14 **Abstract**

15 Landslides and flash floods are geomorphic hazards (GH) that often co-occur and interact. They  
16 generally occur very quickly, leading to catastrophic socioeconomic impacts. Understanding the  
17 temporal patterns of occurrence of GH events is essential for hazard assessment, early warning and  
18 disaster risk reduction strategies. However, temporal information is often poorly constrained, especially  
19 in frequently cloud-covered tropical regions, where optical-based satellite data is insufficient. Here we  
20 present a regionally applicable methodology to accurately estimate GH event timing that requires no  
21 prior knowledge of the GH event timing, using Synthetic Aperture Radar (SAR) remote sensing. SAR can  
22 penetrate through clouds and therefore provides an ideal tool for constraining GH event timing. We use  
23 the open-access Copernicus Sentinel-1 (S1) SAR satellite that provides global coverage, high spatial  
24 resolution (~10-15 m) and a high repeat time (6-12 days) from 2016 to 2020. We investigate the  
25 amplitude, detrended amplitude, spatial amplitude correlation, coherence and detrended coherence  
26 time series in their suitability to constrain GH event timing. We apply the methodology on four recent  
27 large GH events located in Uganda, Rwanda, Burundi and DRC containing a total of about 2500 manually  
28 mapped landslides and flash flood features located in several contrasting landscape types. The  
29 amplitude and detrended amplitude time series in our methodology do not prove to be effective in  
30 accurate GH event timing estimation, with estimated timing accuracies ranging from a 13 day to a 1000  
31 day difference. A clear increase in accuracy is obtained from SAC with estimated timing accuracies  
32 ranging from a 1 day to an 85 day difference. However, the most accurate results are achieved with  
33 coherence and detrended coherence with estimated timing accuracies ranging from a 1 day to a 47 day  
34 difference. The amplitude time series reflect the influence of seasonal dynamics, which cause the timing  
35 estimations to be further away from the actual GH event occurrence compared to the other data  
36 products. Timing estimations are generally closer to the actual GH event occurrence for GH events  
37 within homogenous densely vegetated landscape, and further for GH events within complex cultivated  
38 heterogenous landscapes. We believe that the complexity of the different contrasting landscapes we

39 study is an added value for the transferability of the methodology and together with the open access  
40 and global coverage of S1 data it has the potential to be widely applicable.

## 41 **1. Introduction**

42 Landslides and flash floods are geomorphic hazards (GH) that can occur very quickly, sometimes in a  
43 matter of a few hours. GH frequently co-occur and interact (e.g. Rengers et al., 2016), they have a  
44 significant impact on the landscape (Petersen, 2001, Korup et al., 2010) and are severe threats for  
45 infrastructure and human life (Bradshaw et al., 2007, Kjekstad and Highland, 2009, Froude and Petley,  
46 2018). Landslides and flash floods are often studied in isolation. However, it is their combined  
47 occurrence that can lead to more extreme impacts. For example, in 2013, several people were killed  
48 and ~7000 lost their homes in the Rwenzori Mountains in Uganda by a single debris-rich flash flood fed  
49 by upstream landslides (Jacobs et al., 2016a). Also, in 2011, a combination of flash flooding and  
50 mudslides across the highlands of the state of Rio de Janeiro claimed the lives of 916 people and left  
51 35.000 people homeless (Marengo & Alves, 2012).

52 Understanding the temporal occurrence of GH events is essential for hazard assessment, early warning,  
53 and disaster risk reduction strategies (van Westen et al., 2008, Ali et al., 2017, Liu et al., 2018, Guzzetti  
54 et al. 2020). Temporal information with a few day accuracy is needed to understand the close  
55 association between precipitation and the occurrence of GH events (Guzzetti et al., 2008; 2020,  
56 Turkington et al., 2014, Marc et al., 2018). For site-specific and local-scale investigation, this accurate  
57 information on the timing of GH events can be obtained with field-based approaches such as  
58 watershed/hillslope monitoring (Guzzetti et al., 2012) or a network of observers (Jacobs et al., 2019,  
59 Sekajugo et al., 2022). However, when information on the timing of GH events is needed at a regional  
60 level, the acquisition of such data can only be achieved with satellite remote sensing (Joyce et al., 2009,  
61 Le Cozannet et al., 2020), especially in mountainous regions with difficult field accessibility and where  
62 monitoring and observation capacities are limited (Dewitte et al., 2021).

63 Satellite remote sensing, and more specifically the use of optical imagery, is a well-developed field of  
64 research to accurately determine the location of GH (Stumpf et al., 2014, Behling et al., 2014; 2016,  
65 Mohan et al., 2021). Optical-based satellite approaches can also be used for extracting the information  
66 on the timing of the GH events (e.g. Kennedy et al., 2018, Deijns et al., 2020), however such approaches  
67 are of limited use in cloud-covered environments, especially if temporal information with a few day  
68 accuracy is needed.

69 Synthetic Aperture Radar (SAR) satellite, being an active system with an ability to penetrate cloud cover,  
70 holds a great potential for characterizing the timing of GH. Additionally, the sensitivity of SAR satellite  
71 data to surface changes, including vegetation changes (Hagberg et al., 1995, Balzter, 2001, Barrett et  
72 al., 2012), soil moisture changes (Dobson & Ulaby, 1986, Dubois et al., 1995, Ulaby et al., 1996, Nolan  
73 & Fatland, 2003, Srivastava et al., 2006), and surface texture changes (Dzurisin, 2006) gives SAR the  
74 potential to display GH timing with an accuracy of days.

75 SAR derived products typically used for GH (event) analysis are amplitude data (i.e. changes in surface  
76 backscattering intensity of SAR signal between two images) (e.g. Mondini et al., 2017; 2019, Esposito

77 et al., 2020, DeVries et al., 2020, Handwerger et al., 2022) for which amplitude correlation is a common  
78 method used in amplitude change detection (Mondini et al., 2017, Konishi & Suga, 2018, Jung and Yun,  
79 2020) and the coherence (i.e. the change in the ability of SAR wave fronts to stay spatially and/or  
80 temporally in phase between the two images of an interferometric pair) (Burrows et al., 2019; 2020,  
81 Tzouvaras et al., 2020). Additionally, there is a wide range of studies that use SAR-derived ground  
82 deformation to map landslides (Casagli et al., 2017, Solari et al., 2020) or analyze pre-cursor movements  
83 (Intrieri et al., 2018) and internal variability (Nobile et al., 2018). However, they are dependent on  
84 consistent high coherence values at the GH locations, which will make these methods of limited use in  
85 highly vegetated landscapes (e.g. the tropics) (Komac et al., 2015, Solari et al., 2020) and for fast  
86 moving GH (e.g. shallow landslides and flash floods) (Burrows et al., 2020; Tzouvaras et al., 2020). In  
87 recent GH detection studies, amplitude products are usually preferred over coherence products (Ge et  
88 al., 2019, Jung and Yun, 2020, Mondini et al., 2021), since coherence generally yields less accurate  
89 results due to lower resolution (Burrows et al., 2019; 2020) and a higher number of false-positives  
90 (Aimaiti et al., 2019, Jung and Yun, 2020). Despite the increasing use of SAR imagery for GH detection  
91 (Martinis et al., 2015, Psomiadis, 2016, Twele et al., 2016, Mondini et al., 2019, Burrows et al., 2020,  
92 Jung and Yun, 2020, Tzouvaras et al., 2020, Jacquemart and Tiampo, 2021, Handwerger et al., 2022),  
93 to date, only the recent study of Burrows et al. (2022) used SAR to refine the timing of GH inventories.  
94 Although located in the tropics and showing accurate results, their study was only applied (1) within a  
95 relatively densely vegetated landscape, (2) only on landslides, (3) using pre-processed amplitude  
96 imagery with Google Earth Engine (GEE) (Gorelick et al., 2017), (4) with a-priori knowledge on the  
97 timing of the event (i.e. the year). GH events occur within a variety of landscapes (Emberson et al.,  
98 2020, Dewitte et al., 2021). Therefore, there is a clear need to calibrate and validate any GH timing  
99 method for varying landscape, and land use/land cover characteristics. Additionally, the frequent co-  
100 occurrence of landslides and flash floods (Jacobs et al., 2016b, Rengers et al., 2016) warrants the need  
101 to analyze them using a combined methodology. However, so far, there has never been research  
102 dedicated to their combined temporal detection using radar satellite.

103 The Copernicus Sentinel-1 (S1) constellation is frequently used in GH detection studies (Mondini et al.,  
104 2021). Next to the fact that it is freely available and acquired regionally (from 2016 onwards), it offers  
105 a very good trade-off between frequency of acquisition (6/12 days) and spatial resolution (10-15 m  
106 depending on the pre-processing parameters). These advantages make S1 an attractive tool to integrate  
107 in a regional GH timing methodology.

108 In this study, we aim to develop a regionally applicable methodology that automatically estimates GH  
109 event timing using S1 SAR imagery on GH events spatially located, but with unspecified timing. We  
110 analyze landslides and flash floods together as being co-occurring and interacting events. We create a  
111 methodology that can be applied at the regional scale in complex and various topographic and land  
112 use/land cover environments. The methodology is developed using four GH events either containing  
113 landslides, or a combination of landslides and flash floods located in contrasting landscape types  
114 observed within tropical Africa (see section 2.1). We analyze an unprecedented amount of S1 SAR

115 products, namely: amplitude, spatial amplitude correlation (a metric based on the common amplitude  
116 correlation) and coherence. Specifically, we: (1) create S1 SAR time series and analyze their patterns  
117 and behavior at the location of several GH events, (2) demonstrate and assess the ability to detect the  
118 timing of GH events using changes within the S1 SAR time series and, (3) investigate the influences of  
119 the landscape characteristics on the ability to derive the timing from S1 SAR timeseries through a  
120 sensitivity analysis.

