23

24 **Abstract.** First analyses of landslide distribution and triggering factors are presented for the region
25 affected by the August, 14, 2021, earthquake ($M_w=7.2$) in the Nippes Department, Haiti. Landslide
26 mapping was mainly carried out by comparing pre- and post-event remote imagery (~ 0.5 - 1-m resolution)
27 available on Google Earth Pro® and Sentinel-2 (10-m resolution) satellite images. The first covered
28 about 50% of the affected region (for post-event imagery and before completion of the map in January
29 2022), the latter were selected to cover the entire potentially affected zone. On the basis of the completed
30 landslide inventory, comparisons are made with catalogues compiled by others both for the August 2021
31 and the January 2010 seismic events, including one open inventory (by the United States Geological
32 Survey) that was also used for further statistical analyses. Additionally, we studied the pre-2021
33 earthquake slope stability conditions. These comparisons show that the total number of landslides
34 mapped for the 2021 earthquake (7091) is larger than the one recently published by another research
35 team for the same event, but slightly smaller than the number of landslides mapped by a third research
36 team. It is also clearly smaller than the one observed by two other research teams for the 2010 earthquake
37 (e.g., 23,567, for the open inventory). However, these apparently fewer landslides triggered in 2021 cover
38 much wider areas of slopes (>80 km²) than those induced by the 2010 event (~ 25 km² – considering the
39 open inventory). A simple statistical analysis indicates that the lower number of 2021-landslides can be
40 explained by the missing detection of the smallest landslides triggered in 2021, partly due to the lower
41 resolution imagery available for most of the areas affected by the recent earthquake; this is also confirmed
42 by an inventory completeness analysis based on size-frequency statistics. The much larger total area of
43 landslides triggered in 2021, compared to the 2010 earthquake, can be related to different physical
44 reasons: a) the larger earthquake magnitude in 2021; b) the more central location of the fault segment
45 that ruptured in 2021 with respect to coastal zones; c) and possible climatic preconditioning of slope
46 instability in the 2021-affected area. These observations are supported by (1) a new pre-2021 earthquake
47 landslide map, (2) rainfall distribution maps presented for different periods (including October 2016 -
48 when Hurricane Matthew had crossed the western part of Haiti), covering both the 2010 and 2021
49 affected zones, as well as (3) shaking intensity prediction maps.

50 1 Introduction

51 This paper presents an overview of landslides induced by the August 14, 2021, Nippes (Haiti) earthquake.
52 The epicenter (18.434° N / 73.482° W, hypocentral depth of 10 km) of this event is located in the western
53 part of the southern Haitian peninsula (see Unites States Geological Survey, USGS, Earthquake Hazard
54 Program page, earthquake.usgs.gov, presenting first information on the 2021 M 7.2 - Nippes, Haiti,
55 event).

56 Even though the magnitude of the 2021 earthquake is slightly larger than the one of 2010 (Mw=7.2 and
57 Mw=7.0, respectively, see information on the earthquake.usgs.gov webpage and by Stein et al., 2021),
58 the recent event was far less catastrophic as it hit a less populated area compared to the 2010 earthquake
59 that occurred just near the western entrance of the capital of Haiti, Port-au-Prince. The 2021 earthquake
60 accounts for about 2250 fatalities (2/3 of which occurred in the provincial city of Les Cayes, located in
61 Fig. 1), while the 2010 death toll is up to 300,000. However, it quickly became clear that the last event
62 caused widespread slope failures that could be more intense than in 2010. Therefore, members of our
63 research team completed some ground control during a one-week field visit along segments of important
64 roads hit by rock falls near the epicentral region. Additionally, we mapped landslides over the whole area
65 potentially hit by the 2021 event by using satellite imagery of variable resolution, as it will be explained
66 in section 3. The main target of this mapping task was to produce an input data set for an extensive
67 landslide susceptibility analysis that will be presented in an upcoming publication.

68 Such event-based seismically induced landslide inventories also allow us to complete a more systematic
69 analysis of global patterns of those mass movements, such as size-frequency relationships (Malamud et
70 al., 2004; Tanyas et al., 2019b), estimates of the expected number of landslides and affected area
71 (Havenith et al., 2016; Keefer and Wilson, 1989; Marc et al., 2017), and very general earthquake-
72 triggered landslide susceptibility markers (Tanyas et al., 2019a). At regional scale, event-based landslide
73 inventories are valuable to understand more specific patterns of seismic slope instability, particularly
74 with respect to the earthquake mechanism and the geological and climatic context (Gorum et al., 2011;
75 Tanyas et al., 2022).

76 Below, we will also present statistical characteristics of this new 2021 inventory compared with
77 equivalent results extracted from the USGS landslide catalogue published by Harp et al. (2016) for the

78 2010 Haiti event that occurred at about 100 km in the east of the 2021 earthquake. Some statistical data
79 are also compared with those of two other published inventories completed for the 2021 event, the one
80 by Martinez et al. (2021, USGS Open File report) and the one by Zhao et al. (2022) as well as with those
81 of two additional catalogues compiled for the 2010 event (by Gorum et al., 2013 and Xu et al., 2014).
82 The tectonic setting of both events and also the climatic context of the landslide triggering are introduced
83 in the following section.

84

85 **2 Regional data and context of the earthquake-triggered landslides**

86 Similar to the January 12, 2010, earthquake, the epicenter of the main shock of the 2021 event is located
87 near the surface expression of the Enriquillo-Plantain-Garden Fault (EPGF) that crosses the southern
88 peninsula from west to east; this fault includes a succession of faulted anticlines forming the *Massif de*
89 *la Hotte* mountains in the west (zone affected by the 2021 event) and the *Massif de la Selle* in the east
90 (affected by the 2010 event). With a slip rate of about 7 ± 2 mm yr⁻¹ the EPGF is one of the two main
91 strike-slip faults inferred to accommodate the 20 mm yr⁻¹ relative motion between the Caribbean and
92 North American plates (DeMets et al., 2000). Furthermore, the historical earthquakes of 1701, 1751 and
93 1770 are considered to have occurred along the central EPGF system (Ali et al., 2008; Bakun et al., 2012).
94 Thus, EPGF marks one of the highest seismic hazard zones of the island (see location of the recent
95 epicenters on the seismic hazard map completed by Frankel et al. in 2011 in Fig. A1 in the annex, as well
96 as on the topographic map shown in Fig. 1).

