Grid Map, EQ Frequency, and EQ Frequency Ratio

475

476 Up to this point, we did not incorporate any EQ catalog information into  $\tilde{P}_1$  for each station. Unlike

477 many past EQ studies looking for specific precursory features within the geoelectric data, we made no  
478 specific assumptions regarding what these EQ precursors might look like. Instead, we let the BWA search  
479 for specific precursory features within the 8-dimensional feature space.

480

481 After the HMM modeling, we then checked locally whether  $S_1$  and  $S_2$  would effectively partition time  
482 periods with significantly lower EQ probabilities from those with significantly higher EQ probabilities.  
483 We think of one HS as a *passive* state (with significantly lower EQ probabilities) and the other HS as an  
484 *active* state (with significantly higher EQ probabilities), but we cannot call the former  $S_1$  and the latter  
485  $S_2$  because we have not yet standardized these HS labels across the 20 stations. To do so, we need to  
486 match the HS TS of each station to the EQ catalog to determine the EQ frequencies of  $S_1$  and  $S_2$  for  
487 this station, and use  $S_1$  and  $S_2$  as the HS labels of the active and passive states respectively (relabeling  
488 when necessary). In the remainder of this section, we describe in detail how this is done.

489

490 For each GEMS station we started from  $\tilde{\mathbf{P}}_1$ , and classified time periods across the 7 years as belonging  
491 to two sets  $T_1$  and  $T_2$ . The time point  $t_i$  was assigned to  $T_1$  if  $\tilde{P}_{t_i}(S_1) > 0.5$  and  $T_2$  if  $\tilde{P}_{t_i}(S_2) >$   
492  $0.5$ . After this is done, we checked how EQs are distributed between  $T_1$  and  $T_2$  for different regions  
493 across Taiwan. For this task, we first made a 16-by-16 grid map of Taiwan, so that EQs within the same  
494 grid cell  $(ix, iy)$ , for  $ix$  and  $iy$  in  $[0, 1, \dots, 15]$ , are grouped together (see Fig. 6).

495

496

497 **Figure 6: A sample EQ Grid Map with 16-by-16 divisions, in which each cell measures  $0.3330^\circ$ (longitude)-**  
 498 **by- $0.3418^\circ$ (latitude). All EQs of  $M_L \geq 3$  are labeled with blue circles, with the radius of each circle being**  
 499 **proportional to the natural exponential of EQ's magnitude.**

500

501 For each grid cell  $(ix, iy)$ , we defined the *EQ Frequencies* for HSs  $S_1$  and  $S_2$  as:

$$502 \quad F_{EQ,1} = \frac{N_1}{|T_1|}, F_{EQ,2} = \frac{N_2}{|T_2|}, \quad (6)$$

503 where  $N_1$  is the number of EQs occurring within  $T_1$ ,  $N_2$  is the number of EQs occurring within  $T_2$ ,  
 504  $|T_1|$  is the total duration of  $T_1$  time periods, and  $|T_2|$  is the total duration of  $T_2$  time periods. From  
 505 Fig. 6, we see that the spatial distribution of EQs is highly heterogeneous, so we may find a grid cell with  
 506 about 10 EQs but also another grid cell with about 1000 EQs. This tells us that we should not directly  
 507 compare the EQ frequencies, but should instead compare the *EQ Frequency's Ratio*, defined as:

$$508 \quad R_F = \frac{F_{EQ,1}}{F_{EQ,1} + F_{EQ,2}}. \quad (7)$$

509 For any cell containing at least one EQ, the range of its  $R_F$  is  $[0,1]$ . Intuitively, any cell with  $R_F < 0.5$   
 510 is a region having lower EQ frequency in  $S_1$  compared to  $S_2$ ; and any cell with  $R_F > 0.5$  is a region  
 511 having a higher EQ frequency in  $S_1$  compared to  $S_2$ . For example, for a cell with  $R_F = 0.2$ ,  $F_{EQ,1}$  is

512 only  $1/4$  of  $F_{EQ,2}$ . The  $R_F$  value quantifies how one HS has a higher or lower EQ frequency than the  
 513 other. In Sect. 3, we will present how we deep dived into the spatial-temporal correlations between HS  
 514 TSs ( $\tilde{P}_1$ ) and EQ activities for all 20 stations, starting from 20 grid maps of  $R_F$  values.

515

516

### 517 3 Results and Discussions

518

519 In this section, we present the results obtained for all 20 stations, as well as additional treatments that we  
 520 felt are necessary to investigate whether the HS TSs have significant forecasting power for EQs.

521

#### 522 3.1 EQ Frequency's Ratio ( $R_F$ ) Grid Maps

523

524 Once we obtained the  $\tilde{P}_1$  TS for each station, the natural first step of our analysis was to examine the  
 525  $R_F$  values for all cells in the 16-by-16 grid map. We show this procedure for CHCH station in Fig. 7,  
 526 where we visualize the grid maps for  $N_1$  and  $N_2$  in Figs 7(a) and (b) respectively, to clearly show how  
 527 many EQs occurred during  $T_1$  and  $T_2$ . The resulting  $R_F$  grid map is shown in Fig. 7(c), where there  
 528 are cells with values close to 0.5 (white-color cells) and cells with values far from 0.5 (red for close  
 529 to 0; green for close to 1). White-color cells are regions whose EQ activities are weakly correlated with  
 530 the HSs, since the time periods of  $S_1$  and  $S_2$  are not very different in terms of EQ frequency; whereas  
 531 red/green cells are regions with significantly lower/higher EQ frequencies in  $S_1$ .

