9 **Landslides are different from other natural hazards.** Unlike **volcanoes**, they do not threaten human
10 civilization (Papale and Marzocchi, 2019). Unlike tsunamis, they do not affect simultaneously
11 **several** thousands of kilometres of coastline – although a submarine landslide in Norway has caused
12 a tsunami **to hit** Scotland (Dawson et al., 1988). Unlike floods and earthquakes, they do not cause
13 hundreds of thousands of casualties in a single event – although a landslide has killed thousands in
14 Peru (Evans et al., 2009) **and** debris flows tens of thousands in Colombia (Wieczorek et al., 2001).
15 **But the human toll of landslides is high (Froude and Petley, 2018), and their economic and societal**
16 **consequences are largely undetermined.** Compared to other hazards, landslides are subtle, **often go**
17 **unnoticed, and their consequences are underestimated.**

18 **As with** other hazards, the design and implementation of effective risk reduction strategies depend
19 on the ability to predict (forecast, **project, anticipate**) landslides. I have argued that “*our ability to*
20 *predict landslides and their consequences measures our ability to understand the underlying [...]*
21 *processes that control or condition landslides, as well as their spatial and temporal occurrence*”
22 (Guzzetti, 2021). This assumes that landslide prediction is possible; something that has not been
23 **demonstrated (or disproved)**, theoretically. **Yet**, there is nothing in the literature that prevents
24 landslide prediction; provided that one clarifies the **meaning of “prediction”** (Guzzetti, 2021), that
25 the prediction is scientifically based (Guzzetti, 2015), and that we understand the limits of the
26 prediction (Wolpert, 2001). Efforts are needed to determine the limits of landslide predictions, for
27 all landslide types (Hungr et al., 2014) and at all geographic and temporal scales (**Figure 1**).

28 Here, I outline what I consider to be the main problems that need to be addressed in order to
29 advance our ability to predict landslide hazards and risk. The field is vast, and I limit my perspective
30 to populations of landslides – that is, the hazards and risk posed by many landslides caused by one
31 triggering event, or by multiple events in a short period. In this context, predicting landslide hazard
32 means anticipating where, when, how frequently, how many, and how large populations of
33 landslides are expected (Guzzetti et al., 2005; Lombardo et al., 2020; Guzzetti, 2021). Predicting
34 landslide risk is about anticipating the consequences of landslide populations to different
35 vulnerable elements (Alexander, 2005; Glade et al., 2005; Galli and Guzzetti, 2007; Salvati et al.,
36 2018).

37 Landslides tend to occur where they have previously occurred (Temme et al., 2020). Therefore,
38 one way to assess where they are expected is to map past and new landslides. The technology is
39 mature for regional and even global landslide detection and mapping services based on the
40 automatic or semi-automatic processing of aerial and satellite imagery; optical, SAR and LiDAR
41 data (Guzzetti et al., 2012; Mondini et al., 2021). An alternative – and complementary – way is
42 through susceptibility modelling; an approach for which there is no shortage of data-driven
43 methods, but rather of suitable environmental and landslide data (Reichenbach et al., 2018). The
44 increasing availability of satellite imagery, some of which repeated over time and free of charge
45 (Aschbacher, 2017), opens unprecedented opportunities to prepare event and multi-temporal
46 inventory maps covering very large areas, which are essential to build space-time prediction models
47 (Lombardo et al., 2020), to investigate the legacy of old landslides on new ones (Samia et al., 2017;
48 Temme et al., 2020), to obtain accurate thematic data for susceptibility modelling (Reichenbach et
49 al., 2018), and to validate geographical landslide early warning systems (Piciullo et al., 2018;
50 Guzzetti et al., 2020). However, the literature reveals a systematic lack of standards for
51 constructing, validating, and ranking the quality of landslide maps and prediction models (Guzzetti
52 et al., 2012; Mondini et al., 2021; Reichenbach et al., 2018). This reduces the credibility of the
53 maps and models. A gap that urgently needs to be bridged (Guzzetti, 2021).

54 Predicting when or how frequently landslides will occur can be done for short and for long periods.
55 For short periods – from hours to weeks – the prediction is obtained through process-based models,
56 rainfall thresholds, or their combination. Process-based models rely upon the understanding of the
57 physical laws controlling the slope instability conditions of a landscape forced by a transient trigger

58 e.g., a rainfall, snow melt, seismic, or volcanic event (Bogaard and Greco, 2016, 2018). The major
59 limitation of physically-based models is the scarcity of relevant data, which are hard to obtain for
60 very large areas. New approaches to obtain relevant, spatially-distributed data are needed, as well
61 as novel models able to extrapolate what is learned in sample areas to vast territories (Bellugi et
62 al., 2011; Alvioli and Baum, 2016; Alvioli et al., 2018; Mirus et al., 2020).

63 Thresholds are empirical or statistical models that link physical quantities (e.g., cumulative rainfall,
64 rainfall duration) to the occurrence – or lack of occurrence – of known landslides. Reviews of the
65 literature (Guzzetti et al., 2008; Segoni et al.; 2018) have highlighted conceptual problems with the
66 definition and use of rainfall thresholds for operational landslide forecasting and early warning
67 (Piciullo et al., 2018; Guzzetti et al., 2020), including the lack of standards for defining the
68 thresholds and their associated uncertainty (Melillo et al., 2018), and for the validation of the
69 threshold models (Piciullo et al., 2017, 2018; Guzzetti et al., 2020). The community needs shared
70 criteria and algorithms coded into open-source software for the objective definition of rainfall
71 events, of the rainfall conditions that can result in landslides, of rainfall thresholds (Melillo et al.,
72 2015, 2018), and for the validation of the threshold models (Piciullo et al., 2017). This will not
73 only provide reliable and comparable thresholds, allowing for regional and global studies (Guzzetti
74 et al., 2008; Segoni et al.; 2018), but also increase the credibility of early warning systems based
75 on rainfall threshold models (Guzzetti et al., 2020).