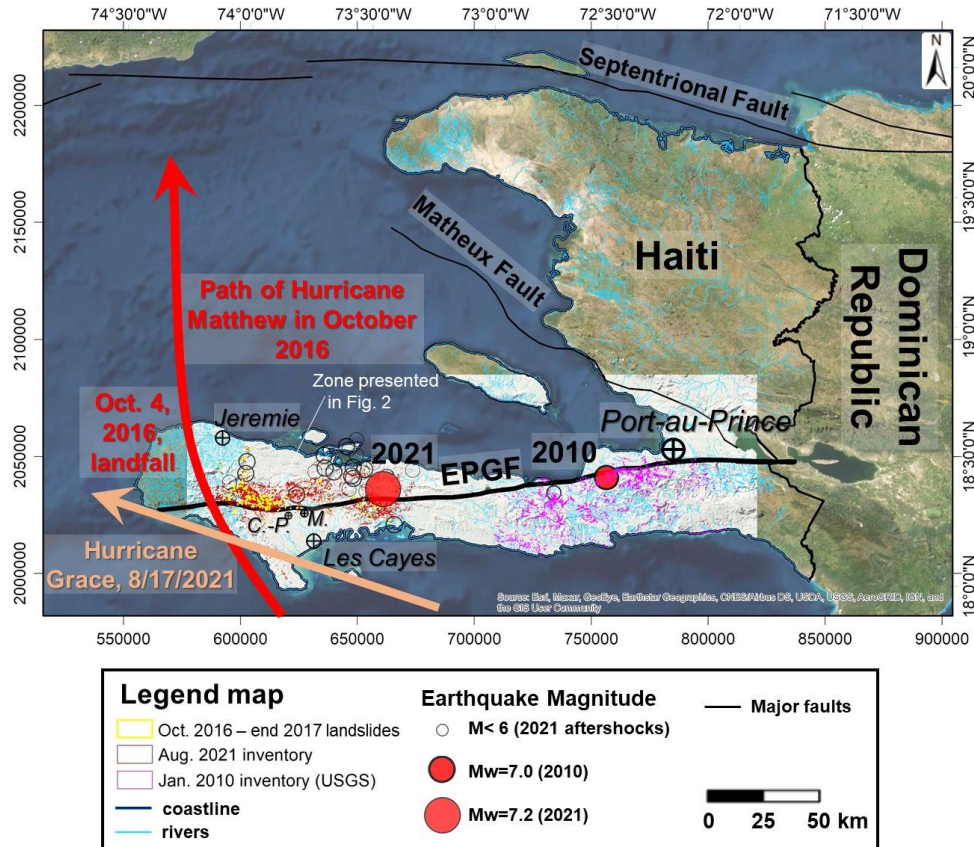

97 For the 2010 event, Calais et al. (2010) and Smithe et al. (2013) showed that this earthquake was caused
98 by the oblique rupture of a formerly unknown fault (called '*Léogane*') dipping towards the north and
99 located immediately in the north of the EPGF. Data provided by the earthquake.usgs.gov webpage
100 (considering the provided moment tensor solution; see also Okuwaki and Fan, 2022) indicate that the
101 situation could be similar for the 2021 event, with a ruptured fault segment dipping towards the north,
102 and mostly located in the north of the EPGF. Thus, also the recently ruptured fault segment would not
103 belong to the EPGF (which is essentially a left-lateral strike-slip fault). It could be related to an adjacent
104 blind fault segment with oblique slip character (left-lateral strike-slip combined with reverse movement)

105 according to the information available on earthquake.usgs.gov, and to Okuwaki and Fan (2022). The
106 latter further indicate that especially the eastern part of the ruptured fault showed a more reverse while
107 the western part a preferential strike-slip mechanism. However, by now there is still no clear answer to
108 the question related to the fault itself. Therefore, below we will use the term of the ‘EPGF zone’ that
109 includes the main strike-slip fault and annexed oblique (or combined) slip fault segments (the two that
110 are now known, i.e., the one ruptured in 2010 and the one that produced the last earthquake) to
111 denominate the tectonic structure that produced those two events.

112 The seismotectonic setting of the two events in 2010 and 2021 introduced above has certainly to be
113 considered when explaining observed earthquake-triggered landslide distributions (see sections 4 and 5
114 below). However, also geological and climatic factors need to be analyzed to improve related
115 interpretations. The geological influence on slope failure development in the earthquake-affected zones
116 will be studied more in detail in a follow-up paper focused on landslide susceptibility analyses (see also
117 Zhao et al., 2022, for a basic analysis of the geological influence on the 2021 landslide distribution),
118 while some possible climatic influence is already investigated in this paper. Therefore, we had also
119 mapped landslides existing before the 2021 earthquake by using high-resolution (≤ 1 m) imagery
120 available on Google Earth Pro®, starting from October 2014 until the end of 2017, to study some
121 preconditioning of slope instability that was induced in 2021. In particular, it is known that the region is
122 often affected by hurricanes – the last catastrophic one, ‘Matthew’ or ‘*Mathieu*’ in French, had impacted
123 the target area in October 2016. In addition, just two days after the main shock, on August 16, another
124 Hurricane, ‘Grace’, hit the area and hampered help convoys to reach the areas most impacted by the
125 earthquake. Right after this event, it was not immediately clear if Grace had contributed to landslide
126 activity or not; this question will be analyzed in the following sections by comparing landslide
127 distributions with monthly precipitation maps produced by the ‘Global Precipitation Measurement’
128 (GPM) Mission (NASA) for different periods.

129 Fig. 1 presents an overview map with outlines of landslides mapped by Harp et al. (2016) (shown by
130 light violet - pink polygons, near the 2010 $M=7$ epicenter), and the recently mapped landslides triggered
131 in August 2021 (outlined in dark red, mainly in the west and south of the 2021 epicenter). This map also
132 shows the approximate paths of the two aforementioned hurricanes near Haiti. Other digital outlines (also

133 those presented in the following figures that also present more detailed views with more clearly visible
 134 outlines), such as roads, rivers, faults and coastline, were provided by the Centre National de
 135 l'Information Géo-Spatiale (CNIGS) of Haiti.

136
 137 **Figure 1: Location of the study region in Haiti: Satellite image view of Haiti (by © ESRI), with study region**
 138 **highlighted by the hillshade. See also location of the 2010 and 2021 epicenters, and the major cities (see also**
 139 **‘C.-P.’ for Camp-Perrin and ‘M.’ for Maniche) by hit by those two events. Outlines of major faults are shown**
 140 **as well as the indication of the approximate paths of Hurricane Matthew in October 2016 and of Hurricane**
 141 **Grace in August 2021. Landslides mapped by Harp et al. (2016) are shown by light violet polygons, and**
 142 **recently mapped landslides triggered in August 2021 are outlined in dark red See also location of the zone**
 143 **presented in Fig. 2.**

144
 145 The following sections will provide more detail about the landslide mapping itself, the completion of
 146 landslide statistics, the collection of climatic data and the computation of seismic intensity maps. All