## 121 **2. Data**

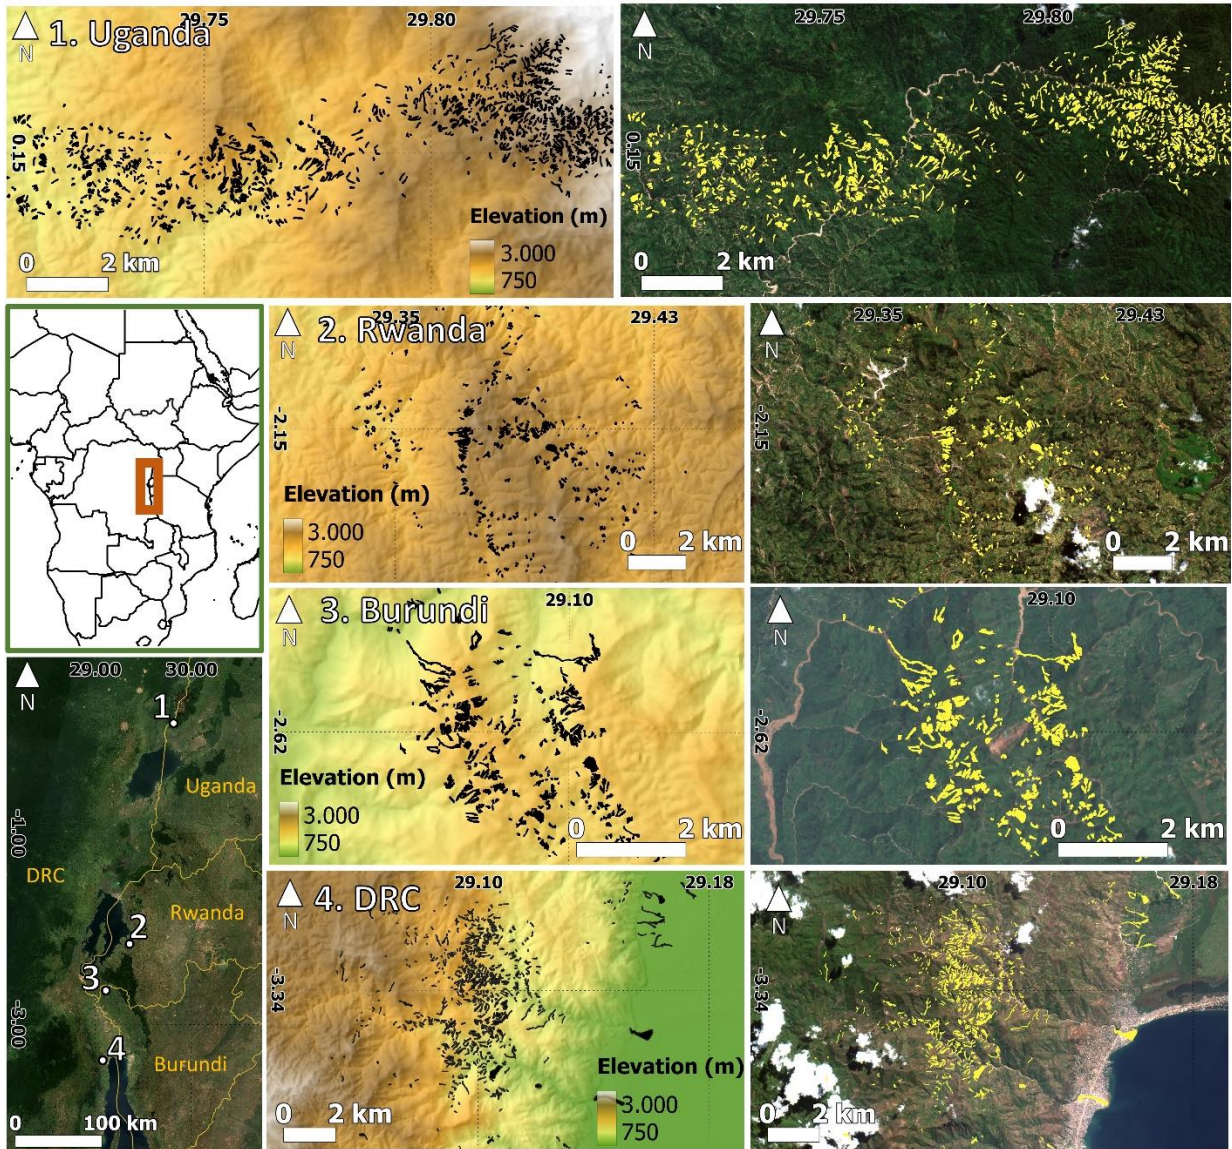

### 122 **2.1. Selection of GH events in a tropical region with diverse landscapes**

123 We focus on the western branch of the East African Rift, a mountainous region with high population  
124 densities and diverse landscape and land use/land cover characteristics (Depicker et al., 2021, Dewitte  
125 et al., 2021). The region has a bimodal precipitation distribution with two rainy peaks (October-  
126 November & March-April) and a main dry season (June-August) associated with the North-South  
127 migration of the Inter Tropical Convergence Zone (ITCZ) (Thiery et al., 2015, Nicholson, 2017,  
128 Monsieurs et al., 2018a) with annual precipitation ranging from ~0.8m along the shores of Lake  
129 Tanganyika to easily more than 2m in the highlands, with the maximum in the Rwenzori Mountains  
130 (Monsieurs et al., 2020, Van de Walle et al., 2020). The seasonality of the precipitation strongly controls  
131 the occurrence of landslides and flash floods (Jacobs et al., 2016a; 2016b, Monsieurs et al., 2018a;  
132 2018b, Kubwimana et al., 2021). Vegetation dynamics are high in the cultivated areas due to the variety  
133 of cropping practices (crop rotations and shifting cultivation, Heri-Kazi & Biolders, 2021). Moreover, the  
134 region is one of the most cloud-covered places in the world (Robinson et al., 2019) and a global hotspot  
135 of thunderstorm activity (Thiery et al., 2016; 2017, Peterson et al., 2021).

136 We investigate four GH events with known days of occurrence, and located in contrasting landscapes  
137 (fig. 1):

- 138 • Event 1 (Uganda GH event) is located in the southern part of the Rwenzori Mountains  
139 (Uganda) and counts 1063 landslide features of which some contribute directly to the sediment  
140 load of the valley river (fig. 1, Uganda). The event occurred between the 21<sup>st</sup> and the 22<sup>nd</sup> of  
141 May 2020. The terrain consists of pristine forests and some cultivated landscape (fig. 2a).
- 142 • Event 2 (Rwanda GH event) is located in the Karongi district (western Province,  
143 Rwanda) and counts 494 features composed of both landslide and flash floods and occurred on  
144 the 6<sup>th</sup> of May 2018 (fig. 1, Rwanda). The terrain consists of an inhabited and highly cultivated  
145 landscape with the presence of agricultural terraces (fig. 2b).
- 146 • Event 3 (Burundi GH event) occurred around the hills of Nyempundu in the Cibitoke  
147 region (north Burundi) and counts 318 features composed of landslides and flash floods and  
148 occurred between the 4<sup>th</sup> and 5<sup>th</sup> of December 2019. Here, many landslides contribute directly  
149 to the sediment load of the rivers (fig. 1, Burundi). The terrain consists of inhabited cultivated  
150 landscape and sporadic tree cover (fig. 2c).

151 • Event 4 (DRC GH event) occurred west of the city of Uvira (DRC), northwest of Lake  
 152 Tanganyika and counts 609 landslides and flash flood features that occurred between the 16<sup>th</sup>  
 153 and the 17<sup>th</sup> of April 2020. Many landslides are connected to the rivers where the flash floods  
 154 occurred. The debris-rich flash floods inundated parts of the city (fig. 1, DRC). The terrain is  
 155 characterized by an urban area, cultivated landscape, grassland, and sporadic tree cover (fig.  
 156 2d).

157  
 158 *Figure 1. The location of the four GH events with their topographic (left: 30m ALOS 3D DEM, GH event*  
 159 *features in black) and optical (right: S2 post-event image, GH event features in yellow) context. Note*  
 160 *that in the close vicinity of the GH events of Uganda and Burundi, large sediment-loaded riverbeds are*  
 161 *visible. This is a consequence of the GH events that contributed directly to the transport of extra material*  
 162 *to the rivers, increasing not only their sediment content, but also their lateral mobility. These river*  
 163 *dynamics are not included in our analysis. The two panels at the lower left depict the location of the GH*

164 sites (S2 imagery). Image credit: Contains modified Copernicus Sentinel data (2022), processed with  
 165 Google Earth Engine. ALOS 3D DEM data provided by Japan Aerospace Exploration Agency (JAXA).

166 The locations of the GH events (fig. 1) are derived using the Copernicus Sentinel-2 (S2) Multispectral  
 167 Instrument (MSI), high resolution (10m), high frequency (6 -12 days) satellite imagery. We manually  
 168 digitized all individual features from the first available cloud-free S2 image after the event and a cloud-  
 169 free S2 image with similar vegetation characteristics (compared to the post-event image) before the  
 170 event. We use PlanetScope Ortho Scenes (Planet Team, 2017) for validation of the GH event inventory  
 171 with a higher resolution satellite image. Planet operates with a constellation of multiple small satellites  
 172 producing very-high resolution (3m), high frequency (up to 1 day) imagery (Table 1).

173 *Table 1: Images information of manual mapping and dating GH events. Planet images are of the type*  
 174 *PlanetScope Ortho Scene (POS)*

GH Event	Sentinel-2				Planet	
	Date – pre	Date - post	Tile	Type	Date	Type
Uganda	2019-08-16	2020-06-01	35NRA	L1C	2020-06-29	POS
Rwanda	2018-03-09	2018-06-12	35MQT	L1C	2019-12-07	POS
Burundi	2019-08-06	2020-01-23	35MQT	L1C	2018-06-12	POS
DRC	2019-07-02	2020-06-06	35MQS	L1C	2020-10-06	POS

175 We prefer the use of Planet and S2 over the Maxar or the Spot/Pléiades images visible in Google Earth  
 176 because of the consistency in temporal and spatial resolution. To note, the Burundi GH event has  
 177 recently been mapped by Emberson et al. (2022) by means of a semi-automated method followed by a  
 178 manual correction using S2 satellite data. We expect our manually mapped Burundi GH event inventory  
 179 to be similar or more accurate since we use a combination of S2 and Planet satellite data and a  
 180 completely manual detection workflow. The date of GH event occurrences is determined from local  
 181 media and field observations, and if not available from these resources, determined by the first- and  
 182 last available imagery from S2 and Planet imagery.

183

184

185 *Figure 2. Close up of the contrasting typical landscapes of the four GH events. Maps Data: Google,*  
 186 *©2022 Maxar Technologies (c, d) Google, ©2022 CNES/Airbus (a,b).*

187 **2.2. SAR time series**

188 SAR time series at the GH location are constructed using the Copernicus S1 Level-1 Single Look Complex  
 189 (SLC) imagery acquired in Interferometric Wideswath (IW). The S1 satellite is side-looking (right) and  
 190 operates both on the ascending (from South to North) and descending (from North to South) tracks  
 191 within the C-band frequency. To study the four GH events (fig. 1) we use all available high resolution  
 192 S1 imagery (~15x15 meter resolution) from January 2016 to January 2021 at the location of the GH  
 193 event at tracks 174 (ascending) and 21 (descending). This equals to between 196 and 208 ascending  
 194 and 120 and 193 descending images per GH event, where images occasionally overlap more than one  
 195 GH event. with a repeat time of six to twelve days with more consistently six days towards recent times.  
 196 We use both amplitude and coherence information. S1 images over the study area are provided in  
 197 vertical-vertical (VV) and vertical-horizontal (VH) polarizations. Different polarizations result in different  
 198 backscattering values (Shibayama et al., 2015, Psomiadis, 2016, Park & Lee, 2019, Burrows et al.,  
 199 2022). Mondini et al., 2019 noted a better definition of landslide-induced changes in vegetated areas

200 using the VH channel. In contrast, Burrows et al. (2022) found VV to perform better than VH for landslide  
201 event timing estimation. Psomiadis (2016) concluded that VV polarization performed better than VH  
202 polarization for flash flood mapping. Finally, VV polarization images are acquired more consistently at  
203 the locations of our GH events. We therefore decide to use VV polarization for our analysis. Due to the  
204 side-looking nature of the S1 satellite it is subjected to foreshortening, layover, and shadowing which  
205 are SAR inherent quality problems that are amplified within mountainous regions and affect image  
206 quality (Hanssen, 2001, Dzurisin, 2006). GH inventories are masked for foreshortening, layover, and  
207 shadow areas to remove the individual landslides and flash floods that fall within these inherently noisy  
208 areas.