532

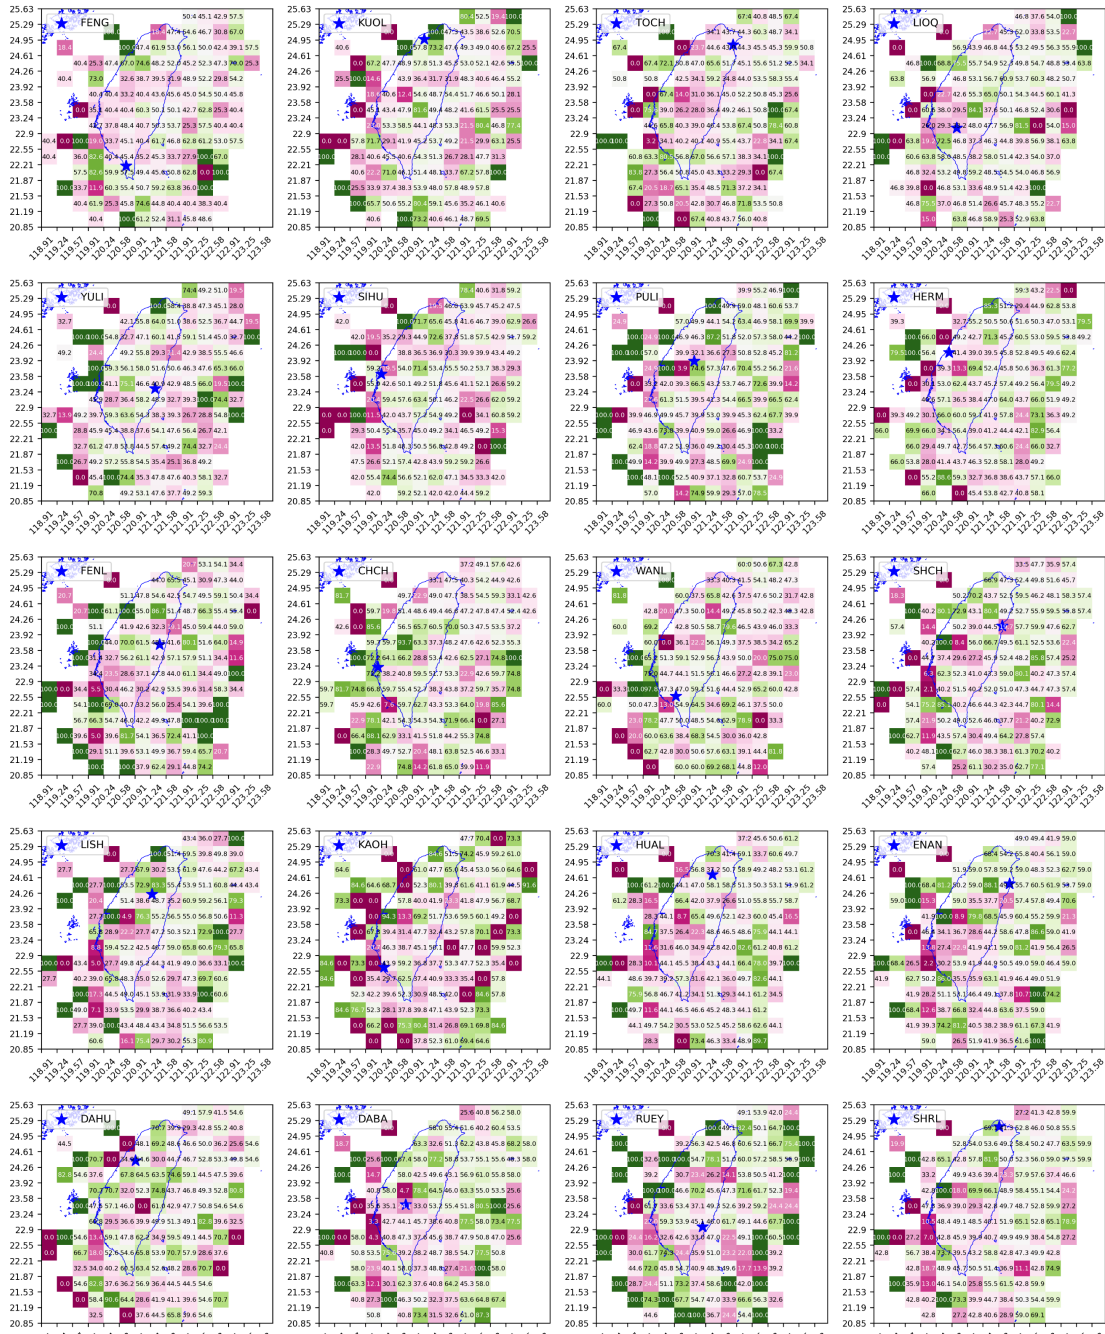

533

534 **Figure 7: The step-by-step data visualization for station CHCH, showing (a) the grid map showing the number**  
 535 **of  $M_L \geq 3$  EQs during  $S_1$ 's time periods,  $N_1$ ; (b) the grid map showing the number of  $M_L \geq 3$  EQs during**  
 536  **$S_2$ 's time periods,  $N_2$ ; and (c) the grid map showing the EQ Frequency Ratio,  $R_F (\times 0.01)$ . Results were**  
 537 **obtained using optimal hyperparameters:  $[L_w, Q] = [0.02 (\text{day}), 30]$ .**

538

539 As can be seen in Fig. 7(c), for different regions the HS with higher EQ activities can be either  $S_1$  or  
 540  $S_2$ . This is true not only for CHCH station, but also for all 20 stations, whose  $R_F$  grid maps are shown  
 541 in Fig. 8. Although there is no consistent pattern of any state corresponding to higher EQ activities  
 542 globally, we see in Fig. 8 that there are regions whose  $R_F$  values are far from 0.5 across many stations.  
 543 This means that statistically speaking, one of the HSs has higher EQ activities than the other. In fact, if  
 544 the active HS has a lot more EQs than the passive HS, it is also likely that the active HS cover most of  
 545 the larger EQs (e.g.,  $M > 5$ ), which is a good attribute for potential EQ forecasting applications. This  
 546 phenomenon is shown in Supporting Information Sect. G, where we visualized the EQ frequency  
 547 distributions across different magnitudes for both HSs, for three selected cells with most EQ events.

549

550 **Figure 8: The grid maps of EQ Frequency's Ratio  $R_F (\times 0.01)$  for 20 stations (obtained using optimal**  
 551 **hyperparameters individually specified for each station in Fig. 12).**

552

553 All in all, the findings in this section is important, but we cannot directly decide  $S_1$  or  $S_2$  to be the  
 554 proxy for increased EQ probabilities, because they cannot be associated consistently with the active or  
 555 the passive state. Instead, we should understand  $S_1$  and  $S_2$  as two high-level, fuzzy labels for tectonic  
 556 dynamics related to EQ activities in different regions. There can be elements such as rock and soil  
 557 formations, the underground water system, and fault lines, forming a complex dynamical system that  
 558 influences where and when EQs become active. A concrete mapping between EQ activities and specific  
 559 elements of the complex dynamical system would be very difficult, as this will involve high-resolution

560 subterrain surveys. Nevertheless, we can still measure how well  $S_1$  and  $S_2$  can partition the time  
561 periods so that one HS can have significantly more EQs than the other. To show this more clearly, we  
562 created grid maps of *discrimination power*  $D$  and present them in the next section.