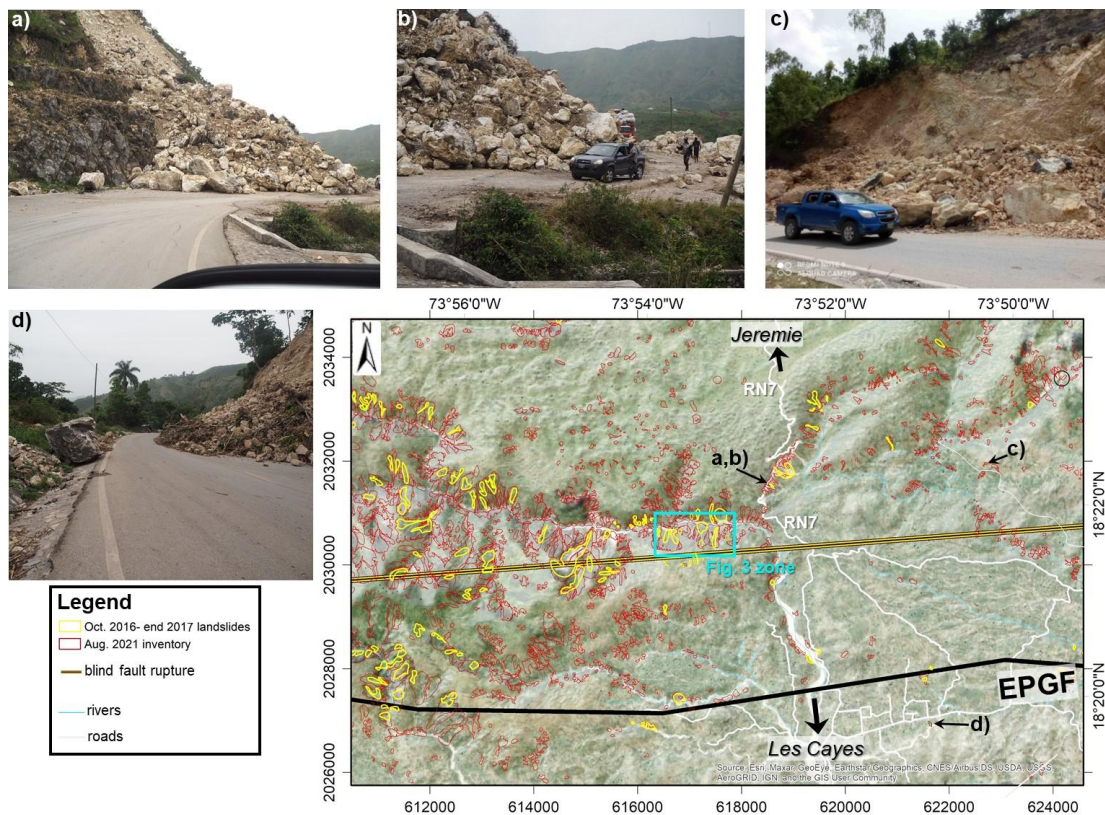

147 those inputs will be used to explain both the common and the different main markers of landslide
148 catalogues, respectively, for the 2010 and the 2021 events.

149 3 Methodological aspects of landslide and seismic trigger factor mapping

150 3.1 Landslide mapping

151 3.1.1 Field observations

152 Right after the main shock that hit Haiti on August 14, 2021 (precisely at 12:29:08 UTC, about 8:30 am
153 local time), it became clear that many landslides were triggered by this earthquake. Within a few hours
154 after the main shock, there were reports about rock falls cutting the main road RN7 connecting the large
155 provincial cities of Les Cayes in the south and Jeremie in the north. Therefore, local members of our
156 research team checked the situation to support local administration with cleaning the roads. Photographs
157 of rock falls in the central part of the target area are shown in Fig. 2 (those shown below all occurred in
158 limestone rocks), together with the locations of the affected sites on a map.

159

160 **Figure 2: Examples of landslides photographed in the field, especially along the national road RN7, connecting**

161 the two provincial cities of Les Cayes in the south and Jeremy in the north. The map (semi-transparent
162 hillshade on high-resolution satellite imagery, by © ESRI) also shows the different ground failure effects
163 mapped before (yellow polygons) and after the earthquake (dark red polygons). See blue rectangle marking
164 the outline of the view extent shown in Fig. 3 (and in Fig. A2).

165

166 These rock falls were typically not very large (with a volume of generally less than 20,000 m³ – note, for
167 volume estimates, we applied the equations proposed by Havenith et al., 2015, using as input the
168 landslide deposit thickness calculations and surface area measurements, but there were many of them
169 and, in some cases, it took several days before the street could be reopened. During the field visits in
170 August 2021, just after the main shock, our teams could confirm that this earthquake had triggered more
171 extensive slope failures (covering wider surface areas) than the previous M=7.0 event in January 2010.
172 After these visits we started to detect and map all landslides caused by the earthquake.

173

174 3.1.2 Regional mapping of landslides using remote imagery of August – November 2021

175 Mapping of earthquake-induced landslides is often done from pre- and post-event optical and radar
176 satellite imagery; both can be publicly accessible. Optical imagery (that was used for this study) includes,
177 amongst others, Sentinel-2 (Tanyas et al., 2022) or Landsat-7 and -8 data, with resolutions starting from
178 10 m, and commercial higher resolution data, which is often made publicly available for disaster response,
179 through Google Earth, with resolutions of down to 0.5 m e.g. (Harp et al., 2016; Kargel et al., 2016;
180 Wartman et al., 2013). Sometimes mapping is also supported by (pre-event) digital elevation data (Gorum
181 et al., 2011; Kargel et al., 2016) or even by field or helicopter reconnaissance. Landslides are mapped at
182 different levels of spatial discretization, e.g. as landslide initiation points (Gorum et al., 2011), centroid
183 points (Wartman et al., 2013), or landslide polygons (Tanyas et al., 2022), and with a varying degree of
184 detail, e.g. regarding the minimum mapped landslide size or the identification of landslide types. The
185 quality and accuracy of the inventories depend typically on the resolution of the satellite data, cloud
186 cover, and the availability of suitable pre-event data for a clear identification of co-seismic landslides. A
187 recent review of earthquake-induced landslide inventories was presented by Tanyas et al. (2017).