### 209 **2.3. SAR controlling factors**

210 SAR amplitude and coherence are influenced by local slope angle (Hanssen, 2001), soil moisture (Ulaby  
211 et al., 1996, Scott et al., 2017), vegetation (Balzter, 2001, Barrett et al., 2012), and terrain roughness  
212 (Dzurisin, 2006). Coherence is additionally influenced by atmospheric changes (Rocca et al., 2000) and  
213 due to the use of image pairs, also by the temporal baseline (time between acquisition of two images),  
214 the perpendicular baseline (distance between the location of acquisition of two images) and the  
215 difference in incident angle of the paired images (Hanssen, 2001). Coherence values are generally very  
216 low (high decorrelation) in densely forested areas due to constant movement of the leaves and stems  
217 (Weydahl, 2001, Tessari et al., 2017), whereas bare soils or urbanized terrains, due to their static  
218 nature, generally reveal relatively high coherence values (Colesanti & Wasowski, 2006). An increase in  
219 coherence values after GH event occurrence is therefore expected. Amplitude values, on the other hand,  
220 show to have a quite complex reaction to terrain change. Due to the influence of soil moisture and  
221 roughness change on the amplitude values, the occurrence of a GH event could both increase and  
222 decrease the amplitude values at the location of the GH event (Mondini et al., 2021, Burrows et al.,  
223 2022). Both precipitation (in changing leaf- and soil wetness) and vegetation patterns, can dynamically  
224 influence SAR amplitude and coherence values, causing a cumulative effect on the time series  
225 (Srivastava et al., 2006, Brancato et al., 2017). This effect is more prominent over sparsely vegetated  
226 areas due to geometric (vegetation growth and farming practices) and dielectric (moisture) changes  
227 (Strozzi et al., 2000). Additionally, a change in atmosphere (precipitation events, ionospheric  
228 disturbances) can dynamically influence the coherence values (Rocca et al., 2000, Jacquemart &  
229 Tiampo, 2021). To better assess the ability to detect GH timing, it is essential to understand the dynamic  
230 factors controlling the behavior of the signal.

231 We derive precipitation estimates from the GPM Level 3 IMERG Final Daily (10km spatial resolution)  
232 dataset that has been validated through rain gauge data within the area (Nakulopa et al. 2022). General  
233 vegetation patterns per GH event are visualized using the Normalized Difference Vegetation Index  
234 (NDVI; Tucker, 1979). NDVI time series are derived from the Landsat-8 (30m spatial resolution) archive  
235 and processed within the GEE environment We use the Landsat 8 atmospherically corrected surface

236 reflectance images provided within the GEE environment. We masked them for clouds using the quality  
237 assessment band resulting from the CFmask algorithm (Foga et al., 2017).

238 We choose the lower resolution Landsat-8 over the higher resolution S2 imagery to reduce any  
239 unwanted local effects of NDVI change captured in the higher resolution S2 imagery, and since we are  
240 only interested in the general vegetation trends within the area this should be sufficient. From the cloud-  
241 masked images, a spatial-average NDVI time series is created spanning from 2016-2020 over the  
242 undisturbed areas of the GH event area. The NDVI time series are further processed to monthly  
243 averages, since we are interested in general vegetation patterns visible in the NDVI time series rather  
244 than changes on smaller temporal timescales.

245 We use the ESA Climate Change Initiative Land Cover product (ESA, 2016) to categorize GH based on  
246 their prior land cover to assess the influence of land cover on the timing detectability. This product has  
247 been validated within the region by Depicker et al. (2021), showing an accuracy of  $86.1 \pm 2.1\%$  in land  
248 cover classification. All above mentioned factors are considered during the analysis of the SAR timeseries  
249 and the GH event timing estimations.

### 250 **3. Methods**

#### 251 **3.1. Sentinel-1 pre-processing**

252 The S1 images are pre-processed using the "InSAR automated Mass processing Toolbox for  
253 Multidimensional time series" (MasTer) (Derauw et al., 2020, d'Oreye et al., 2021) processing chain (fig.  
254 3, step 1). MasTer is a tool for automated SAR and SAR interferometry (InSAR) mass processing  
255 (Samsonov & d'Oreye, 2012, Derauw et al., 2019; 2020, d'Oreye et al., 2019; 2021), that is incremental  
256 (i.e. only computes the minimal required information when a new image is available) and optimized for  
257 mass processing. The MasTer workflow is applied on both the ascending and descending track and  
258 consists of:

259 (1) the application of orbit correction using the precise orbit files provided with the S1 data.

260 (2) The creation of time series of amplitude maps per track. Amplitude maps of each given track are  
261 co-registered on a reference image taken from that track. Every amplitude image in the radar geometry  
262 of that track is cropped and provided with the same grid and dimensions framing the area of interest.  
263 Amplitude values are calibrated to sigma nought values. The amplitude images are multi-looked by a  
264 factor 2 in azimuth and in range, to reduce speckle, leading to a roughly 28x5 m slant range resolution.  
265 Radiometric terrain correction is applied to account for the local incidence angle varying with slope  
266 angle resulting in amplitude values that are independent of slope angle (Small, 2011).

267 (3) The creation of coherence maps using consecutive images throughout the time series with a  
268 maximum temporal baseline of 12 days and a maximum perpendicular baseline of 150 m. The coherence  
269 maps are provided with the same multi-look factor, grid, and ground range resolution as the  
270 amplitude images.

271 (4) All the amplitude and coherence maps from all the tracks spanning a given GH area are geocoded  
 272 from slant range to ground range on a common grid with a 15 by 15 m resolution using the 30 m ALOS  
 273 Global Digital Surface Model. We decided to geocode the SAR imagery to make it compatible with all  
 274 our other data products and to allow for an easier visual comparison with optical imagery.

### 275 **3.2. Spatial amplitude correlation**

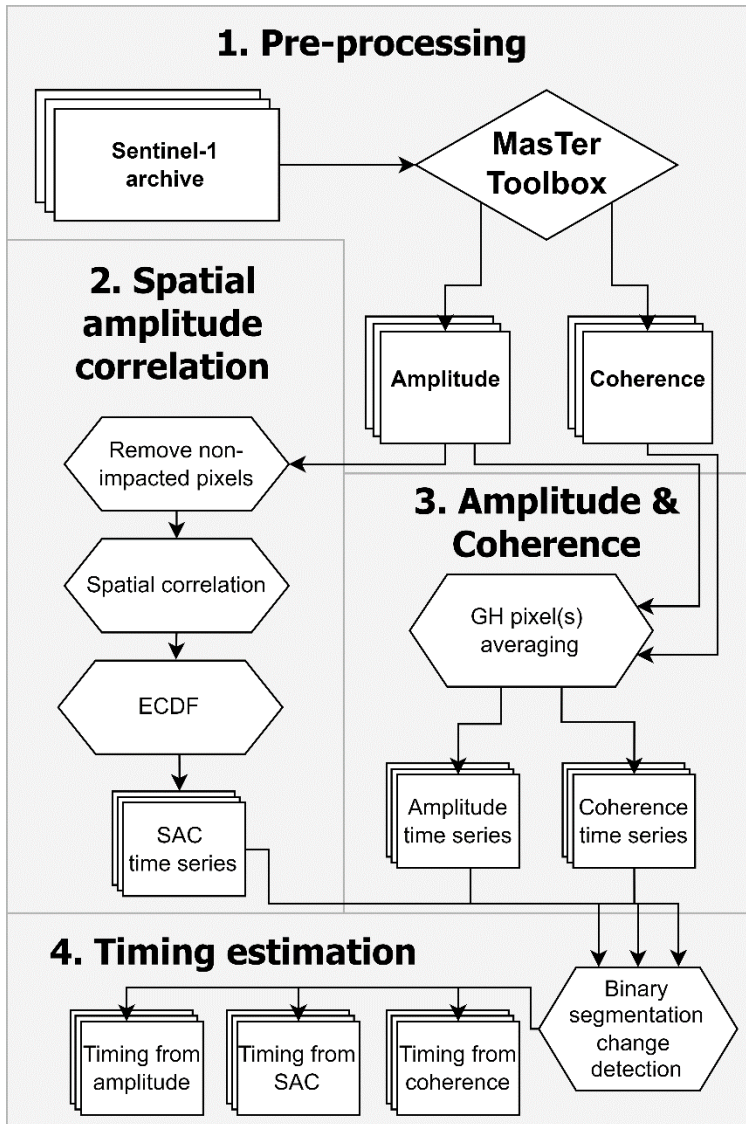

276 We adapt the amplitude correlation approach, initially used for GH spatial detection (Mondini et al.,  
 277 2017, Konishi & Suga, 2018, Jung & Yun, 2020), to allow for GH timing detection at the location of the  
 278 GH event using the amplitude image stacks (fig. 3, step 2). We reason that the spatial correlation is  
 279 generally lost when the inter-pixel relationships between two images change at the location of a GH  
 280 event. Therefore, a significant change within the landscape such as a landslide or a flash flood will cause  
 281 a significant decorrelation. Due to the sensitivity of SAR amplitude to changes in vegetation (Balzter,  
 282 2001, Barrett et al., 2012), seasonal greening and browning trends have a pronounced influence on the  
 283 amplitude time series (Balzter, 2001, Barrett et al., 2012), which potentially limits the detectability of  
 284 the GH event within the time series. Since spatial correlation is only changing when the inter-pixel  
 285 relationships change, general trends that affect the entire area (lowering or increasing the SAR  
 286 amplitude values) do not influence the inter-pixel relationships (i.e. no spatial correlation change). Only  
 287 when significant inter-pixel change occurs, due to landslides or flash floods, the spatial correlation will  
 288 change. The spatial amplitude correlation (SAC) can therefore highlight the GH event occurrence within  
 289 the time series, while reducing the seasonal dynamics. To calculate the SAC, we use equation 1 that we  
 290 adapted from Jung & Yun (2020).

$$291 \text{ SAC}_{x,y,\text{poly}} = \frac{\sum\{(A_{r,\text{poly}} - \overline{A_{r,\text{poly}}})(A_{x,\text{poly}} - \overline{A_{x,\text{poly}}})\}}{\sqrt{\sum\{(A_{r,\text{poly}} - \overline{A_{r,\text{poly}}})^2\}\sum\{(A_{x,\text{poly}} - \overline{A_{x,\text{poly}}})^2\}}} \quad x = \text{date}_1 \dots \text{date}_{N+1}; x \neq r \quad (1)$$

292 with  $\text{SAC}_{x,r,\text{poly}}$  the spatial amplitude correlation for the impacted area of date x in reference to date r,  
 293  $A_{x,\text{poly}}$  the amplitude pixels of impacted area at date x, and  $A_{r,\text{poly}}$  the amplitude pixels of impacted area  
 294 at reference date r. Instead of calculating correlation between two subsequent images over a given  
 295 window, we calculate the correlation using one reference image ( $A_r$ ) and all the other images within the  
 296 time series ( $A_x$ ) using only the pixels within a designated impacted area (e.g. single GH feature or  
 297 complete GH event) ( $\text{poly}$ ). Consequently, every image within the amplitude image stack can be used as  
 298 a reference image and due to slight changes within every amplitude image this will inevitably result in  
 299 different SAC time series, one better highlighting the GH event than the other. We apply the equation  
 300 separately for ascending and descending images in a parallel workflow. Figure 4 shows schematically  
 301 how the SAC time series should behave using different reference images. Taking a reference amplitude  
 302 image before the GH event occurrence (fig 4a), results in high SAC before and low SAC after GH event  
 303 occurrence. The opposite is expected when using a reference amplitude image after the GH event (fig  
 304 4b).