563

### 564 **3.2 Discrimination Power ( $D$ ) Grid Maps**

565

566 We defined the discrimination power  $D$  for each cell as:

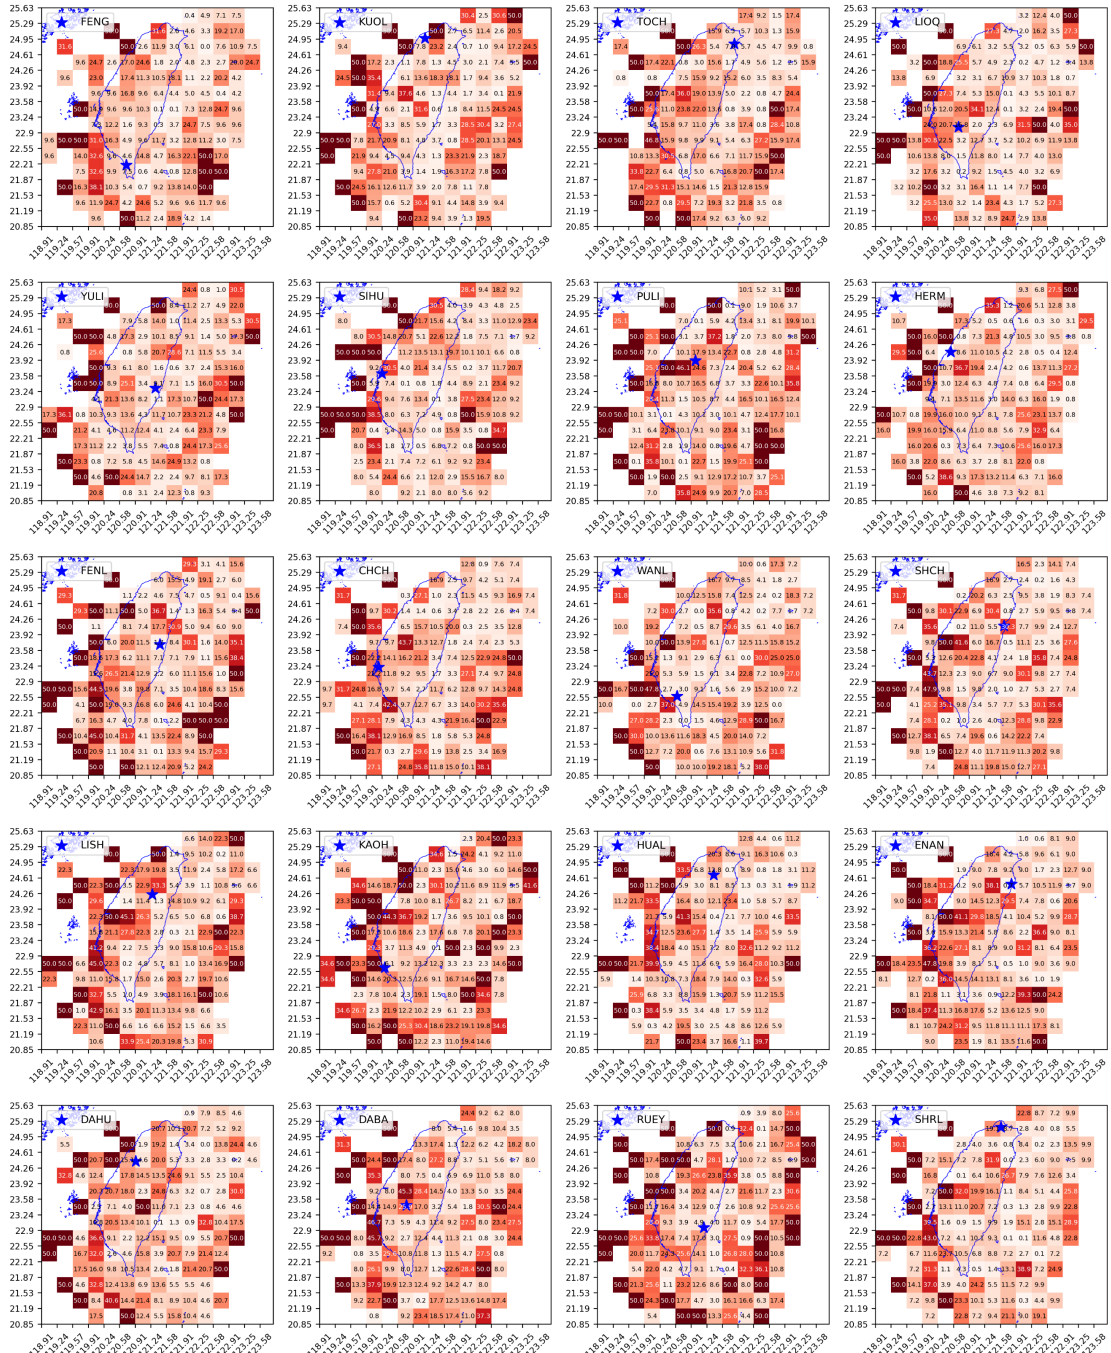

$$567 \quad D = |R_F - 0.5|. \quad (8)$$

568 The value of  $D$  ranges from 0 to 0.5, with 0.5 being the most discriminative since all EQs are found  
569 in one HS, and 0 being the least discriminative since EQ frequencies are identical between the two HSs.

570 We show the grid maps of  $D$  for 20 stations in Fig. 9, which are easier to interpret compared to the grid  
571 maps in Fig. 8 where we had to use two different colors. Intuitively, for a region with  $D = 0.25$  (not  
572 uncommon), one of its HSs would have an EQ frequency three times that of the other HS. It can be noted  
573 that cells around the edge of the map tend to have very high  $D$  values, because there are very few EQ  
574 events in these cells. This is not a problem, as we will take the number of EQs into account later in Sect.  
575 3.3.

576

577

578 **Figure 9: The grid map of discrimination power  $D (\times 0.01)$  for 20 stations (obtained using optimal**  
 579 **hyperparameters individually specified for each station in Fig. 12).**

580

581 In some cells, we find  $D$  values close to 0.5, which seems to suggest that the seismicity associated with  
 582  $S_1$  is very different from that associated with  $S_2$ . However, looking at Fig. 9, we see large variations in  
 583  $D$  values across the cells, and more importantly among some neighboring cells. We therefore wonder  
 584 whether regions with high  $D$  values are statistically significant, or the products of random temporal  
 585 clustering of EQs (Dieterich, 1994; Frohlich, 1987; Holbrook et al., 2006; Batac and Kantz, 2014). For  
 586 example, if all EQs in a cell occurred within a single day in the 7-year period, any random assignment  
 587 of HSs would produce the highest  $D$  value of 0.5. To address this concern, we investigated the  
 588 significance of the grid maps of  $D$  through statistical tests in the next section.