188 In our case, medium-resolution imagery available from the Copernicus Open-Access Hub was used for
189 the landslide mapping over the whole potentially affected area: Sentinel-2, with 10-m spatial resolution

190 bands B2 (490 nm), B3 (560 nm), B4 (665 nm) and B8 (842 nm) collected for eight different dates, every
191 five to six days, between August 14, 2021 (the first one was available about two hours after the main
192 shock), and the end of September 2021 (an example of a Sentinel 2 image view of this period is shown
193 in the annex, in Fig. A2a, presenting a view of the zone located in the map in Fig. 2). Analyzing all
194 images was necessary due to the extensive (but spatially variable) cloud cover present on each image.
195 Considering that only this medium-resolution imagery was freely available in the beginning, the authors
196 are aware that the landslides could not be mapped with the highest precision, and that not all smaller
197 landslides could be identified (especially those smaller than 2000 m², corresponding roughly to 4 by 5
198 pixels on a Sentinel-2 image). However, during the following months, also higher resolution (0.5-1 m)
199 imagery became available on Google Earth Pro® (GEP) for about 50% of the potentially affected
200 region (before December 2021). For these areas, the initial landslide outlines could be refined, and also
201 smaller slope failures could be mapped; an example of the ‘resolution’ effect on landslide mapping is
202 shown in the annex, by Fig. A2, comparing the aforementioned Sentinel 2 image (black-white, projected
203 on the topography in GEP) with a higher resolution image of the same landslide zone that became
204 available on GEP in September 2021. On the basis of such comparisons between higher and lower
205 resolution imagery, we could see that most larger landslides are actually composed of multiple initially
206 smaller and narrower slides and flows, which had coalesced to form a larger coherent mass. Even on the
207 higher resolution imagery no clear separation could be outlined within these landslide areas; indeed, the
208 refinement could only help identify distinct sources of those larger mass movements, but the outline of
209 the main sliding mass often remained the same. Furthermore, for most landslide zones, no clear
210 distinction could be made between landslide scarp and deposits, as it can often be observed for such kind
211 of disrupted mass movements.

212

213 3.1.3 Regional mapping of landslides using remote imagery of November 2014 – August 2021, with
214 focus on pre-seismic changes that occurred in October 2016

215 For the entire area, also a comparison with pre-event imagery was completed to be sure that only ‘co-
216 seismic’ (or nearly co-seismic – see explanation below) slope failures had been mapped; this check was
217 especially necessary for the identification of the smaller co-seismic landslides. Therefore, the impacted
218 region was screened by using high resolution (0.5-1 m) imagery available on GEP for the period

219 between 2014 and August 2021. A pre-earthquake image (of November 28, 2014) of the same landslide-
220 impacted area is shown in Fig. 3a, highlighting the contrast between the vegetated slopes present in the
221 target region and the extensive denudation that occurred during the earthquake of August 2021 (see
222 images shown in Fig. 3d, identical to the one shown in the annex in Fig. A2a). However, we could also
223 observe by comparing multiple images available for the pre-event period that some denudation had
224 already appeared for smaller zones before 2021. Zones marked by narrow debris slides and flows could
225 be outlined especially on images available for the time just after October 10, 2016. Fig. 3b presents an
226 image of October 12, 2016 that shows the ‘freshest’ type of denudation since 2014 (see yellow polygons
227 outlining such denudation zones), some of which disappeared after a few years (see Fig. 2c), due to
228 revegetation of the slopes (rapid revegetation can be observed as the whole area is located in tropical
229 regions). This image and others available for the same period were added to GEPro after Hurricane
230 Matthew had impacted, in early October 2016, the same area as the one hit by the 2021 earthquake. The
231 consequences of this ‘double’ impact on the target region will be analyzed in the sections 3 and 4 on the
232 basis of precipitation distribution maps.

233 Actually, Haiti is quite often (at least once per year) crossed by hurricanes or severe tropical storms, some
234 of which can trigger slope failures over wide areas. One such tropical storm that later developed into the
235 hurricane called Grace had also crossed southern Haiti, just two to three days after the August 14, 2021,
236 main shock. We introduce this fact here in the methodological part as it had two consequences for the
237 landslide mapping. First, right after the earthquake wide areas were covered by clouds during several
238 days (some higher mountain parts even for weeks); thus, multiple satellite images of different dates (both
239 Sentinel-2 and higher resolution imagery on GEPro) had to be inspected to map landslides over the whole
240 area. Second, we had to consider that Grace might also have induced slope failures and that landslides
241 mapped by using post-hurricane imagery were not all seismically triggered, or were at least enlarged by
242 the effects of Grace. Therefore, by comparing the post-seismic, August 14, Sentinel-2 image (collected
243 before the Hurricane Grace event) with the one of August 29, 2021 (post-seismic and post-hurricane),
244 we checked if additional or enlarged slope failures had appeared on the latter. An example of such a
245 comparison is presented in Fig. A3, where red arrows point to zones marked by larger slope failures on
246 the Sentinel-2 image of August 29, 2021. The latter were thus most likely reactivated by rainfall during
247 the Grace climatic event (disregarding here the possible additional influence of aftershocks occurring at

248 the same time in the region that could not be checked due to missing new high-resolution imagery after
249 each event; it should also be noted that none of the aftershocks had a magnitude, M_w , larger than 6).
250 Unfortunately, due to the extensive cloud cover in mid-August 2021, such a comparison could only be
251 completed for about 10% of the seismically impacted area. For those cloud-free zones, we estimate that
252 Grace had mainly induced a widening of the initially seismically triggered slope failures, but the
253 importance of this reactivation process cannot be quantified due to the extensive cloud cover and related
254 shadow effects on the surface. However, we could at least see that no new landslides had been triggered
255 within the earthquake-affected cloud-free zones. Effects of Hurricane Grace outside the region marked
256 by stronger shaking have not been studied – this would require a completely new mapping approach.
257
258

259
260
261 **Figure 3: Evolution of landslides within the zone marked in Fig. 2 between November 2014 (view a), after**
262 **Hurricane Matthew (Oct. 2016, b), a view of the area of Feb. 2019 (c) and of Oct. 2021, about two months of**
263 **the earthquake (an image of August exists, but it is partly cloudy). Landslides that occurred during or directly**
264 **after the Hurricane Matthew event are outlined in yellow and those that were triggered by the August 14,**
265 **2021, earthquake are shown by dark red polygons; see also black arrows marking the coalescence of landslides**
266 **with distinct sources (only for three examples shown). All views on © Google Earth Pro.**

267

268 **3.2 Landslide distribution statistics, climatic context and a first size-frequency analysis**

269 In sub-section 4.2, observed total landslide numbers and surface areas as well as other parameters
270 characterizing the statistics of the two inventories, the new one presented here for 2021 and the one for
271 2010 by Harp et al. (2016), are compared with ‘predicted’ ones. The latter numbers are computed
272 according to prediction laws proposed by Havenith et al. (2016) and Malamud et al. (2004). To estimate
273 the total number (N_{LT} , see Eq. 1) of landslides triggered by a specific earthquake, Havenith et al. (2016)
274 recommend to take into consideration the shaking intensity factor, (I , based on the Arias Intensity, see
275 Arias (1970), and thus on the earthquake magnitude, M ; see Eq. 6b in the next sub-section), the fault
276 factor F (depending on the type, FT , and size of the fault rupture, considering also the influence of a
277 possible surface rupture), the topographic energy (TE , using mainly as parameter the maximum altitude
278 difference in the affected region), the climatic background (CB) conditions, and the lithological factor
279 (LF , depending on the presence of soft soils for instance). Related factor values used for the calculations
280 are compared with estimated minimum and maximum values in Table 2, in the following section.