76 The projection of landslide frequency for long periods – decades to millennia – is much more
77 difficult and uncertain, as it depends on climatic and environmental characteristics that are poorly
78 known and difficult to measure and model (Crozier, 2010; Gariano and Guzzetti, 2016), as well as
79 on the inherent incompleteness of the historical landslide records (Rossi et al., 2010). The literature
80 on the analysis of historical landslide records remains scarce, but the number of studies projecting
81 the future occurrence of landslides is increasing (Gariano et al., 2017; Peres and Cancelliere, 2018;
82 Schlögl and Matulla, 2018; Patton et al., 2019; Schlögel et al., 2020; Gariano and Guzzetti, 2021).
83 In this field, studies will be relevant if they compare analyses and validation methods in different
84 areas. This requires the exchange of data and information.

85 Predicting *how many and how large* landslides are expected means anticipating the size (e.g., area,
86 volume, length, width, depth) and number of landslides in an area – with size and number correlated

87 in a population of landslides. This information is obtained by constructing and modelling
88 probability distributions of landslide sizes obtained typically from landslide event inventory maps
89 (Stark and Hovius, 2011; Malamud et al., 2004). The literature on the topic is limited, and with
90 differences in the way the distributions are modelled. This hampers comparisons from different
91 areas. Although models have been proposed to explain the probability size distributions (Katz and
92 Aharanov, 2006; Stark and Guzzetti, 2009; Klar et al., 2011; Bellugi et al., 2021), further efforts
93 are needed to explain the observed distributions of landslide sizes, and to evaluate their variability
94 and uncertainty.

95 By combining probabilistic information on *where, when or how frequently*, and *how many or how*
96 *large* landslides are, one can evaluate landslide hazards for different landslide types. However, the
97 existing models are crude, they work under assumptions that are difficult to prove (Guzzetti et al.,
98 2005), and the possibility to export them in different areas is limited, or untested. Novel efforts are
99 needed to prepare reliable landslide hazard models (Lombardo et al., 2020; Guzzetti, 2021).

100 Assessing landslide hazard is important but, for social applications what is needed is the estimation
101 of the landslide consequences, which means assessing the vulnerability to landslides of various
102 elements at risk (Alexander 1999; Galli and Guzzetti 2007), and evaluating landslide risk (Cruden
103 and Fell, 1997; Glade et al., 2005; Porter and Morgenstern, 2013), including risk to the population
104 (Petley, 2012; Froude and Petley, 2018; Salvati et al., 2018; Rossi et al., 2019). Here, the main
105 limitation is the difficulty to obtain data on landslide vulnerability, and reliable records of landslide
106 events and their consequences (Petley, 2012; Froude and Petley, 2018; Salvati et al. 2018). Where
107 the information is available, comprehensive landslide risk models can be constructed, and validated
108 (Rossi et al., 2019). It is important that efforts are made to collect reliable records of landslides and
109 their consequences, and that the records are shared to test different risk models.

110 Of the various factors governing landslide hazard the most uncertain and the one requiring more
111 urgent efforts is the time prediction (*when, how frequently*), followed by the prediction of the size
112 and number of expected failures. For both, multi-temporal inventories and landslide catalogues are
113 essential to build innovative predictive models. To construct the records, systematic efforts are
114 needed for landslide detection and mapping (Mondini et al., 2021). For susceptibility (*where*), the
115 challenge is to prepare reliable regional, continental, or global assessments (Stanley and

116 Kirschbaum, 2017; Broeckx et al., 2018; Wilde et al., 2018; Mirus et al., 2020). Critical are also
117 novel modelling frameworks combining the hazard factors (Lombardo et al., 2020). But the goal
118 is to reduce risk (Glade et al., 2005). For that, vulnerability studies, improved early warning
119 capabilities, quantification of the benefits of prevention, and better risk communication strategies
120 are crucial (Guzzetti, 2018). Much work is needed on these largely unexplored subjects.

121 Ultimately, I note that in medicine – a field of science conceptually close to the field of landslide
122 hazard assessment and risk mitigation (Guzzetti, 2015) – the paradigm of “convergence research”
123 is emerging (Sharp and Hockfield, 2017), where “convergence comes as a result of the sharing of
124 methods and ideas ... It is the integration of insights and approaches from historically distinct
125 scientific and technological disciplines” (Sharp et al., 2016). The community of landslide scientists
126 should embrace the paradigm of “converge research”, exploiting the vast amount of data,
127 measurements, and observations that are available and will be collected, expanding the making and
128 use of predictions, assessing the economic and social costs of landslides, designing sustainable
129 mitigation and adaptation strategies, and addressing the ethical issues posed by natural hazards,
130 including landslides (Bohle, 2019). I am persuaded that this will contribute to advancing
131 knowledge and building a safer society (Guzzetti, 2018).