589

590 **3.3 Cellular-level Significance Tests of the Forecasting Power**

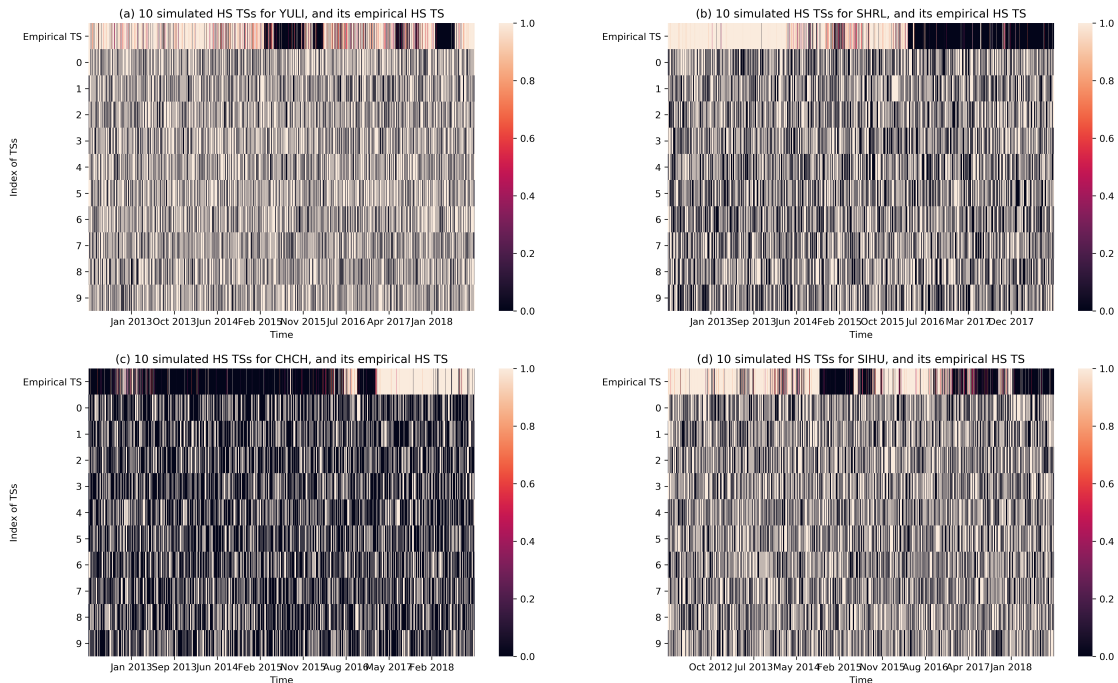

591

592 Since we had the optimal HMMs for the 20 stations, we can test cellular statistical significance levels  
 593 that their HSs can indeed separate time periods of higher/lower EQ probabilities, using  $D$  grid maps  
 594 shown in Fig. 9. Specifically, for each grid cell and an empirical HS TS we carried out a statistical  
 595 hypothesis testing using the following null hypothesis: any random HS TS would achieve the same or  
 596 higher performance (in terms of  $D$  value). To create random HS TSs for the hypothesis testing, we chose  
 597 to directly simulate the HMM using the same model parameters  $(\tilde{A}, \tilde{B}, \tilde{\pi})$  as the empirical HMM of the  
 598 corresponding station. For each hypothesis testing of an empirical HS TS (actual HS TS obtained for  
 599 each station), we created 400 simulated HS TSs, which were then used to create 400 grid maps of the  
 600 Discrimination Power  $D$ . In Fig. 10, we show the empirical HS TSs alongside a random sample of 10  
 601 simulated HS TSs for YULI, SHRL, CHCH, and SIHU to illustrate the simulated counterparts. After this,  
 602 in each cell, we had one empirical value of  $D$  that we can compare against a distribution of 400  
 603 simulated values of  $D$ . This allows us to compute for each cell the probability that its empirical  $D$   
 604 is higher than its simulated counterparts. We named this quantity the *Discrimination Reliability*  $R_D$ ,  
 605 defined for each cell in the grid map as:

606 
$$R_D = \frac{\#(\text{simulated } D < \text{empirical } D)}{400}. \quad (9)$$

607 In the language of statistical hypothesis testing, the p-value for the test is given by  $p = 1 - R_D$ . The  
 608 value of  $R_D$  ranges from 0 to 1. If  $R_D$  is close to 1, we are confident that the discrimination power  
 609 of the empirical HS TS is statistically significantly high; otherwise, we have no such confidence.

610

611

612 **Figure 10: The empirical HS TS and 10 simulated HS TSs, for stations (a) YULI, (b) SHRL, (c) CHCH, and**  
 613 **(d) SIHU. The simulated HS TSs have HS transition frequencies and HS total durations similar to the**  
 614 **empirical HS TS, but have none of the temporal correlations in the empirical HS TS. Results are obtained**  
 615 **using optimal hyperparameters individually specified for each station in Fig. 12.**