$$281 \quad N_{LT} = 1000 \times I \times F \times TE \times CB \times LF , \quad (1)$$

282 Compared with the prediction of the total number of landslides triggered by a specific earthquake
283 proposed by Havenith et al. (2016), the one recommended by Malamud et al. (2004) is much simpler (Eq.
284 2) and only based on the earthquake magnitude, M .

$$285 \quad N_{LT} = 10^{(1.29M - 5.65)} , \quad (2)$$

286 For the calculation of the total area potentially affected by landslides (A_{Lext} , area within the maximum
287 extent of landslide occurrence, equivalent to the area of distribution defined by Marc et al., 2017, and
288 Tanyas and Lombardo, 2019) Havenith et al. (2016) propose the following Eq. (3), which also directly
289 considers the earthquake magnitude, M , and the hypocentral Depth, D :

$$290 \quad A_{Lext} = I \times FT \times TE \times CB \times LF \times M \times D^2 , \quad (3)$$

291 As Havenith et al. (2016), Keefer and Wilson (1989) also propose an equation to estimate the total area
292 potentially affected by landslides during one earthquake event. Their estimate of A_{Lext} is purely based on

293 the earthquake magnitude, similar to Eq. (2) proposed by Malamud et al. (2004) to estimate N_{LT} :

$$294 \quad A_{L_{ext}} = 10^{(M-3.46)} \quad , \quad (4)$$

295 Malamud et al. (2004) do not propose any formula to estimate the total area potentially affected by
296 landslides during an earthquake event as Havenith et al. (2016) (see Eq. 3), but recommend the following
297 prediction law (Eq. 5) to estimate the total area effectively covered by co-seismic landslides, A_{LT} , based
298 on the observed or predicted (using Eq. 2, or any other related prediction law, such as the one in Eq. 1)
299 total number of landslides:

$$300 \quad A_{LT} = 0.00307 N_{LT} \quad , \quad (5)$$

301 All the previous equations were used to compute the respective values presented in Table 1 in sub-section
302 4.2.

303 Size-frequency relations were computed for the 7091 landslide outlines in terms of frequency-density
304 function (FDF) on the basis of the measured surface areas, $f(A_L)$. The same statistics were also computed
305 for the 23,567 landslides mapped by Harp et al. (2016). Therefore, we used the method introduced by
306 Malamud et al. (2004) for surface areas (Eq. 6):

$$307 \quad f(A_L) = \frac{\delta N_L}{\delta A_L} \quad (6)$$

308 where δN_L is the number of landslides with areas between A_L and $A_L + \delta A_L$ (representing the difference
309 between two landslide surface area classes). Surface areas were calculated in km^2 . Related distributions
310 computed, respectively, for each landslide catalogue (for the 2010 one by Harp et al., 2016; and for the
311 new 2021 inventory) are then compared with theoretical frequency-density distributions, as proposed by
312 Malamud et al. (2004). The latter are based on the three-parameter inverse-gamma probability
313 distribution (see equation 3 in Malamud et al., 2004) that is multiplied by the total number of landslides
314 of simulated events (100, 1000, etc.). In this regard, it should be noted that the original technique
315 proposed by Malamud et al. (2004) to complete the size-frequency statistics is based on the probability-
316 density values, corresponding to the frequency-density values divided by the total number of mapped
317 landslides, N_{LT} (which can be fit by the aforementioned three-parameter inverse-gamma probability
318 distribution). However, as indicated above, due to the limited amount of high-resolution imagery
319 available for the area potentially affected by seismic shaking in August 2021, not all small landslides

320 could be mapped; therefore, the total number of landslides seismically triggered in August, N_{LT} , is likely
321 to be higher than 7091 (even if the potential ‘hurricane-effect’ is removed, as explained below), and the
322 probability-density function cannot be correctly computed. For such cases, Malamud et al. (2004)
323 recommend the computation of the frequency-density function to assess the completeness of the
324 inventory by comparison with the aforementioned predefined theoretical frequency-density functions, as
325 it will be shown for the 2010 and 2021 inventories in the following results section.

326 To provide information about the climatic context covering different periods of time, we used the Global
327 Precipitation Measurement Mission (GPM, by NASA) data obtained via the
328 <https://giovanni.gsfc.nasa.gov/> website, corresponding to the merged satellite-gauge monthly
329 precipitation estimate (in mm), assessed with a resolution of 0.1° . Related maps were extracted for all
330 months between August 2000 and July 2021, and also for the specific months of October 2016 and August
331 2021, as well as for all October months between 2000 and 2020. Note, we also extracted maps for shorter
332 periods around the climatic events of Matthew in 2016 and Grace in 2021, but those did not provide any
333 additional information. Additionally, we tried to support these merged satellite - rain gauge estimates by
334 additional ground measurement data. However, the *Centre National de l'Information Géo-Spatiale*,
335 *CNIGS*, of Haiti, informed us that such data would not be available; therefore, we can only rely on these
336 regional estimates.

337 **3.3 Mapping of seismic landslide triggering factors**

338 The aforementioned climatic data are supposed to help us better understand the pre-conditioning of slope
339 stability in the target area and thus will also be used below for the interpretation of the landslide
340 distribution statistics. However, it is obvious that for such an event the main trigger factors are still related
341 to earthquake shaking; those have to be assessed to understand why extensive slope instability could be
342 observed in one zone and only isolated minor failures occurred in another one. Such an analysis is
343 completed both for the 2010 and 2021 events, by computing the Arias Intensity distribution maps (for
344 2010, comparing the results with the landslide distribution as observed by Harp et al., 2016).

345 The Arias Intensity, I_a , can be considered as a quantitative measure of the degree of shaking (in m/s) on
346 the surface. With respect to any other intensity characterization (including the one based on surveys) it
347 has the advantage to be more objective and comparable for different earthquakes (according to Harp and

348 Wilson, 1995). Wilson and Keefer (1985) were the first to try to correlate seismically triggered landslide
349 distributions with this intensity measure. They also defined the following empirical attenuation
350 relationship (Eq. 7a) in terms of magnitude (M) and hypocentral distance (R):

$$351 \log(I_a) = -4.1 + M - 2 \log(R) + 0.5P , \quad (7a)$$

352 where P considers a possible deviation from the main law (P=0 stands for the average value).

353 Afterwards, Keefer and Wilson (1989) have reviewed the application of this formula and defined a new
354 one (Eq. 7b), for magnitudes greater than 7:

$$355 \log(I_a) = -2.35 + 0.75M - 2 \log(R) , \quad (7b)$$

356 We applied the latter equation as both the 2010 and 2021 can be considered as $M \geq 7$ events. The R-
357 value represents the hypocentral distance map, here computed by using as source zone the blind fault
358 rupture segments of the 2010 and 2021 events (with 0 km epicentral distance and 10 km hypocentral
359 depth along the respective segment; information extracted from earthquake.usgs.gov).