305 We use every available image within the amplitude image stack as a reference image and calculated  
 306 the respective SAC time series from it. From here, it is necessary to identify the most appropriate  
 307 reference image.

308

309

310 *Figure 3. Flowchart of the four-step methodology. Rectangles represent initial input imagery, output*  
 311 *image stacks or time series products. The rhombus represents the external software product. Hexagons*  
 312 *represent methodological steps, which are described in the text. (1) Pre-processing of the S1 imagery*  
 313 *using the MasTer processing chain to acquire amplitude and coherence image stacks. (2) Application of*  
 314 *the spatial amplitude correlation (SAC) method using Empirical Cumulative Distribution Functions (ECDF)*  
 315 *on the amplitude image stack resulting into SAC time series. (3) GH pixel(s) averaging for every image*  
 316 *in the amplitude and coherence image stacks resulting into amplitude and coherence time series. (4)*  
 317 *Application of binary segmentation change detection to acquire the date of the most significant change*  
 318 *within the amplitude, SAC, and coherence time series.*

319 Hence, we develop a new methodology that identifies the most suitable reference amplitude image by  
320 finding the SAC time series that most distinctively shows changes related to the GH event occurrence.  
321 We distribute every SAC time series as Empirical Cumulative Distribution Functions (ECDF) resulting in  
322 multiple ECDF curves equal to the amount of reference images. A SAC time series that contains a distinct  
323 change indicative of the GH event occurrence will show a similar distinct change in its ECDF.  
324 Contrastingly, SAC time series that fail to distinctively highlight the GH event, show an ECDF that is  
325 similar to a normally distributed ECDF. Therefore, we create a normally distributed ECDF, using the  
326 mean and standard deviation derived from the ensemble of ECDF curves, and identify the ECDF that  
327 deviates most from it. Per ECDF we calculate and cumulate the difference from the normally distributed  
328 ECDF. The ECDF with the highest cumulative difference is chosen as most representative and the related  
329 SAC time series was used.

### 330 **3.3. Geomorphic hazard event timing estimation**

331 GH event timing is determined on two scales within separate workflows:

- 332 • Timing workflow 1: the complete GH event scale. In this workflow, the steps outlined in figure  
333 3 are carried out once using all pixels encompassing the full GH event. This results in one  
334 ascending and one descending track time series for amplitude, SAC, and coherence.
- 335 • Timing workflow 2: the individual GH scale. In this workflow, the GH event is subdivided in  
336 multiple individual GH features and the steps outlined in figure 3 are carried out separately for  
337 each individual GH feature. This results in multiple ascending and multiple descending track  
338 time series, equal to the amount of individual GH features, for amplitude, SAC, and coherence.

339 In both workflows we do not choose to remove fuzzy pixels (i.e. edge pixels that contain both impacted  
340 and non-impacted landscape), since we do not know the effect of these pixels on the SAR time series  
341 and GH event timing estimations. This allows us to establish baseline results. The ascending and  
342 descending track data are processed separately throughout the two workflows. Amplitude and  
343 coherence time series are generated by averaging the values within the identified impacted area per  
344 image (fig 3, step 3) and the SAC time series are generated by applying the SAC method (fig 3, step 2;  
345 section 3.2) within both workflows. The resulting time series are normalized using the time series  
346 average to improve comparability.

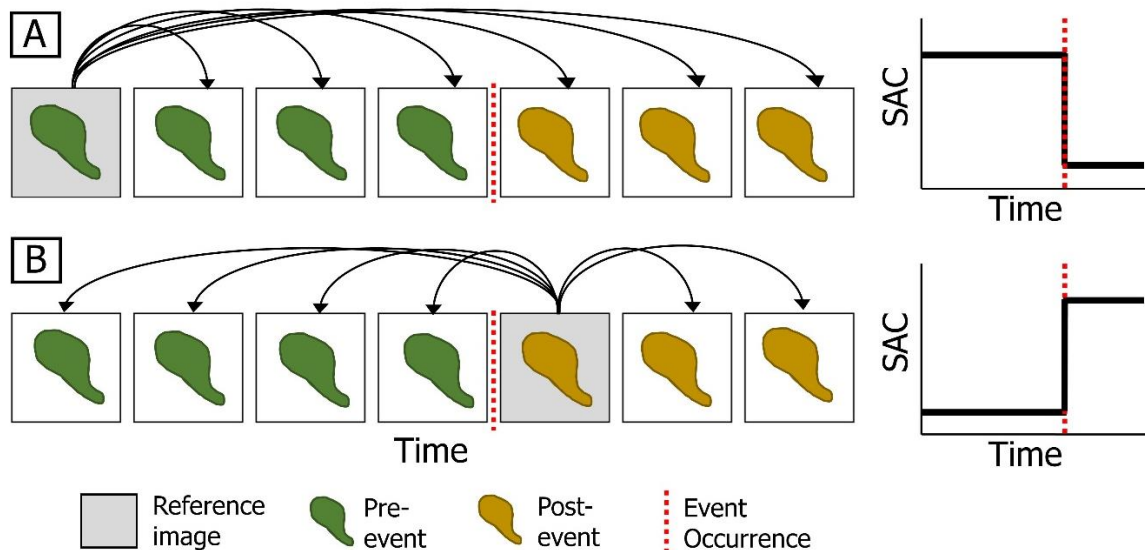

347 Additionally, we make an effort to remove the seasonal influence and atmospheric effect on the  
348 amplitude and coherence time series by subtracting the regional amplitude and coherence trend (i.e.  
349 time series) from the GH event scale amplitude and coherence time series (timing workflow 1). Both  
350 precipitation events and seasonal vegetation dynamics are expected to cover the complete GH event  
351 and its surrounding area. This detrending will therefore emphasize the change induced by the GH event  
352 occurrence while removing any regional changes induced by either seasonal vegetation dynamics or  
353 atmospheric effects (e.g. Jacquemart & Tiampo, 2021). The regional amplitude and coherence time  
354 series are established by following step 1 and 3 in the methodology flowchart (fig. 3), using a larger

355 area surrounding the GH events as input (i.e. a square of approx. 1.5 times the GH event area, excluding  
356 the exact location of the GH event). This results in the detrended amplitude and detrended coherence  
357 data products. SAC is created to already consider seasonal vegetation dynamics so no additional  
358 detrending for this data product is performed.

359 We decide not to detrend individual GH feature time series (timing workflow 2), which could include the  
360 use of a detrending buffer (e.g. Burrows et al., 2022). Since we deal with complex heterogenous land  
361 cover, proximate land cover does not necessarily represent the land cover at the GH feature, which  
362 prohibits from accurate detrending. Additional research is required before implementing such a method  
363 within a wide variety of environments.

364 Timing is defined on every time series (for amplitude, SAC and coherence) using a binary segmentation  
365 change detection approach (Bai, 1997, Fryzlewicz, 2014) using the python package 'Ruptures' (Truong  
366 et al., 2020) (fig. 3, Step 4). The algorithm was set to predict only one breakpoint since we aim to  
367 detect the most significant change in the time series. The output of the applied binary segmentation  
368 change detection algorithm is a value that represents the location of an image within the image stack.  
369 The date of this image is extracted and assigned as the earliest date after the GH event occurrence.  
370 This applies for the amplitude and SAC time series. However, since coherence is based on image pairs,  
371 it would identify the image pair right after the GH event. We therefore assign the first date from this  
372 image pair as the earliest date after the GH event occurrence. On the complete GH event scale (timing  
373 workflow 1) this results in two dates (from ascending and descending track) per data product  
374 (amplitude, detrended amplitude, SAC, coherence, detrended coherence). On the individual GH scale  
375 (timing workflow 2), this results in several dates, equal to two times (one for ascending and one for  
376 descending track) the amount of individual GH features per data product (amplitude, SAC, coherence).  
377 Here we identify the date that occurred most frequently (majority) as representing the timing of the  
378 event. We define the minimal uncertainty in timing estimation by the difference between the estimated  
379 date of occurrence and the date of the image prior to that (i.e. a maximum of 12 days).

380

381 *Figure 4. Idealized schematic of the SAC method using two different reference images: one before and*  
 382 *one after the occurrence of the GH event (A, B). Squares represent images, the red dotted line indicates*  
 383 *the occurrence of a GH event. Inside the images are the conditions of the impacted area (represented*  
 384 *here as single GH feature but is similar for complete GH event). Pre-event conditions are displayed in*  
 385 *green. Post-event conditions are displayed in brown. The black curved lines represent the combination*  
 386 *of images on which equation 1 is applied to achieve the resulting SAC time series. The schematic SAC*  
 387 *graphs (right) depict the expected results using a reference image before the event (A) with high*  
 388 *correlation before and low correlation after the event, and using a reference image after the event (B)*  
 389 *with low correlation before and high correlation after the event.*