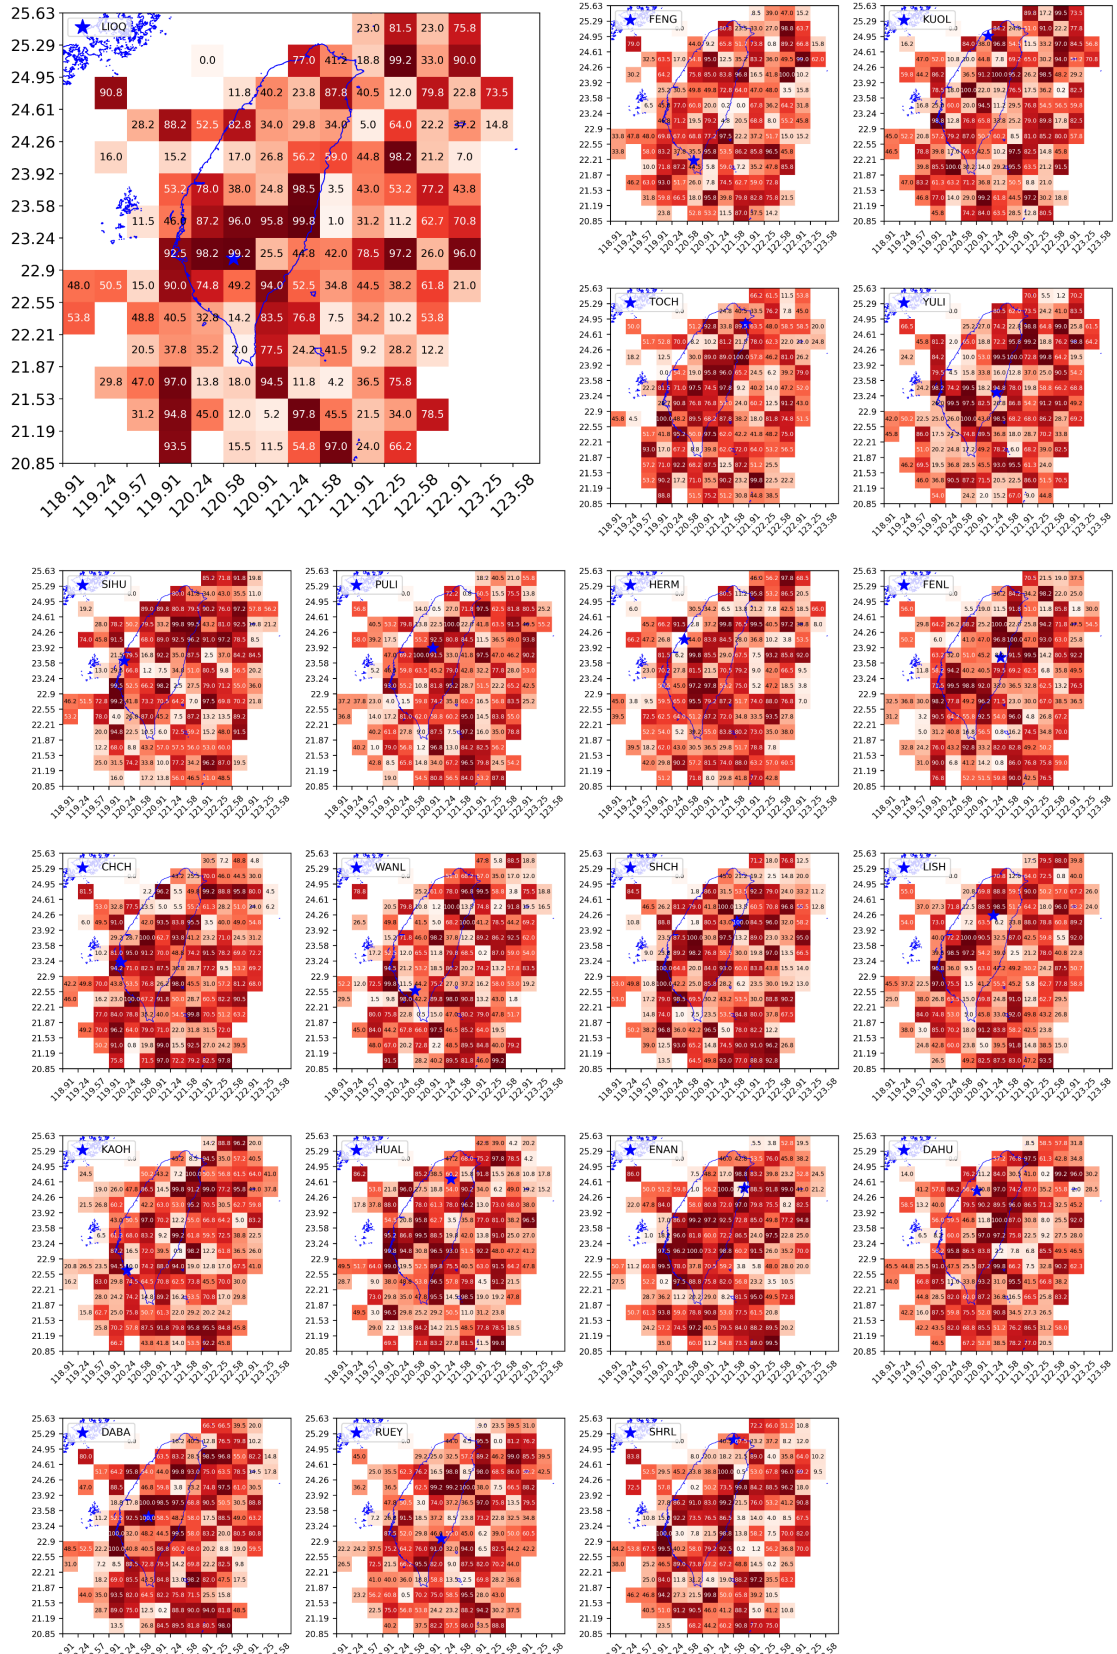

616

617 In Fig. 11, we show the grid maps of  $R_D$  values (in percentage) for all 20 stations. Dark-red cells are  
618 regions with  $R_D$  close to 1, and white-pink cells are regions with  $R_D$  close to 0. From these grid maps,  
619 we can better appreciate the utility of HS TSs across the grid map, since the  $R_D$  value is a statistical  
620 significance measure of the HS-EQ correlation, unlike the discrimination power  $D$ . To explain this, let  
621 us take the example of station LIOQ (upper left of Fig. 11), whose physical location is marked by the  
622 blue star, within a dark-red grid cell of  $R_D = 0.992$ . This means that the empirical HS TS performs  
623 better than random guesses (i.e., simulated HS TSs) at separating time periods of low/high EQ  
624 frequencies, with a statistical significance of  $p = 0.008$ . This means that it is improbable for a simulated  
625 HS TS to have such a high  $D$ , and therefore the empirical HS TS is unlikely to be a product of random  
626 chance. This is a very strong demonstration of the mutual information between the HS TS obtained from  
627 geoelectric TS, and the EQ catalog that was not used to train the HMM.

628

629 In the proximity of station LIOQ located within  $22.55\text{--}23.58^\circ N$ , we can see a clear pattern of cells  
630 with  $R_D \geq 0.9$  (dark-red color), while  $R_D \geq 0.9$  occasionally for most cells outside this general region.  
631 This pattern suggests the geoelectric information from station LIOQ is approximately local. This is  
632 consistent with the logical requirement for direct/indirect structural relation between station LIOQ and  
633 region X, such as being close to the same subterranean fault line, for the information at station LIOQ to be  
634 useful for region X. As a corollary, information given by station LIOQ is less likely to be useful for far  
635 away regions, as they are less likely to have such structural relations with station LIOQ. In application  
636 scenarios, this means that the state of EQ probabilities of region X can be estimated using stations closer  
637 to the region. Last but not least, it is also worth mentioning that most cells at the edge of the map seldom  
638 have high  $R_D$  values. This is consistent with the fact that these cells typically have very few EQ events  
639 to provide high statistical significance.

640

641

642 **Figure 11: The grid map of Discrimination Reliability  $R_D$  ( $\times 0.01$ ) for 20 stations (obtained using gridmap**  
 643 **hyperparameters individually specified for each station in Fig. 12).**

644

645 Based on our discoveries on the HS-EQ correlations so far, we claim that the HS TSs can provide usable  
646 EQ forecasts for real-world applications. We understand that for all EQ forecasting, whether short-,  
647 medium-, or long-term, we must specify **(A)** a time window, **(B)** a space window, and **(C)** the magnitudes  
648 of EQs expected. We shall next explain how the HS TSs can be useful for EQ forecasting from these  
649 three aspects. **(A)** Let us consider an HMM that started out in the passive state, where EQs of all  
650 magnitudes are less frequent, compared with the active state. In most stations that we tested, we noticed  
651 that once an active state has persisted for a few weeks, it is unlikely to switch back to the passive state  
652 until a few months have elapsed. This minimum lifetime found in historical data can be used as a  
653 prediction time window. Based on this time scale, we can say that our HMM model can be useful for  
654 short-to-medium-term EQ forecasting, depending on the station of interest. **(B)** Next, let us consider the  
655 grid cells covering Taiwan. For a given grid cell, it may be satisfactory ( $R_D$  being high-enough) for a list  
656 of stations. The more stations in this list becoming persistently active, the more likely large EQs within  
657 this grid cell should occur. This is the spatial window we work with for making ‘predictions’. **(C)** Finally,  
658 let us describe how our HMM model can help assessing the magnitudes of EQs expected. To answer this  
659 question, we can examine the distribution of EQ frequencies across magnitudes 3.0 to 6.0 for both active  
660 states and passive states (in Supporting Information Sect. G,). It turns out that for a given grid cell with  
661 high  $R_D$ , the active state has proportionally more EQs than the passive state across all magnitudes.  
662 Therefore, we expect EQs of all magnitudes to be more frequent in a positive ‘prediction’.

663

664 For grid cells with high  $R_D$ , the corresponding HS TS alone is sufficient to make intermediate-term EQ  
665 forecasts. However, we also have grid cells where none of the 20 stations provide sufficiently high  $R_D$   
666 value for intermediate-term EQ forecasting on their own. These HS TSs could still be useful if we  
667 combine all 20 HS TSs as input features, for higher-level forecasting algorithms trained individually for  
668 each grid cell. For example, for any region (grid cell), if we want to decide whether it currently belongs  
669 to the active regime or the passive regime, an algorithm use the input from all 20 stations to decide the  
670 “local” HS for the given grid cell. This high-level algorithm can for example be weight-based model  
671 averaging (Marzocchi et al., 2012) or decision trees (Asim et al., 2016). Additionally, the value of  $R_D$   
672 can be helpful for the algorithm to decide how to weigh the information given by all 20 stations. For  
673 example, we can consider only stations with  $R_D \geq R_{D,min}$  at the given grid cell. The user-defined  
674 threshold  $R_{D,min}$  can take on constant values (e.g., 0.9) across the grid map, or be location specific,  
675 such as being lower (e.g., 0.8) for grid cells where few of the 20 stations have  $R_D \geq 0.9$ . We hope to  
676 explore this in future works.

677

678 Due to the nature of our HSs, we cannot use them to forecast specific EQs or issue evacuation alarms.  
679 What the HSs can do, however, is to provide information with forecasting skill to decision makers, in  
680 regions where the HS switched from the passive state to the active state convincingly (i.e., the observed  
681 active state is persistent and not a temporary fluctuation), to take courses of action that can lower the  
682 potential damage with minimal costs. For example, in the passive state, the building inspection authority  
683 can prioritize the inspection and issuing safety permits to new projects over re-inspections of old  
684 buildings. With the arrival of an active state that might last a few months to a few years, local authorities  
685 would have the incentive to clear up pending re-inspection works, so that fewer old buildings are exposed  
686 to potential EQ damage. Other than the re-inspection of old buildings, local authorities could also  
687 increase the frequency of safety education and drills to vulnerable groups such as students and  
688 construction workers, to reduce potential injuries or fatalities due to panic or lack of understanding.

689 Additionally, disaster relief services may use the HS’s information to re-deploy the stockpile of relief  
690 materials such as food, clothing, tents, and first-aid kits, whenever necessary. In doing so, the stockpile  
691 of relief materials can be brought closer to high-risk regions within a convincing active state, to be  
692 distributed to victims more cost-effectively after a major EQ.