360 All equations introduced above have been applied to obtain the computation results presented below, in
361 the sub-sections 4.2 and 4.4.

362 **4 Results: landslide inventory statistics and analysis of trigger conditions**

363 This section first summarizes a series of landslide type and general distribution characteristics. Second,
364 landslide inventory and size-frequency statistics are presented and supported by an inventory
365 completeness analysis. Third, a study of possible climatic slope failure preconditioning and post-seismic
366 landslide surface changes is presented, which also compares landslide distributions with monthly
367 precipitation maps (using output maps of the Global Precipitation Measurement Mission, GPM, produced
368 by the NASA, for different periods, according to Acker and Leptough, 2007). Fourth, the landslide
369 occurrence observed in 2010 and in 2021 is compared with respective shaking intensity prediction maps.

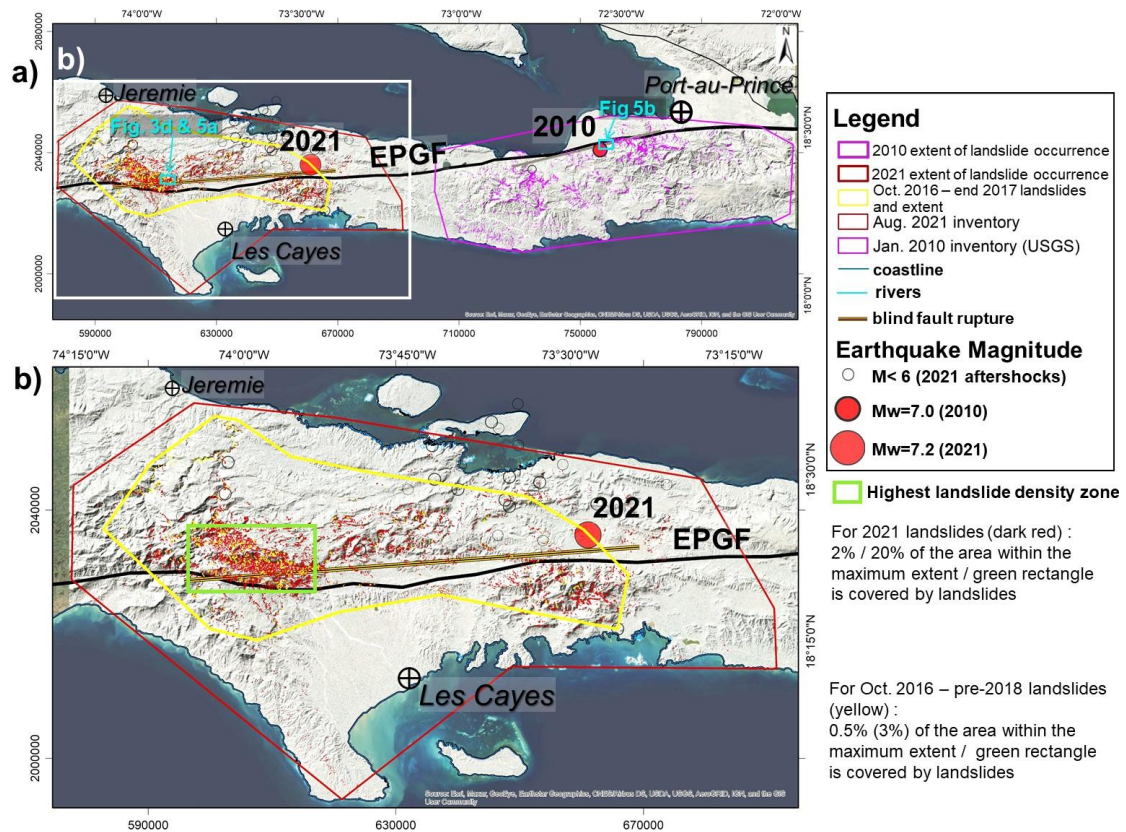

370 **4.1 Landslide type and distribution characteristics**

371 Before analyzing specific statistical values of the two landslide inventories, the one compiled by Harp et
372 al. (2016) for the 2010 event and ours completed after the August 2021 earthquake, we first have a look

373 at the general respective spatial landslide distributions and provide basic information on the type of the
374 mapped landslides.

375 The map presented in Fig. 4a shows that the global extent of landslides triggered in 2010 (pink outlines
376 within the pink maximum extent polygon) and in 2021 (dark red outlines within the dark red maximum
377 extent polygon) is quite similar (exact values are presented in Table 1). This map also shows the location of
378 the main shock and aftershocks (empty circles, from earthquake.usgs.gov) and the outline of the (roughly 80 km
379 long) blind fault rupture (extracted from USGS page:
380 <https://earthquake.usgs.gov/earthquakes/eventpage/us6000f65h/finite-fault>). Outlines of mapping zones presented
381 in Fig. 5 are shown by light blue rectangles. A major difference between the two landslide distributions can
382 mainly be observed with respect to the location of the EPGF zone. While most landslides occurred in the
383 south of the fault zone in 2010, a relatively symmetric distribution of landslides with respect to the
384 location of the EPGF zone can be observed for the 2021 event. This is mainly due to the fact that the
385 fault segment that ruptured near EPGF in 2010 is located close to the coast (actually just in the south of
386 the coast, as can be seen in the map in Fig. 4a), and thus only limited onshore surface areas could be
387 affected by landslides in the north of the EPGF zone in 2010. However, the location of the fault segment
388 that ruptured in 2021 is more central within the southwestern peninsula of Haiti (see focus on this region
389 in Fig. 4b).

390 Another important observation is that there seems to be a gap between the zone affected by landslides in
391 2010 and the one affected in 2021. This means that, according to our present observations, the 2021
392 earthquake did not reactivate landslides triggered in 2010 – due to the large distance (> 60 km) between
393 the fault ruptures. However, it should be noted that this check could only be completed so far with the
394 10-m resolution Sentinel-2 imagery. Now, we cannot exclude that very small landslides (that we cannot
395 identify on Sentinel 2 imagery) triggered in 2010 had been reactivated in 2021.