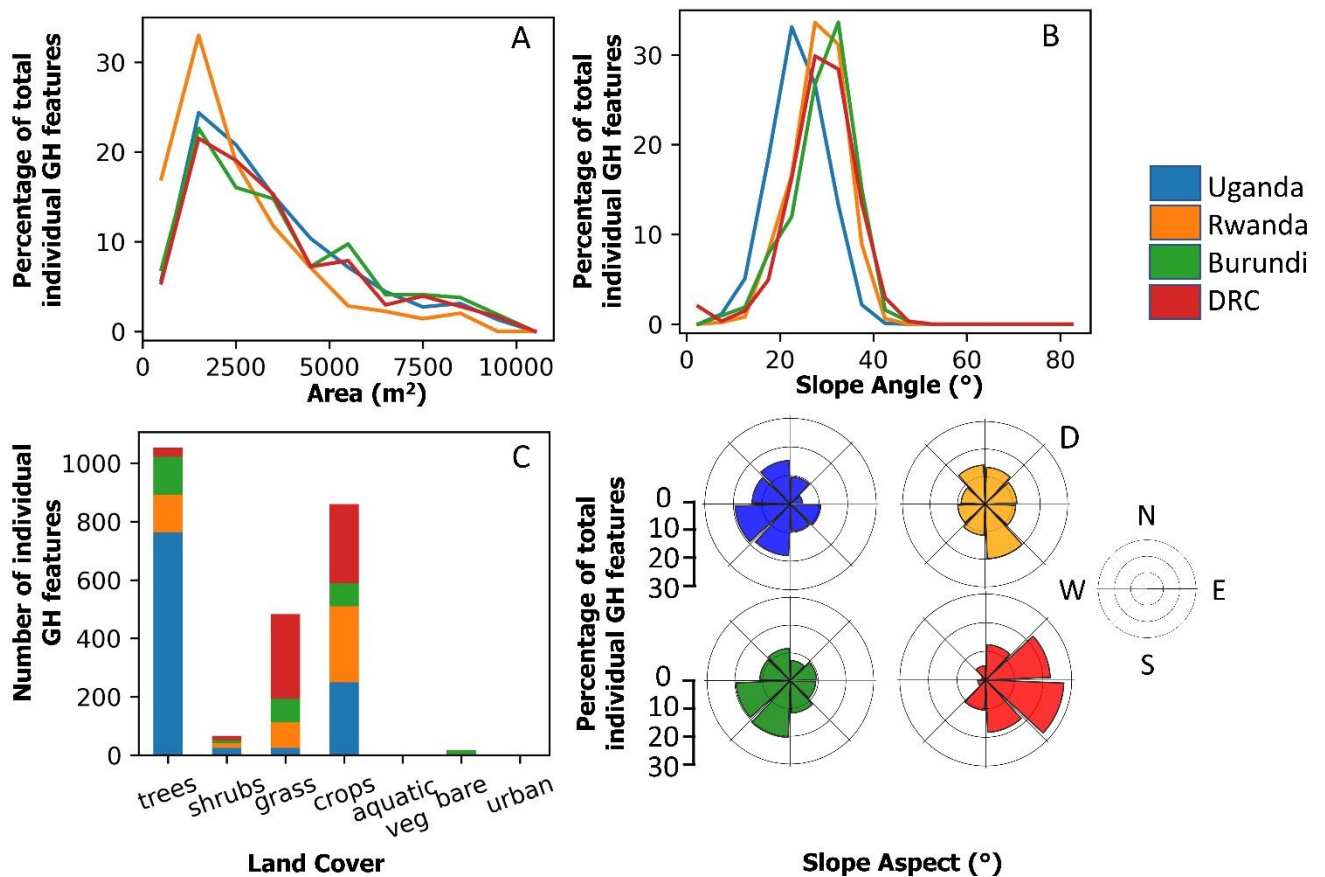

### 390 **3.4. Sensitivity analysis with respect to landscape characteristics**

391 In section 2.3 we discuss the controlling factors on the SAR signal. Here, we aim to understand the  
 392 influence of these controlling factors plus the influence of individual GH properties on the detectability  
 393 of the event timing. We carry out a sensitivity analysis on GH area (effect of a changing number of  
 394 pixels/pixel mixing, Deijns et al., 2020), slope angle (change in image acquisition geometry, Zebker &  
 395 Villasenor, 1992, Hanssen, 2001), land cover (changing vegetation and soil moisture patterns, Giertz et  
 396 al., 2005), and slope aspect (different effect of layover, shadowing within ascending and descending  
 397 track, Hanssen, 2001, Dzurisin, 2006). We carry out the analysis separately for the ascending and  
 398 descending track images. Per individual GH feature we derive the average value of the above-mentioned  
 399 parameters. We find more smaller-sized GH in the Rwanda GH event (fig 5a), a slight deviation (peak  
 400 more to the left) in slope distribution for the Uganda GH event (fig. 5b) and a large variation in slope  
 401 aspect distribution for different GH events (fig. 5d). Additionally, land cover distribution is different for  
 402 every GH event (fig. 5c) which corroborates with what we see in figure 2.

403 The sensitivity analysis is carried out iteratively over every parameter from a minimum value to a  
 404 maximum value using predefined steps (Area: 1000 m<sup>2</sup>, Slope: 5°, Land Cover: per individual land cover

405 type, Slope aspect: 45°). Per iteration the GH inventory is reduced to contain only individual GH features  
 406 that meet the iteration conditions. We exclude bins that contained less than 20 individual GH features  
 407 to avoid non-sense (very high or very low) values that would negatively influence the quality of the  
 408 trend.

409 Per bin-size, we calculate the timing for every individual GH feature, and the percentage of timing  
 410 estimates that fall within one month of the actual event occurrence over the total amount of individual  
 411 GH features. Higher percentages indicate more timing estimates closer to the actual event occurrence.  
 412 The variations within this percentage are subsequently analyzed to relate changing characteristic to  
 413 performance.

414  
 415 *Figure 5. Parameter distributions per GH event (Uganda, Rwanda, Burundi, and DRC). (A) Percentage*  
 416 *of individual GH over total amount of individual GH against area (m<sup>2</sup>), bins of 1000 m<sup>2</sup>. (B) Percentage*  
 417 *of individual GH over total amount of individual GH against slope angle, bins of 5°. (C) Number of*  
 418 *individual GH against land use/land cover. (D) Percentage of individual GH over total amount of*  
 419 *individual GH against slope aspect, bins of 15°.*

## 420 **4. Results**

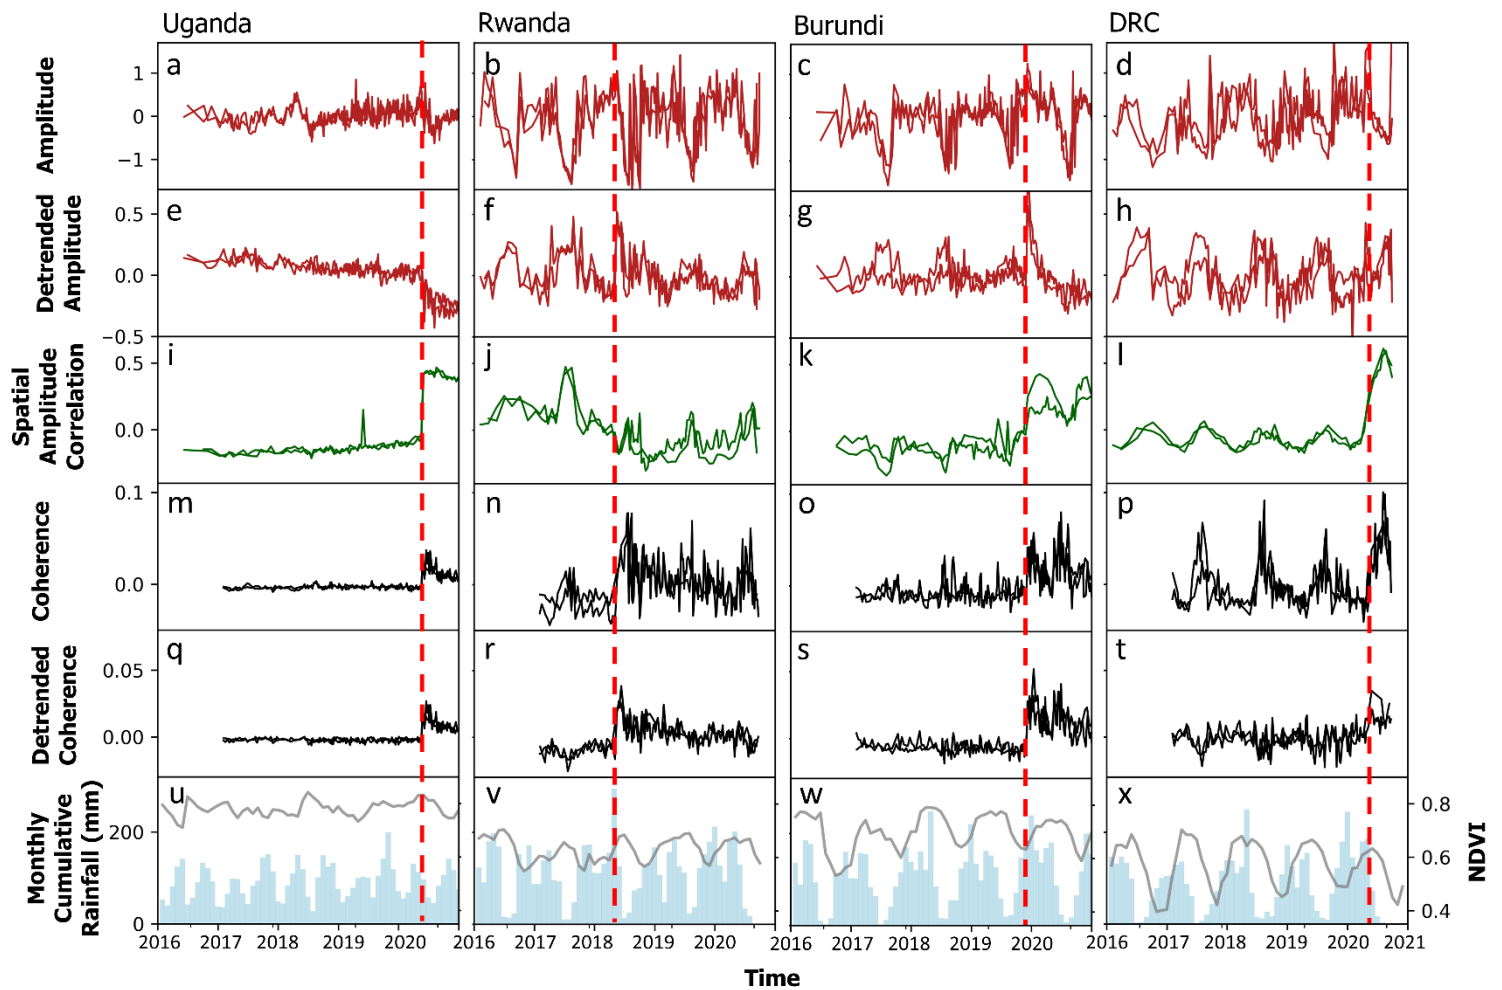

### 421 **4.1. Geomorphic hazard event time series**

422 We created amplitude, detrended amplitude, SAC, coherence, detrended coherence time series for the  
423 four GH events in Uganda, Rwanda, Burundi, and DRC (location in fig. 1) and present it in figure 6  
424 together with the average monthly Landsat 8 NDVI and IMERG monthly cumulative precipitation.

425 The distinctiveness of the GH event occurrence within the time series varies significantly per data  
426 product (fig. 6). SAC (fig. 6i-l) and coherence (fig. 6m-t) time series showcase the timing of the event  
427 with a significant change of value at the time of the event occurrence. A significant decrease in co-event  
428 (the coherence value from the pre- and post-event image) coherence is not visible.

429 The amplitude time series do not show any distinct change at the time of the GH event occurrence (fig.  
430 6a-h), except for the Uganda GH event (fig 6a,e). Particularly in the amplitude time series, and to a  
431 minor extent in the coherence time series, clear cyclicity can be observed, that correspond with the two  
432 drier periods (December-February and June-August) that are prevalent in the region (Bonfils, 2012,  
433 Nicholson 2017, Monsieurs, 2018a). The NDVI shows seasonal correlation with the precipitation  
434 patterns, where NDVI patterns follow precipitation patterns with a short time lag (fig 6u-x). Stronger  
435 NDVI variations align with a stronger cyclicity within the amplitude, SAC, and coherence time series  
436 which is particularly visible when comparing the Uganda GH event (weak amplitude SAC and coherence  
437 cyclicity, limited NDVI fluctuations) and the DRC GH event (stronger amplitude, SAC, and coherence  
438 cyclicity, large NDVI fluctuations). The cyclicity clearly influences the distinctiveness of the GH event  
439 within the time series. When comparing the landscape of both GH events (fig. 2a,d) a sharp contrast is  
440 observed. The Uganda GH event region is mostly covered by forest, whereas the DRC GH event region  
441 is mostly covered by grass- and cropland. Consequently, we find that seasonal NDVI oscillations vary  
442 significantly from one study area to another given the difference in landscape.

443 Time series detrending clearly reduces seasonal cyclicity within the time series, which is particularly  
444 visible for the coherence time series (fig. 6q-t) and to a much smaller degree for the amplitude time  
445 series (fig. 6e-h). For example, the DRC GH event coherence time series benefits from this detrending  
446 procedure such that seasonal cyclicity is almost completely removed, leaving a distinct increase in  
447 coherence values after the occurrence of the GH event (fig. 6t). Detrending the amplitude time series  
448 shows a minor reduction in cyclicity, but the distinctiveness of the GH event within the time series  
449 remains low.