693

### 694 3.4 Global-level Significance Tests of the Forecasting Power

695

696 From Fig. 11 alone, we have demonstrated the HS TSs are able to separate time periods of low/high EQ  
697 probabilities for regions (cells in the grid map) with high  $R_D$  values. While the forecasting power of HS  
698 TSs in each of these cells is statistically significant, the more critical among us may wonder whether  
699 some of these cells can be significant purely by chance, even though there is in reality no persistent  
700 correlation between EQs and HSs. For example, any simulated HS TS in Fig. 10 would have at least a  
701 few cells with high  $R_D$  values. Therefore, in this next section, we will answer the question of “whether  
702 these HS TSs indeed contain useful information about EQs, or the number of ‘significant’ cells can be  
703 explained by a random null model where the EQs and HSs are mutually uninformative, because we test  
704 a large number of cells assuming that they are statistically independent.”

705

706 In order to answer this question, we need to define a performance metric that can quantify the  
707 performance of each station with a single value, instead of a grid map of  $R_D$  values. We start by  
708 assuming that all stations have zero forecasting skill, but as a result of our statistical test, some cells may  
709 still end up with high  $R_D$  by chance. A truly informative station should have significantly more cells  
710 with high  $R_D$  than random guesses. Taking the number of EQs into the consideration, we further propose  
711 that a truly informative station should have significantly higher EQs counts located in high-performing  
712 cells. On the grid map, let us define cells with  $R_D \geq R_{D,min}$  as *satisfactory* cells, and the rest as  
713 *unsatisfactory* cells, where  $R_{D,min}$  is the user-defined threshold that determine how high the  $R_D$   
714 should be in order to be considered “high-performing”. As mentioned earlier, it is possible to work out  
715 schemes that allow for regionally acceptable  $R_{D,min}$ . Here for simplicity let us consider a scheme with  
716 a uniform  $R_{D,min}$  across all cells in the grid map. With this setting we can proceed to define the single-  
717 value performance metric for each station, as the *ratio of EQs in satisfactory cells*, or  $R_{EQS}$  as:

$$718 \quad R_{EQS} = \frac{\sum_{\text{satisfactory cells}} N_{EQ}}{\sum_{\text{all cells}} N_{EQ}}, \quad (10)$$

719 where  $N_{EQ}$  is the number of EQs in each cell. This *ratio of EQs in satisfactory cells* takes on values  
720  $0 \leq R_{EQS} \leq 1$ . Intuitively, if  $R_{EQS} = 0.4$ , it means that given the  $R_{D,min}$  value, 40% of all EQs are  
721 located within satisfactory cells, and are therefore “forecasted” by the station to the level required by the  
722 user (i.e.,  $R_{D,min}$ ). Therefore, to show that a station has more forecasting power than random guesses,  
723 we proceed to test a given station against the null hypothesis is that a random guess (simulated HS TS)  
724 can have the same or higher  $R_{EQS}$  than the empirical HS TS.

725

726 We carried out this hypothesis test station by station, by first computing the  $R_{EQS}$  values of its empirical  
727 HS TS as well as for 400 HS TSs simulated using the HMM parameters for the given station. We then  
728 defined the *global confidence level* as:

$$729 \quad GCL = \frac{\# (\text{simulated } R_{EQS} < \text{empirical } R_{EQS})}{400}. \quad (11)$$

730 Similar to the p-value for the cellular-level hypothesis test, the p-value for this global-level hypothesis

731 test is given by  $p = 1 - GCL$ , where  $GCL$  ranges from  $[0,1]$ , and gives the probability that the  
 732 empirical HS TSs having higher  $R_{EQS}$  than its simulated counterparts. For example, if a station has  
 733  $GCL = 0.99$ , we can say that given the specified  $R_{D\_min}$ , we are 99% confident that the empirical HS  
 734 TS yields higher  $R_{EQS}$  than its simulated counterparts.

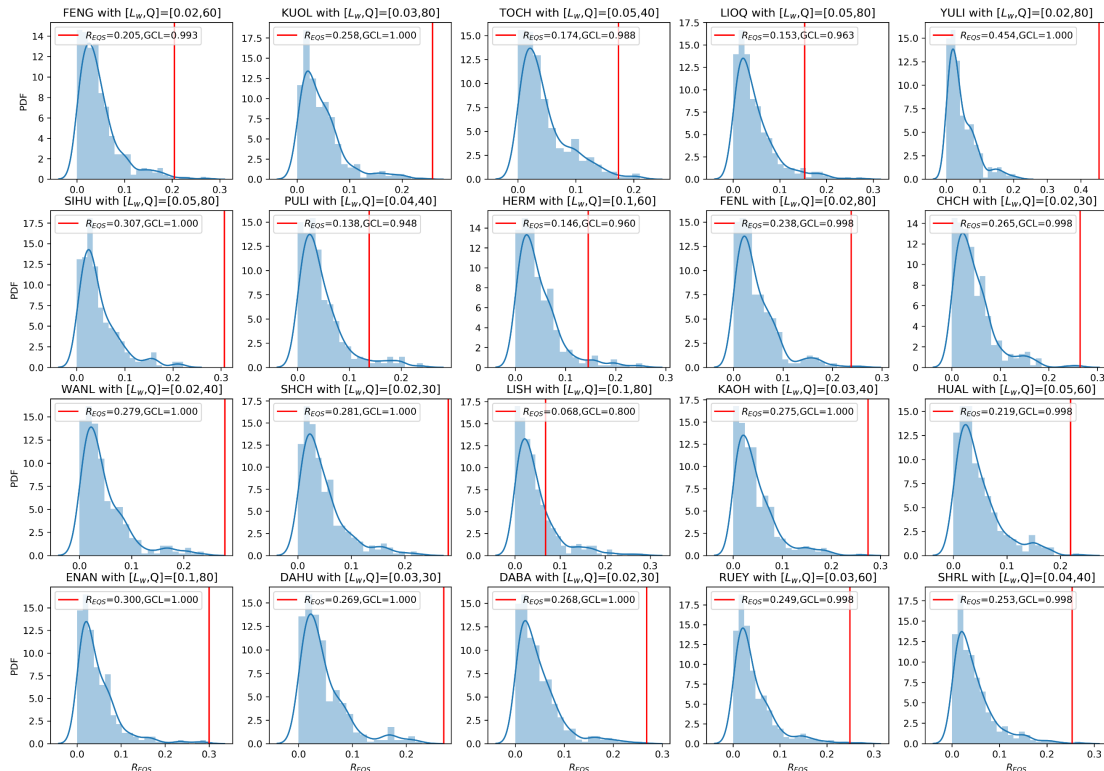

735

736 In Fig. 12, we show the results of our global-level significance tests, for a choice of  $R_{D\_min} = 0.95$ , in  
 737 the form of histograms of the 400 simulated  $R_{EQS}$  values, compared against the empirical  $R_{EQS}$  values.  
 738 Except for LIOQ and LISH stations, we can see from Fig. 12 that all the other stations have  $GCL$  values  
 739 close to 1. This tells us that the empirical  $R_{EQS}$  values of the 18 stations are statistically significant. We  
 740 also observed that for  $R_{D\_min} = 0.95$ , the simulated  $R_{EQS}$  values are mostly around (or below) 0.05,  
 741 meaning that only 5% of EQs are located in satisfactory cells by chance. In contrast, the empirical  $R_{EQS}$   
 742 values are mostly above 0.2, except for TOCH, LIOQ, PULI, HERM, and LISH. This is an important  
 743 finding, as it shows the HS TSs' EQ forecasting utility to be significant at the global level, through the  
 744 use of  $R_{EQS}$  and its significance level  $GCL$ .