396

397 **Figure 4: a) Study region with areas affected, respectively, by the two Mw \geq 7 events. Individual landslides**
 398 **triggered in 2010 (Harp et al., 2016, inventory) and our landslides mapped for the 2021 earthquake and**
 399 **October 2016 hurricane events are shown, respectively, as pink, dark red and yellow polygons. The maximum**
 400 **extent of landslides triggered in 2010, in 2021 and 2016 is outlined, respectively, by the large pink, dark red,**
 401 **and yellow polygons. b) Focus on the region hit by the August 2021 earthquake, with 7091 landslide locations.**
 402 **Map background by © ESRI.**

403

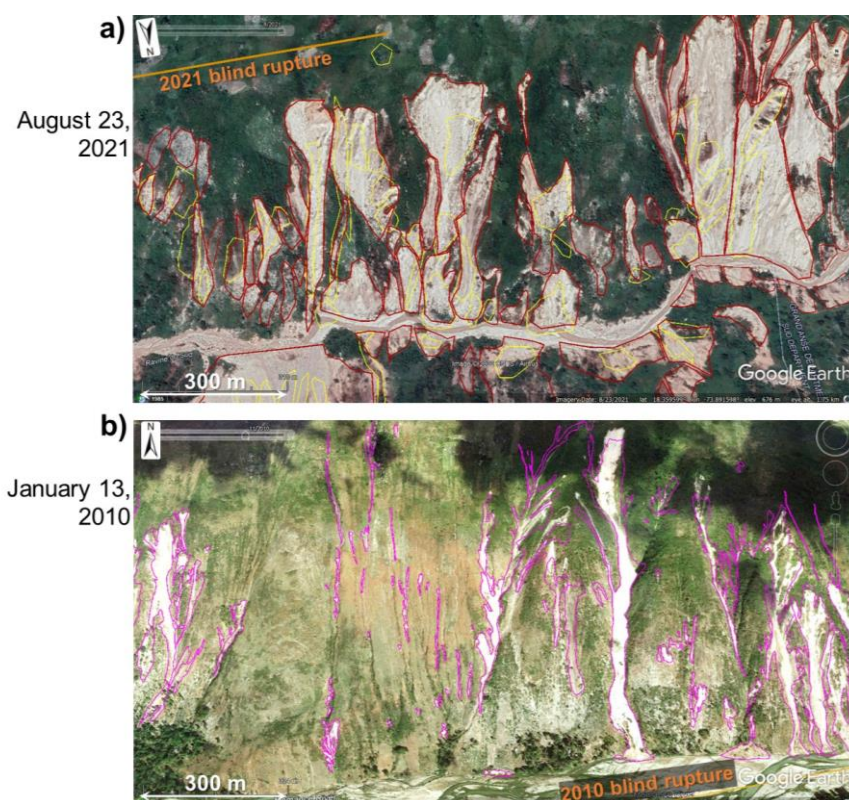

404 An important consequence of the specific location of the ruptured fault segments is that a few dozens of
 405 landslides with a surface area larger than 2000 m² had occurred along the shore in 2010, where the two
 406 or three largest ones (likely including an important submarine part) had massively impacted the ocean
 407 and, thus, had produced up to 3 m-high tsunami waves (see Olson et al., 2011; Poupardin et al., 2020;
 408 Fritz et al., 2013; Sassa and Takagawa, 2018). However, there is not a single report of a major coastal
 409 landslide for the 2021 event – as the fault rupture occurred at a distance of minimum 10 km away from
 410 the nearest shoreline. Instead, a wider onshore area was exposed to high intensity earthquake shaking

411 during the 2021 event. The related impact will be analyzed below on the basis of the statistical values
412 presented in Table 1.

413 Concerning the types of landslides triggered by the 2021 earthquake, we can say that by far most of them
414 can be classified as debris slides or flows (see examples in the GEPPro view presented in Fig. 5a) and as
415 medium-size (most with a volume of less than 20,000 m³) rockfalls (as shown above in Fig. 2). Thus, we
416 estimate that at least 95% of all landslides mapped are relatively shallow (with a depth of less than 10
417 m). Actually, not a single large massive landslide (> 10⁷ m³) could be identified. A similar observation
418 was made by Harp et al. (2016) for the landslides triggered in 2010 (see view in Fig. 5b). However, when
419 comparing individual landslides induced in 2021 with those triggered in 2010, the latter are almost
420 systematically narrower than those of 2021 (compare the very narrow slides and flows in Fig. 5b with
421 the typically wider ones in Fig. 5a), while located in similar geological (limestone) and topographic
422 (hilly-mountainous) environments. Actually, in the so-called *Ravine du Sud* (Gorge of the South), part of
423 which is shown above in Fig. 3 (and in the annex, in Figs. A2 and A3), numerous very extensive slope
424 failures (but still relatively shallow) could be observed; most of them formed by coalescent neighboring
425 debris slides. Thus, entire slope units (delimited by upper and lateral slope crests and the valley bottom)
426 finally collapsed as one single mass movement. Such kind of extensive slope failures occurred far less
427 frequently in 2010 – at least onshore, while at least a few aforementioned coastal and mostly submarine
428 landslides must have been quite massive as their impact had triggered tsunami waves, as indicated above.
429 This assumption cannot be further verified as no higher resolution marine floor surface data are available.
430 However, we are aware that a full mapping of submarine or mixed subaerial-submarine slope failures
431 would be necessary to better understand the landslide distribution characteristics, especially for the 2010
432 event, as further discussed below.

433 The fact that no really massive landslides had occurred (onshore), both in 2010 and 2021, also explains
434 why only a few longer lasting landslide dams had formed on the rivers. We could identify only about 100
435 minor dams (with a volume of less than 50,000 m³, according to our estimate, based on the maximum
436 surface area value of about 5000 m² measured for the largest observed dam and a related maximum
437 possible thickness of 15 m, compared with the local morphological setting) after the August 2021 main
438 shock, most of which had disappeared before the end of October 2021; and, only a few dozens of them
439 were impounding temporary lakes. In this regard it should be noted that Zhao et al. (2022) do not make

440 any reference to landslide dams formed in 2021 while Martinez et al. (2021) have outlined almost 300
441 (at least partial) landslide dams after the event. However, the latter also indicate that most of them failed
442 a few days after formation; still, at the time of publication of their open file report in December 2021,
443 they consider 35 of the remaining dams as potentially hazardous. Here, we will not further analyze this
444 aspect as any related hazard assessment would require a site-specific approach that is not targeted by this
445 first study completed at regional scale.
446

447
448
449 **Figure 5: a) GEPPro view (© Google Earth Pro) of landslides triggered by the August 2021 earthquake. b)**
450 **GEPPro view (© Google Earth Pro) of landslides induced by the January 2010 main shock (with landslide**
451 **outlines by Harp et al., 2016).**

452
453 While debris slides are the predominant type of 2021 slope failures in the central mountain ranges,
454 widespread soil slides (but of smaller volume, typically of less than 10,000 m³) had occurred along the

455 hills (with an absolute crest altitude of less than 400 m, and a relative height of less than 200 m with
456 respect to the nearby valley bottom) of the peninsula located in the southwest of Les Cayes (southern
457 part of map in Fig. 4b). As the slopes are very gentle, often seem to be less than 5°, it could be that those
458 failures, many of which affected agricultural areas (marked by brownish disrupted fields), are related to
459 liquefaction phenomena. However, also this observation has to be reexamined, by ground-control and
460 site-specific studies, as the remote analysis based on 1-m resolution imagery does not allow us to fully
461 confirm this interpretation.