450 *Figure 6. GH event (detrended) amplitude (red), spatial amplitude correlation (SAC, green) and*  
 451 *(detrended) coherence (black) time series. The dashed red line represents the timing of the GH event*  
 452 *occurrence within the time series. All coherence, amplitude and SAC time series show two lines of a*  
 453 *similar color representing the ascending and descending track time series. The time series are created*  
 454 *according to the complete GH event scale workflow described in sections 3.3. The bottom row shows*  
 455 *the monthly cumulative precipitation (light blue bars) from IMERG satellite data and the monthly*  
 456 *averaged NDVI values (grey line) from Landsat 8 (method described in section 2.3).*

#### 457 **4.2. Geomorphic hazard event timing**

458 Figure 7 shows the timing estimation at the GH event scale (timing workflow 1) from the (detrended)  
 459 amplitude, SAC and (detrended) coherence time series. The difference in days from the actual  
 460 occurrence of the GH event is visualized by a range that incorporates the minimal uncertainty in timing  
 461 estimation (fig. 7 and fig. 8; see section 3.3). Timing estimations from the amplitude time series  
 462 generally have lower accuracies with estimated timing ranging from a 46 day difference (Uganda,  
 463 descending) to a 1000 day difference (Uganda, ascending). Estimations from the SAC time series range  
 464 between a 1 day (Uganda) and an 85 day (Rwanda) difference and estimations from the coherence  
 465 time series range between a 1 day (Uganda) and a 47 day (Rwanda) difference. Highest accuracies are

466 achieved with time series showing less seasonal fluctuation and a steep change at the time of event  
467 occurrence (fig. 5). Timing estimations from the detrended amplitude time series show an increased  
468 accuracy compared to amplitude time series with the most significant change for the Uganda GH event  
469 from a 46-1000 to a 13-22 day difference, but performance is still poor and generally useless for accurate  
470 timing estimation. Detrending the coherence time series increases timing estimation accuracy compared  
471 to the non-detrended coherence timing estimation for the DRC event (25-32 to a 1-5 day difference),  
472 but in general the estimations remain the same.

473 Figure 8 shows the timing estimation based on the individual GH features within the GH event (timing  
474 workflow 2). Here, the estimated timing represents the date that is estimated most frequently between  
475 all individual GH features (as explained in section 3.3). The percentage of individual GH features that  
476 estimate this (most frequently estimated) date over the total amount of GH features (%maj) are shown  
477 in figure 8.

478 In general, timing estimation from the amplitude time series have low accuracies with estimated timing  
479 ranging from a 13 day difference to an 831 day difference. A distinct increase in accuracy is seen for  
480 the Uganda GH event compared to the GH event scale (fig. 7) However, the other GH events do not  
481 show any distinct increase in timing estimation accuracy. The %maj ranges between 13% and 32.4%  
482 and shows that for some GH events a large portion of the individual GH features estimate a date that  
483 is far from the actual date of the GH event occurrence. The percentage of individual GH features that  
484 estimate a date within one month of the actual GH event occurrence from amplitude time series is  
485 24.2% (ascending) and 26.9% (descending) for the Uganda GH event, but much lower for the other  
486 GH events, corroborating the fact that the timing detection method performs poorly for the amplitude  
487 data product.

488 Timing estimations from the SAC time series from individual GH features (fig. 8) differ compared to the  
489 timing estimations at the GH event scale (fig. 7). An increase in accuracy is seen for Rwanda (ascending)  
490 and DRC (ascending) and a decrease in accuracy for Burundi (ascending) and DRC (descending). The  
491 estimated timing ranges from a 1 day difference to an 85 day difference. Although estimated timing  
492 accuracy is higher for SAC compared to amplitude, %maj values are quite low, indicating weak  
493 estimations. The percentage of individual GH that estimate a date within one month of the actual GH  
494 event occurrence ranges from 0.2 (Rwanda, descending) to 38,1 (Uganda, descending). Exceptionally,  
495 for the Uganda GH event, %maj and estimated timing within one month of the GH event occurrence  
496 from the SAC time series is highest in comparison with amplitude and coherence (fig. 8).

497 Timing estimations from the coherence time series from individual GH features (fig. 8) are similar to  
498 those achieved at the GH event scale (fig. 7), and have, generally, the highest accuracy for all data  
499 products. The %maj values ranged from 13.5 (Burundi, ascending) to 38.4 (DRC, descending). The  
500 percentage of individual GH features that estimates a date within one month of the actual GH event  
501 occurrence ranges from 0 (Rwanda, descending) to 38,4 (DRC, descending). The low percentages from

502 the Rwanda descending track can be attributed to the fact that the estimated date is 37 days from the  
 503 GH event occurrence and therefore just falls outside the one-month threshold.

504

 514 *section 3.3). Dashed lines on the bars represent the overlap between the ascending and descending*  
 515 *track results. In the %maj column we present the percentage of individual GH features over the total*  
 516 *amount of individual GH features that were included in the majority vote separated for the ascending*  
 517 *(asc) and descending (dsc) track. In the 'within one month' column we present the percentage of*  
 518 *individual GH features over the total amount of individual GH features that estimated a date within one*  
 519 *month of the actual event occurrence.*

520 **4.3. Sensitivity analysis with respect to landscape characteristics**

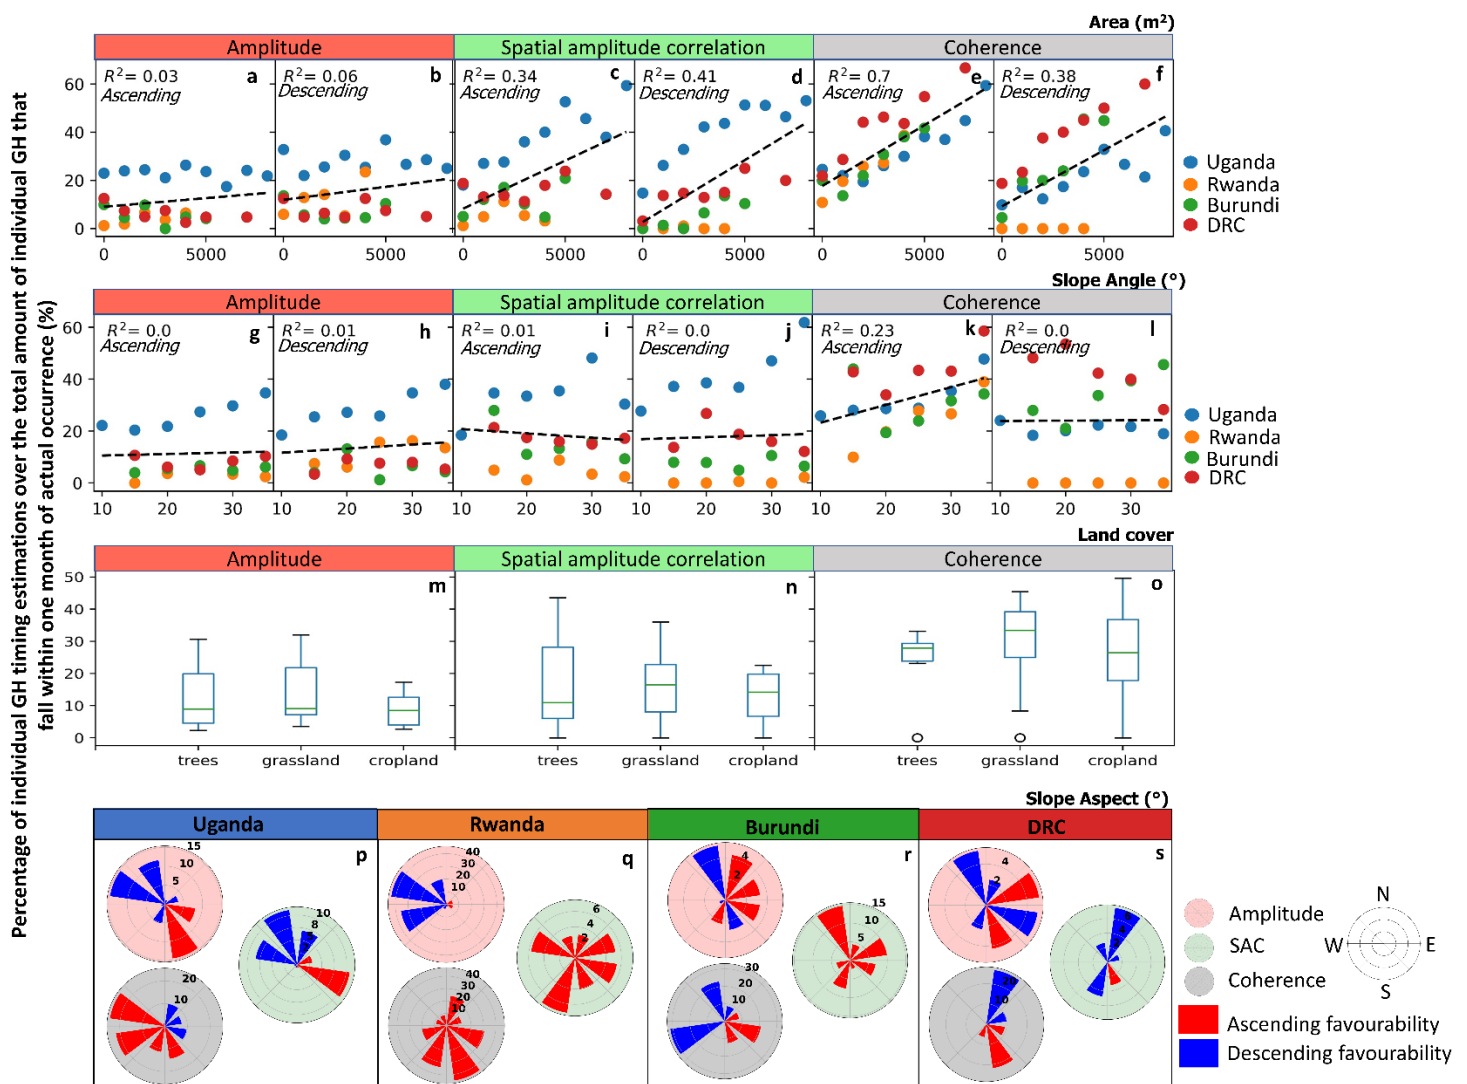

521 GH size seems to have a clear influence on time estimation accuracy. Specifically, the SAC and coherence  
 522 show a clear increase in percentages of estimated timing within one month of the GH event occurrence  
 523 with increasing GH size (fig. 9 a-f).  $R^2$  values show a relatively reliable fit for both SAC and coherence.  
 524 Amplitude shows a slight increasing trend, but associated  $R^2$  values are non-significant.

525 Slope trend lines (fig. 9 g-l) show in general little to no inclination and  $R^2$  values are non-significant,  
 526 except for the coherence ascending track. Here, a clear increase in slope angle becomes visible with a  
 527 comparatively higher  $R^2$  (although clearly less significant than  $R^2$  from the GH size analysis).