745

746 Last but not least, the histograms for each station in Fig. 12 are created with individually optimized  
 747 hyperparameters, namely  $L_w$  (length of time window to compute indices  $C$ ,  $V$ ,  $S$ , and  $K$ , in days) and  
 748  $Q$  (number of clusters for the k-means clustering). The optimal hyperparameter values for each station  
 749 are indicated in the titles for each station. Let us discuss the details of this optimization process in the  
 750 next section.

751

752

753 **Figure 12: Histograms (blue) of 400 simulated  $R_{EQS}$  values compared against the empirical  $R_{EQS}$  (red**  
 754 **vertical line) for 20 stations and  $R_{D\_min} = 0.95$ , with the  $GCL$  values in the legends. The hyperparameters**  
 755 **of  $[L_w, Q]$  optimized for each station are shown at each subplot's titles.**

756

757 **3.5 Significance Levels Across the Hyperparameter Space**

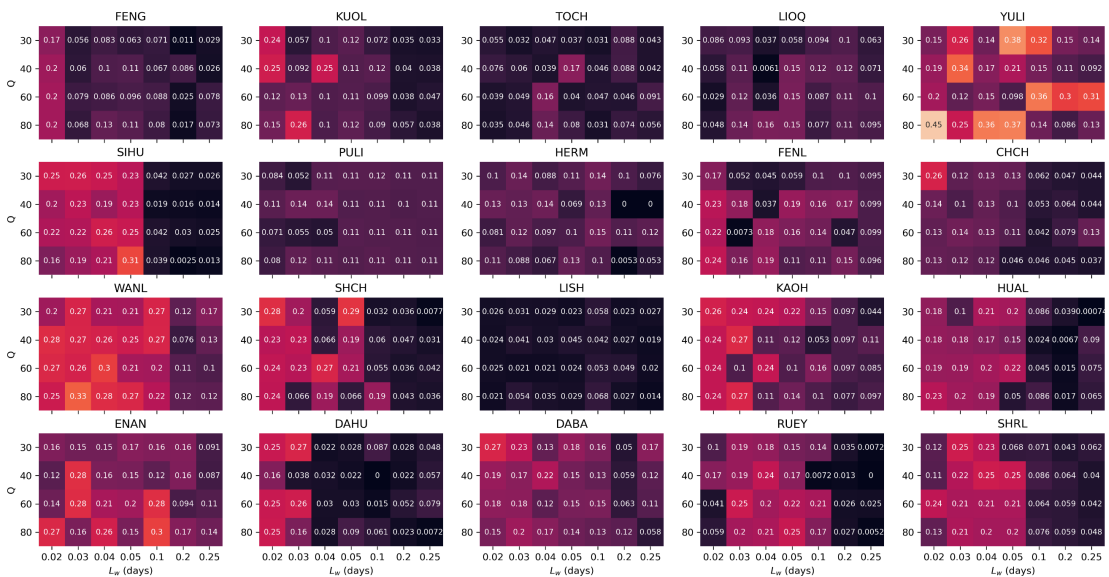

758

759 Typically, a forecasting model’s performance may be sensitive to our choice of hyperparameters. If  
 760 possible, we would like to choose hyperparameters that make the model the most predictive. If there are  
 761 too many hyperparameters, this optimization would be challenging in the high-dimensional search space.  
 762 Fortunately, there are only two hyperparameters needed to obtain the HS TS:  $[L_w, Q]$ . In this section, we  
 763 show how the model performance ( $GCL$ ) will vary across the tested hyperparameter space, as well as  
 764 how we chose the hyperparameters  $[L_w, Q]$ , for each station. Due to the high computational cost to test  
 765 each combination of  $[L_w, Q]$  (about 40 mins per station on a desktop with 4-GHz quad-core i7  
 766 processors, 16-GB of RAM, running macOS Mojave 10.14.6), we performed a coarse grid search over  
 767 28 points in the parameter space, consisting of 7 different  $L_w$  values:  
 768  $[0.02, 0.03, 0.04, 0.05, 0.1, 0.2, 0.25]$  days (or  $[28.8, 43.2, 57.6, 72, 144, 288, 360]$  mins) and 4 different  
 769  $Q$  values:  $[30, 40, 60, 80]$ . We decided on this search space based on our experience during the model  
 770 development stage. For real-world applications, where more computational resources can be invested,  
 771 this hyperparameter optimization can be done over a larger and finer grid, in which case better results  
 772 can be expected.

773

774 For each choice of station and hyperparameter, we followed the same procedure of computing 1+400  
 775  $R_{EQS}$  values, as well as the resulting  $GCL$  value. In Figs 13 and 14, we show the 20 heatmaps of  $R_{EQS}$   
 776 and  $GCL$  across the hyperparameter space, respectively for  $R_{D\_min} = 0.95$ . The results shown in Fig.  
 777 14 are more intuitive, where we found that for many stations, the  $GCL$  values approach 1 across broad  
 778 regions of the hyperparameter space. This can for example be the full hyperparameter space for YULI  
 779 station, or a patch within the hyperparameter space for KUOL station. There is just one station (LISH)  
 780 with poor  $GCL$  values everywhere in the hyperparameter space, indicating that there might be exclusive  
 781 factors that severely limit station LISH’s forecasting power. For all other 19 stations, the  $GCL$  values  
 782 are close to 1 either across a large area of the parameter space, or almost the entire parameter space (e.g.,  
 783 YULI, WANL, ENAN, DABA). This result is compelling, and is exactly what we needed for our goal:  
 784 *to demonstrate the forecasting skill of the HS TS, which does not depend on highly optimized*  
 785 *hyperparameters, but is valid over a broad range of hyperparameters.*

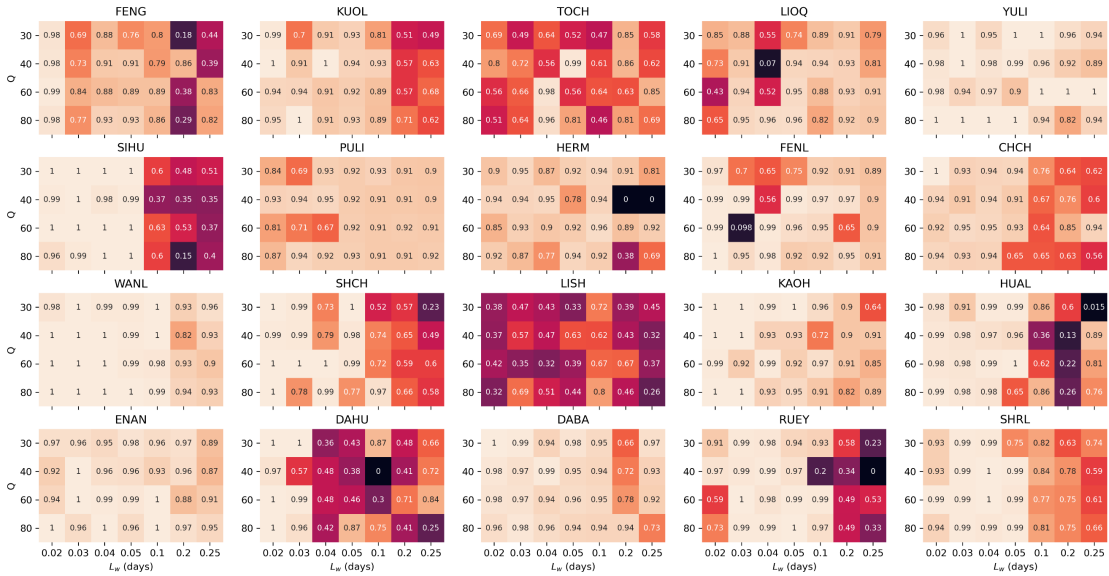

786

To wrap up this section, let us describe how to select the optimal hyperparameter for each station. We did this in two steps: first, we selected the hyperparameters with highest  $GCL$  values (1 for many stations); next, in case of ties, we chose the hyperparameter with the highest  $R_{EQS}$  as the winner. For example, for WANL station in Fig. 14, there are many cells with  $GCL = 1$ . We therefore proceeded to check the heatmap for station WANL in Fig. 13, and identified the hyperparameter combination  $L_w = 0.03$  and  $Q = 80$  as optimal, since it has the highest  $R_{EQS}$  value. Using this selection procedure, we identified the optimal hyperparameter for each station, and used these individually optimal hyperparameters to create Figs 7 to 12. This selection procedure could also be adapted for real-world applications, when more historical data and computational power are available, to provide even better model performances.

EQ forecasting is an important research topic, because of the potential devastation EQs can cause. As pointed out by many past studies, there is a correlation between features within geoelectric TSs and individual large EQs. In those studies, different features of geoelectric TSs were explored for their use of EQ forecasting, among which the GEMSTIP model was the first one to directly use statistic index TSs of geoelectric TSs to produce TIPs for EQ forecasting. Inspired by this, we took a second look at the relationship between these statistic indexes and the timing of EQs, and found out that there is an abrupt shift of the indexes' distribution along the TTF axis. This suggested that there are at least two distinct geoelectric regimes, which can be modeled and identified using a 2-state HMM. This motivation is further backed by the knowledge that there can be drastic tectonic configuration changes before and after a large EQ, one important aspect of which being the telluric changes identified in the region around the

819 epicenter of the EQ (Sornette and Sornette, 1990; Tong-En et al., 1999; Orihara et al., 2012; Kinoshita  
820 et al., 1989; Nomikos et al., 1997). Therefore, should there be two higher-level tectonic regimes featuring  
821 higher/lower EQ frequencies, we would expect to also find two matching geoelectric regimes with  
822 contrasting statistical properties, which can be of good utility for EQ forecasting.

823

824 Specifically, we modeled the earth crust system as having two HSs identifiable with distinctive  
825 geoelectric features encoded by 8 index TSs from each station. To obtain the HMM for each station, we  
826 needed to run the BWA, which is most convenient to use with a discrete observation TS input. Therefore,  
827 we used the k-means clustering to convert the continuous TS of 8-dimensional index vectors into a  
828 discrete observation TS, and subsequently obtained a converged HMM for each station. We then  
829 investigated whether these HS TSs provide informative partitions of EQs, i.e., one of the HS can be  
830 interpreted as a passive state with less frequent EQs, while the other one as an active state with more  
831 frequent EQs. For this task, we defined the *EQ frequency's ratio* ( $R_F$ ), which is the frequency of EQs in  
832 one of the HSs divided by the total frequency of the EQs. Using  $R_F$  we further defined the  
833 *discrimination power* ( $D$ ), to measure how differently one HS is from the other HS in terms of the EQ  
834 frequency. We then plotted 16-by-16 grid maps of  $R_F$  and  $D$  for all 20 stations, and tested the statistical  
835 significance of  $D$  in each cell, by comparing the empirical value against the distribution of  $D$  from 400  
836 simulated HS TSs, to end up with the grid maps of *discrimination reliability* ( $R_D$ ) for all 20 stations. To  
837 further investigate the statistical significance level at the global scale, we defined  $R_{EQS}$  to measure the  
838 percentage of total EQs located within satisfactory cells, i.e., cells having  $R_D \geq R_{D,min}$  for a user-  
839 specified  $R_{D,min}$  value. This  $R_{D,min}$  value can be easily customized for different cells, but in this paper,  
840 we used a constant  $R_{D,min}$  value across the grid map for demonstration. By comparing the  $R_{EQS}$  value  
841 of the empirical model against those of 400 simulated models, we obtained one global significance value  
842 for each station, namely the *global confidence level* ( $GCL$ ). This tells us how confident we can be that  
843 information contained in the empirical HS TSs can be used for EQ forecasting.

844

845 Finally, we showed how we optimized the  $GCL$  values through a grid-search in the 2-dimensional  
846 hyperparameter space and obtained the optimal combination of  $[L_w, Q]$  individually for each station.  
847 As a result, among the 20 stations with optimized hyperparameters, there are 19 stations with  $GCL >$   
848 0.95, 15 of which having  $GCL > 0.99$ . Additionally, the confidence levels are also robust across the  
849 hyperparameter space for most stations. Based on these positive results, the Hidden Markov Modelling  
850 of the index TSs computed from geoelectric TSs is indeed a viable way to extract information that can  
851 be useful for EQ forecasting.

852

853 To the best of our knowledge, while there have been previous applications of HMM for earthquake  
854 forecasting, this paper is the first to demonstrate the ability to do so with statistical confidence. As  
855 discussed in greater detail in Sect. 3.3, in real-world scenarios, the HS TSs can be useful for intermediate-  
856 term EQ forecasting either directly (for high  $R_D$  cells) or as input features for higher-level algorithms  
857 that take information from all 20 stations (for low  $R_D$  cells). Beyond our demonstration of extracting  
858 EQ-related information from geoelectric TSs, the HMM approach described in this paper can also be  
859 explored on other high-frequency geophysical data, such as those from geomagnetic, geochemical,  
860 hydrological, and GPS measurements, for EQ forecasting.

861

862 At this point, we would like to address the issue of out-of-sample testing (or cross-validation) to support

863 the validity of our model. There are two ways to do this: (1) split a long time series into a training data  
864 set to calibrate the model, and a testing data set to validate the model; and (2) use whatever time series  
865 data is available to calibrate the model, before collecting more data to validate the model. If the model is  
866 statistically stationary (its parameters do not change with time), both approaches are acceptable. However,  
867 many would agree that an out-of-sample test with freshly collected data (approach (2)) is more  
868 impressive, especially if it is done in real time. We would certainly like to try this, and are writing a grant  
869 application to fund such a validation study. For this paper, however, we were not even able to use  
870 approach (1), because our geoelectric time series are not long enough. This is especially so if we require  
871 **(A)** the validation data is always temporally *after* the training data; and **(B)** the validation data is also  
872 intermediate-term for intermediate-term EQ forecasting. These two requirements cannot be fulfilled on  
873 our limited 7-year data, if we want to have a significant number (e.g., 10 times) of validations to produce  
874 confident claims. Therefore, in this paper, we limited our scope to demonstrating that our model has  
875 *forecasting skill*, without quantifying its *exact forecasting accuracy*. We argue that we have indeed  
876 achieved this, without the use of out-of-sample testing, because in Sect. 3.5, we showed *the forecasting*  
877 *skill is statistically significant regardless of the choice of the hyperparameters*, for 19 out of the 20  
878 stations that we tested. Furthermore, the statistical hypothesis test has the advantage of giving rigorous  
879 p-value with moderate computation cost, through simulating the HMM for multiple null-hypothesis tests.