528 To assess the general influence of land cover on the ability to estimate GH event timing we combined  
 529 both the ascending and descending track results for all four GH events in each boxplot (fig. 9 m-o).  
 530 Each boxplot therefore contains a total of eight data points per land cover type. The major land cover  
 531 classes within the GH events were tree covered area, grassland, and cropland (Fig 4d). Median  
 532 percentage values range around 9-10 % for amplitude, 11-16 % for SAC, and 27-34 % for coherence.  
 533 Although median values within the grassland land cover type seem to be systematically higher among

534 the three data products (amplitude, SAC, and coherence), differences with other land covers are quite  
 535 small. No specific land cover shows a significant better performance.

536 To assess the influence of the slope orientation, we derive the difference between ascending and  
 537 descending track percentages per bin and determine which track shows better performance (fig. 9p-s).  
 538 At the results for the Rwanda GH event (fig. 9q) we see for SAC and coherence an all-round favorability  
 539 for the ascending track, that can be explained by the fact that, like the results in figure 8, the Rwanda  
 540 GH event had almost no estimations within one month of the GH event occurrence for the descending  
 541 track. The results presented for Uganda, Burundi and DRC GH events (fig. 9p,r,s) show a general  
 542 favorability of the ascending track for individual GH features that have an aspect of approximately 45-  
 543 180°, whereas a general favorability of the descending track for individual GH features that have an  
 544 aspect of approximately 225-360°. In contrast to this general trend, the opposite seems to be visible  
 545 for the Uganda GH event coherence.

546 *Figure 9. Timing estimation performance over changing individual GH feature area (a-f), slope angle (g-*  
 547 *l), land cover (m-o) and slope aspect (p-s). The y-axis displays the percentage of individual GH features*

548 *that estimated a timing that falls within one month of the actual GH event occurrence over the total*  
549 *amount of individual GH features per GH event. Bin sizes: area=1000m, slope angle=5°, slope*  
550 *aspect=45°. Area (a-f) and slope angle (g-l) plots are separated per track, and the colors indicate the*  
551 *different GH events. The black dashed lines present the linear trend lines fitted to the data (a-l) for*  
552 *which the associated  $R^2$  values are included. Land cover (m-o): boxplots give lower and upper quartiles*  
553 *and median. The whiskers of each box represent 1.5 times the interquartile range. Outliers beyond*  
554 *whiskers are shown as dots. Slope aspect (p-s): the polar plots present the favorability of the ascending*  
555 *(ASC) or descending (DSC) track per slope aspect (see section 4.3). The color of the polar plot*  
556 *background indicates the SAR data product.*

## 557 **5 Discussion**

558 In this study we present a regionally applicable methodology to automatically determine GH event timing  
559 using S1 SAR data. Our study improves on the recent advances in GH event timing estimation research  
560 as: (1) we are one of the firsts to use amplitude, SAC and coherence time series in a systematic manner  
561 to detect the timing of GH events (Mondini et al., 2021), (2) we defined a methodology where no prior  
562 knowledge of the GH event timing is required, (3) we applied our methodology on contrasting  
563 landscapes and (4) we combined, for the first time, landslides and flash floods in a single detection  
564 approach. Here we discuss our insights, results considering recent developments, and the potential  
565 improvements and future perspectives of our methodology.

### 566 **5.1. Insights in geomorphic hazard event timing estimation from SAR**

#### 567 **5.1.1 Geomorphic hazard event timing estimation**

568 The use of amplitude or detrended amplitude time series in our methodology does not prove to be an  
569 effective approach to accurately determine the timing of GH events since it gives an estimation accuracy  
570 of 13 to 1000 days with the actual time occurrence of the events. A clear increase in accuracy is obtained  
571 from SAC with an accuracy of 1 to 85 day. However, the most accurate results are achieved with  
572 coherence and detrended coherence with a 1 to a 47 day accuracy.

573 GH event timing accuracies are higher for GH events that occurred in remote areas with low amounts  
574 of cultivation and human influence (highest accuracies for Uganda GH event, lowest for Rwanda GH  
575 event). The magnitude of the seasonal vegetation oscillations, which shows connectivity with the  
576 precipitation patterns (fig. 6), varies significantly with changing landscapes and results in profound  
577 seasonal cyclicity in both the amplitude and coherence timeseries. Although the coherence is additionally  
578 influenced by atmospheric effects (Rocca et al., 2000), the influence of both the vegetation and  
579 atmosphere on the coherence does not obscure the GH event induced change within the time series.  
580 Notably, after detrending, the effects of both seem to be almost negligible. Denser and taller vegetation,  
581 result in lower seasonal cyclicity within the amplitude and coherence time series. S1 operates in C-band  
582 frequency, meaning that the emitted signal penetrates the canopy layer and subsequently bounces on  
583 the branches, and leaves underneath (Dzurisin, 2006). A reduction in vegetation after a seasonal dry

584 period within sparsely vegetated areas, i.e. the grass- and croplands in the DRC GH event, will likely  
585 expose the soil underneath and have a pronounced influence on the backscattering signal given the  
586 difference in backscattering properties of vegetation and soil (Strozzi et al., 2000, Weydahl, 2001,  
587 Colesanti & Wasowski, 2006, Tessari et al., 2017). In contrast, a seasonal dry period in a dense forest,  
588 (i.e. Uganda GH event) would affect the density of the canopy cover. However due to the height and  
589 close vicinity of the vegetation to each other a dry period does not necessarily lead to more soil  
590 exposure. This is corroborated by the fact that the NDVI does not change much for the Uganda GH  
591 event, despite the seasonal patterns in precipitation (fig. 6). The regions that are covered with the  
592 denser and most uniform vegetation are commonly environments with the lowest chance of getting  
593 timing information from other sources (media, citizen-observer networks) as compared to GH events in  
594 more inhabited landscapes (Jacobs et al., 2019, Monsieurs et al., 2019).

595 The complex reaction of the SAR signal to soil moisture and roughness change can causes both an in-  
596 and decrease of the amplitude at the same GH event location (Mondini et al., 2021, Burrows et al.,  
597 2022). Next to the seasonal influence (fig. 6), this can also be a potential reason why no significant  
598 changes at the timing of the GH event are distinguished for all GH events. The inter-pixel variation  
599 captured in SAC proves to be a good tool to account for both this potential in- and decrease and any  
600 seasonal variation in amplitude values at the location of the GH event and increased timing estimation  
601 accuracy.

602 The pre-event, co-event, and post-event coherence values of our four GH events correspond with the  
603 study of Tzouvaras et al. (2020), where a distinct difference in pre- (low) and post- (high) GH event  
604 coherence values is observed at the location of a landslide occurrence. We observe the same patterns  
605 with the GH events that contain flash floods, likely because a clear landscape change is observed after  
606 the occurrence of the (often sediment-rich) flash floods (fig. 1). The co-event coherence drop as  
607 observed by Tzouvaras et al. (2020) and Burrows et al. (2019) at the location of a landslide occurrence  
608 does not prove to be significant enough to be able to determine GH event timing. This is most likely  
609 attributed to the fact that the GH events occurred in low-coherence (vegetated) areas (Weydahl 2001,  
610 Tessari et al., 2017).

### 611 **5.1.2 Geomorphic hazard event distribution**

612 An increase in GH area improves the accuracy of timing detection, which can likely be related to the  
613 increased number of pixels fully covering the GH feature relative to the fuzzy edge pixels (e.g. Foody  
614 and Mathur, 2006, Deijns et al., 2020, Zhong et al., 2021).

615 Generally, accuracy is not correlated with slope angle (fig. 9). However, an increase in accuracy with  
616 increasing slope with a relative low reliability is observed for coherence. Nevertheless, this trend must  
617 be considered with a certain caution: (1) the trend is dependent on the quality of terrain correction  
618 during the pre-processing step (section 3.1), which should make SAR values independent of slope angle  
619 (Small, 2011), (2) a changing slope angle could influence the GH size (Chen et al., 2016), (3) we take

620 the average slope angle per GH. Elongated GH features (mainly the flash flood features in the GH  
621 inventories) will have an average slope angle that is not representative for every part of the GH.

622 Although a clear difference can be observed in time series response to GH events located in different  
623 landscapes (fig. 6), the comparison with the land cover does not allow to find a clear relationship with  
624 the type of vegetation (fig. 9). Since the land cover distribution is not equal amongst GH events (fig.  
625 5), the results are, for some GH events, based on a low amount of individual GH features. The general  
626 trends could therefore also be influenced by additional underlying trends such as GH size and GH slope  
627 angle. The observed large variation in values per box plot (fig. 9m-o) might be an indication of this.

628 By using the right-looking S1 satellite data, foreshortening, and layover effects should be limited with  
629 descending track acquisitions for GH exposed towards the west (180-360°) and with ascending track  
630 acquisitions for GH exposed towards the east (0-180°). The shadow affects in the opposite direction  
631 and is dependent on the slope of the terrain (Bamler, 2000). We see that, generally, the individual GH-  
632 features on the descending slope tend to have a higher timing estimation accuracy for the west facing  
633 slopes and the individual GH features on the ascending track for the east facing slopes, which is as  
634 expected. However, there remains variability in the result, for example, an opposite pattern is visible  
635 for Uganda GH event with the coherence and a partial favorability for the descending track acquisition  
636 on east facing slopes is visible for the DRC GH event. Future research on the detailed effect of changing  
637 GH feature aspects on the ascending and descending SAR time series can provide additional valuable  
638 information in this context.

639 Our derived trends are established from GH events with each 318 to 1063 individual GH features and  
640 provide a good indication of the SAR response to changing landscape parameters. It remains interesting  
641 to see if these trends sustain with the addition of more GH events from different landscapes.

## 642 **5.2. Result considering recent developments in SAR timing detection**

643 Our results are somewhat in contrast with Burrows et al., (2022), who argue that coherence is less  
644 performant than amplitude for GH event timing. Using amplitude data, they were able to estimate the  
645 timing of ~ 30% of landslides per inventory with an accuracy of ~80% and an average precision of 12  
646 days. Whereas by using coherence (60x60m resolution) they acquired much less accurate results (24-  
647 47% correctly estimated). Their study, however, differs in several aspects from our analysis:

648 1. Burrows et al., (2022) applied their method with a pre-defined notion of GH event timing, i.e. known  
649 year and season. For our GH events, we see distinct seasonal dynamics mainly within the amplitude  
650 time series. Zooming in on a specific time frame (3 months before and 3 months after the GH event  
651 occurrence like Burrows et al. (2022)) reduces the overall seasonal dynamics, which could be the  
652 cause of a wrongly identified GH event change. Reducing this time window will potentially improve  
653 the detectability of the GH event within the time series. However, our methodology is intended to  
654 be applicable in areas such as the western branch of the East African Rift, an area characterized by  
655 data scarcity (Dewitte et al., 2021). In areas like these, information on the temporal distribution of

656 GH events may not always be available. We therefore defined a methodology that requires no  
657 knowledge on GH event timing before application, which is an advantage if no GH event timing is  
658 present, however, this increases the chance of any seasonal influence visible within the time series.

- 659 2. They applied their method on landslides only. In our case, the addition of flash floods to the  
660 inventories introduces different types of contrasting GH shapes, slopes and land cover (flash floods  
661 tend to be elongated, occur in the valleys with shallower terrain, whereas landslides occurred mainly  
662 on the steeper hillslopes) that can influence the SAR time series, specifically if the flash flood enters  
663 urbanized area (such as in the DRC GH event) or run through a seasonally dynamic channel with  
664 seasonally changing soil moisture levels influencing the SAR signal (Ulaby et al., 1996, Scott et al.,  
665 2017).
- 666 3. Their used landslide inventories (from Roback et al., 2018 and Emberson et al., 2022) are located  
667 in densely vegetated areas (NDVI between 0.6 and 0.8). In agreement with Burrows et al. (2022)  
668 our results show that the Uganda GH event, where most of the landscape consists of dense  
669 vegetation (i.e. the highest NDVI values), estimated GH event timing accuracies are the highest  
670 among all GH events, obtaining a 1-2 images difference from the actual GH event occurrence for  
671 SAC (1-16 days) and (detrended) coherence (1-8 days). Although amplitude is overall less  
672 performant for the Uganda GH event, we still achieve an accuracy off 13-22 days for the detrended  
673 amplitude.
- 674 4. We do not threshold on individual GH area. Specifically, the Rwanda GH event contains a GH event  
675 size distribution that includes many small individual GH features below the threshold used in Burrows  
676 et al. (2022) (fig. 5). Together with the complexity and large fraction of cultivation of the landscape  
677 this clearly results in reduced estimation accuracies.
- 678 5. They removed landslide timing estimations using the magnitude of change caused by the landslide  
679 within the SAR time series, which allowed them to improve the estimation accuracy.

### 680 **5.3 Improvements and perspectives**

681 The current methodology successfully allows to analyze GH event timing from SAR, but several  
682 improvements can be considered in future research.

#### 683 **5.3.1 Improvements**

- 684 1. In the current methodology we do not detrend individual GH feature time series (see section 3.3).  
685 Because detrending does increase timing accuracy within our study, further research on accurate  
686 detrending of individual GH time series can potentially greatly benefit timing estimation accuracy.
- 687 2. We use one change detection algorithm (ruptures: Truong et al., 2020) to estimate GH event timing.  
688 Comparing multiple change detection algorithms (e.g. Deijns et al., 2020, Burrows et al., 2022),  
689 could potentially benefit GH event timing estimation accuracy.
- 690 3. The quality of the amplitude and coherence imagery is dependent on the quality of the pre-  
691 processing applied with the MasTer tool (Derauw et al., 2020, d'Oreye et al., 2021) and how it deals  
692 with the different steps such as co-registration, radiometric terrain correction and geocoding. Quality

693 of the imagery in its turn is also dependent on, among others, the multi-look factor (amplitude),  
694 the interferometric multi-look factor and the maximum temporal and perpendicular baselines  
695 (coherence). In addition, different polarizations may yield different results (Shibayama et al., 2015,  
696 Psomiadis, 2016, Park & Lee, 2019) and the use of a different polarization can potentially improve  
697 event detectability within the time series. Improvements within the SAR imagery might be achieved  
698 by tweaking and closely investigating different pre-processing steps to achieve better image quality.

- 699 4. The SAC result depends on the ability to find the best reference image (section 3.2). Additional  
700 efforts can be made to better find the SAC time series that shows the most significant change  
701 related to the GH event occurrence. For example, a preliminary filtering of very noisy SAC time  
702 series (before applying our developed method using the ECDF's) can potentially benefit the ability  
703 to acquire the best reference image.

704

### 705 **5.3.2 Perspectives**

- 706 1. We have studied, for the first time in a GH event timing detection approach, both landslides and  
707 flash floods in a combined methodology. Since these GH often co-occur and interact (Marengo &  
708 Alves, 2012, Jacobs et al., 2016a, Rengers et al., 2016) they should be analyzed in a multi-hazard  
709 approach. Our methodology can be well applied within such an approach. For example, multi-hazard  
710 inventories can serve as input for our methodology if there is a need to improve their timing  
711 accuracy. Results can subsequently be used in hazard assessment, early warning, and disaster risk  
712 reduction strategies.
- 713 2. Our study shows that there is a clear advantage to analyzing different S1 SAR data products when  
714 estimating GH event timing. The fact that Burrows et al. (2022) shows better results for amplitude  
715 compared to coherence data is in contrast with our results but reinforces the idea of investigating  
716 both data products when applying the methodology to new regions.
- 717 3. Given the clear influence of landscape and climate as controlling factors for SAR time series behavior  
718 (section 2.3), we aimed to develop our methodology within a variety of contrasting landscapes and  
719 contrasting vegetation dynamics. This offers perspectives for transferability. We show that slope  
720 angle does not seem to influence accuracy (fig. 9). Based on landscape characteristics,  
721 transferability to other regions seems therefore likely to acquire good results, specifically for the  
722 SAC, coherence and detrended coherence time series as they do seem less influenced by seasonal  
723 dynamics than the amplitude and detrended amplitude time series (fig. 6). However, climate drivers  
724 could also potentially play a role. For example, since soil moisture and wetness have an influence  
725 on amplitude and coherence time series (Ulaby et al., 1996, Srivastava et al., 2006, Brancato et al.,  
726 2017, Scott et al., 2017), contrasting precipitation regimes within other regions could potentially  
727 influence the response of the SAR time series and the estimated GH event timing accuracy.  
728 Examples of contrasting precipitation regimes are: (1) a lower amount of precipitation in more arid  
729 regions, or lower/higher amounts in other tropical regions (Fick and Hijmans, 2017); (2) a change  
730 in precipitation seasonal variability due to spatially different oscillation of the ITCZ (Nicholson, 2017,  
731 Dewitte et al., 2022); (3) the effect of local topography and the presence of lakes on the local

732 precipitation patterns (e.g. Thiery et al., 2015; 2016; 2017, Monsieurs et al., 2018b). The influences  
733 of these contrasting precipitation regimes on SAR-based GH timing detection, however, remains to  
734 be investigated. Additionally, in its current form, the methodology does not account for the GH  
735 events that occur within a time span that is longer than the acquisition time (> 6-12 days) of S1  
736 images (i.e. multi-temporal GH events). In that case one would require a time window of  
737 occurrence, rather than a specific date. The methodology can be adapted to allow it to derive a  
738 time window of GH occurrence. This could mainly be done following the GH event scale, where the  
739 start and the end date of the GH event inducing change within the SAR time series (applicable for  
740 all data products) should be indicative of the time window of GH event occurrence. However, this  
741 remains to be investigated.

- 742 4. The open-access S1 satellite with its high resolution, high repeat time and global coverage proves  
743 to be an excellent data product for estimating GH event timing and allows for our developed  
744 methodology to be applied on every region of the world. The use of our methodology with different  
745 satellite products (e.g. COSMO-SkyMed, upcoming NISAR satellite) is not straightforward. Different  
746 available SAR satellite products operate in different bands with their own characteristics (e.g. X-  
747 band for COSMO-SkyMed (Covello et al., 2010) and L-band for NISAR (NISAR, 2018)), that will likely  
748 have implications on the ability for accurate GH event timing estimation. For example, the varying  
749 vegetation penetration depths associated with different SAR bands (Dzurisin, 2006) will likely have  
750 an influence on the impact of seasonal vegetation dynamics on the SAR time series as observed for  
751 our GH events (fig. 6).
- 752 5. The methodology can benefit (in terms of data availability, scalability, and processing time) from  
753 implementation on a cloud computing service. Cloud computing platforms such as GEE only provide  
754 pre-processed amplitude imagery (i.e. amplitude ground range detected imagery). As such, they  
755 allow for the applicability of our methodology using the amplitude, detrended amplitude and SAC  
756 data products. To our knowledge, so far, no cloud computing platform offer the possibility for  
757 processing and using coherence data. Additionally, the use of pre-processed amplitude imagery  
758 restrains us from manual input during the pre-processing step (as the MasTer Toolbox allows).
- 759 6. The methodology can potentially be combined with optical data (e.g. Deijns et al., 2020) that could  
760 serve as additional data to help narrow down the time window and filter out any non-sense timing  
761 estimations.

## 762 **6. Conclusion**

763 We established a regionally applicable methodology to automatically determine GH event timing from  
764 SAR images, that can be applied without prior knowledge of the GH event. We successfully assessed  
765 the use of multiple SAR derived data products in their ability to accurately detect GH event timing in  
766 contrasting landscapes. We show that landslides and flash floods can be detected and studied together,  
767 hence we open new perspectives in the study of multi-hazards, that can subsequently aid in hazard  
768 assessment, early warning, and disaster risk reduction strategies. Our methodology has the potential to

769 be combined with existing spatial detection methods to support inventory creation and boost GH event  
770 research in remote inaccessible areas such as the African cloud-covered tropics.

771 From a data processing point of view, the methodology is established around an unprecedented analysis  
772 of various SAR products coming from Sentinel-1 (S1) images. We show that there is a need to investigate  
773 different SAR data products when estimating GH event timing (amplitude, spatial amplitude correlation,  
774 and coherence) since the signal response can be different and sometimes contradictory when looking  
775 at one single event. The implementation of our methodology on a cloud computing platform can be  
776 beneficial in terms of scalability, data availability and processing time. However, the main limitations in  
777 this context are: (1) no control in pre-processing of S1 imagery and, (2) S1 coherence data is so far not  
778 available within these platforms.

779 With a focus on four events containing a total of about 2500 landslides and flash flood features in  
780 contrasting landscapes, we propose a methodology that is adapted to be applied to other regions. Here,  
781 we focused on tropical environments where climate conditions and land use dynamics are rather specific.  
782 However, we believe that the complexity of these landscapes is an added value for the transferability  
783 of the methodology. Additionally, the use of the globally available open access S1 satellite data allows  
784 our methodology to be applied on every region of the World.

#### 785 **Acknowledgement**

786 This study was supported by the Belgium Science Policy (BELSPO) through the PASTeCA project  
787 (BR/165/A3/PASTECA) entitled "Historical Aerial Photographs and Archives to Assess Environmental  
788 Changes in Central Africa" (<http://pasteca.africamuseum.be>), and the GEOTROP project  
789 (B2/223/P1/GEOTROP) entitled "Geomorphic hazards and compound events in a changing tropical East  
790 Africa". The compilation of the inventory data benefited from field-based insight and discussion with  
791 Arthur Depicker, Josué Mugisho Bachinyaga, John Sekajugo and Judith Uwihirwe. PlanetScope data  
792 provided by the European Space Agency.

793 **Code and data availability**

794 Sentinel-1 and Sentinel-2 data are provided open-access by the European Space Agency. Landsat 8 data  
795 are provided open access by the U.S. Geological Survey. The Python scripts for the GH event timing  
796 estimation, sensitivity analysis, and precipitation analysis and the Google Earth Engine code for  
797 vegetation analysis can be accessed at: <https://doi.org/10.5281/zenodo.7198346>. The four GH  
798 inventories can be downloaded at: <https://doi.org/10.5281/zenodo.7198322>

799 **Author contribution**

800 AAJD, OD, FK and WT conceived the study. AAJD compiled the landslide and flash flood inventory with  
801 the support of OD. AAJD processed and analyzed the data. OD conducted field work for the validation  
802 of the inventory. AAJD wrote the original draft of the manuscript, with key initial input from OD and FK.  
803 NO trained AAJD in SAR image pre-processing. All the authors contributed to reviewing and editing the  
804 manuscript. OD obtained funding for this work.

805 **Competing interests.**

806 The authors declare no conflict of interest.