462 **4.2 Landslide inventory and size-frequency statistics**

463 4.2.1 Landslide inventory statistics

464 Table 1 presents an overview of general landslide inventory statistics, for both the 2010 and 2021 events.
465 The numbers in the first row show that apparently fewer landslides have been triggered in August 2021
466 (considering also the numbers of 4893 landslides published in the open file report by Martinez et al.,
467 2021, and of 8444 landslides mapped by Zhao et al., 2022) than in January 2010. At least two inventories,
468 the one by Harp et al. (2016) and the one of Xu et al. (2014), include far more landslide outlines (23,567
469 for the first, 30,828 for the second) than our catalogue for 2021 (7091). Only the inventory by Gorum et
470 al. (2013) that was the first one to be completed for the 2010 event contains fewer data (4490 points –
471 not polygons - marking the landslide location). However, paradoxically, a much wider surface area is
472 covered by the apparently fewer 2021 landslides (a total area of 84 km², see row 3 in Table 1, also to be
473 compared with a smaller total area of 2021 landslides indicated by Zhao et al., 2022, of 45.6 km²) than
474 by the more numerous 2010 landslides (sum of surface areas of about 25 km², calculated for the Harp et
475 al., 2016, inventory). This discrepancy will be discussed below, considering the fact that 2021 landslides
476 could only be mapped from higher resolution imagery for about half of the potentially affected area (in
477 the eastern part). For the western zone, only Sentinel-2 images were available until the end of 2021.
478 Those 10-m resolution images typically do not allow for the (complete) mapping of landslides smaller
479 than 2000 – 3000 m². Therefore, we focus only general landslide inventory statistics, first, by comparing
480 the observed landslide numbers with those predicted by Havenith et al. (2016) and Malamud et al. (2014),
481 respectively, for the two earthquakes – always keeping in mind that the 2021 inventory is not complete
482 for landslides smaller than about 3000 m² (this value will also be analyzed below on the basis of the size-

483 frequency relationship). As introduced above (see Eq. 1), according to Havenith et al. (2016), this number
484 depends on the seismic intensity (I , using as input the I_a value computed for the respective earthquake
485 magnitude), the fault factor (type, size and possible surface rupture), the topographic energy (maximum
486 difference of altitudes in the affected area), the climatic background (in this case marked by tropical wet
487 climate), and the lithological factor (here using an average type, for rocks in general). For the precise
488 classification of the different factors, the reader is referred to Table 1 in Havenith et al. (2016). Here, we
489 used the values presented below in Table 2 (considering both events in 2010 and 2021), which indicate
490 the following:

491 1) the shaking intensity values, $I=0.74$, in 2010, and $I=1$ in 2021 are characteristic for the respective
492 magnitudes (note, this factor can reach a value of up to 3.5 in the case of high-magnitude earthquakes,
493 with $M_w > 8$);

494 2) the fault factor, $F=2.25$, can be considered as similar in both cases, marked by an oblique slip that
495 occurred along a fault segment with a length of 50-100 km, with no clear surface rupture (note, F can
496 reach a value of up to 6 in the case of a surface rupture of an activated reverse fault segment with a length
497 of more than 300 km, such as observed for the Wenchuan earthquake in 2008);

498 3) the topographic energy value, $TE=2$, in both cases characterizes a surface morphology marked by local
499 altitude changes of more than 500 m within a hilly region (only smaller mountains, with an altitude of
500 less than 2500 m can be found in the regions affected by the 2010 and 2021 events; note, Havenith et al.,
501 2016, selected a value 4 to mark the high steep slopes in the Longmenshan Mountains affected by the
502 Wenchuan earthquake in 2008);

503 4) the climatic background factor, $CB=1.5$ marks relatively wet conditions for the 2021 event while $CB=1$
504 indicates average conditions for the 2010 event (the higher value chosen for 2021 considers some
505 preconditioning of slope instability by Hurricane Matthew, as explained in the next section; note,
506 Havenith et al., 2016, selected a value $CB=2$ for the very wet conditions that can be found in the
507 Longmenshan Mountains affected by the Wenchuan earthquake, characterized by yearly precipitation
508 values of more than 3000 mm – while the target areas in Haiti are marked by values of about 2000 mm);

509 5) the lithological factor, $LF=2$, indicates that both weathered rocks and soft soils can be found in the
510 affected area (note, Havenith et al., 2016, selected a maximum value, $LF=4$, for the Haiyuan-Gansu-
511 Ningxia earthquake event, China, in 1920, as it affected an area that is almost entirely covered by Loess

512 deposits, which are highly susceptible to slope failure).

513 When these different factor values are combined according to Eq. (1) presented above, the total numbers
514 of landslides, N_{LT} , predicted for the 2010 and 2021 events are, respectively, 6694 and 13,476. These
515 values can be compared with the numbers predicted by the simple equation (Eq. 2), proposed by
516 Malamud et al. (2004), using only the earthquake magnitude as input: 2399 for the 2010 event and 4345
517 for the 2021 event. The latter prediction seems to clearly underestimate the observed numbers of
518 triggered landslides, while those predicted by using Eq. (1) by Havenith et al. (2016) provide intermediate
519 values: larger than the number observed by Gorum et al. (2013) but smaller than the numbers observed
520 by Harp et al. (2016) and by Xu et al. (2014). The two predictions (Eq. 1 and 2) were also applied to the
521 2021 event; the first one producing a higher N_{LT} (=13,476) than the observed value, the second one
522 producing a lower value (=4345).

523 As shown on the maps in Fig. 5, also the total area within the maximum extent of landslide occurrence,
524 A_{Lext} , was outlined and then measured for the 2010 and 2021 events. Actually, related areas are relatively
525 similar: 4400 km² for 2021 and 4100 km² for 2010. It should be noted that Zhao et al. (2022) identified
526 all 2021 landslides within a smaller extent area of 2700 km². This can partly be explained by the fact that
527 they did not map any landslides in the southern zone (marked by the presence of the smaller soil slides).
528 All these values can be compared in Table 1 with the predictions by Havenith et al. (2016) and by Keefer
529 and Wilson (1989), corresponding, respectively, to 3124 and 3467 km², for the 2010 event, and to 6470
530 and 5495 km², for the 2021 event. In this case, the very simple equation proposed by Keefer and Wilson
531 (1989) provides an estimate of A_{Lext} that is closer to the observed values than the one produced by the
532 more complex relationship proposed by Havenith et al. (2016).

533 The third row of Table 1 compares the total observed slope areas affected by landslides, A_{LT} ,
534 corresponding, respectively, to a value of 24.86 km² for the 2010 event and of 84.38 km² for the 2021
535 event (the latter value being significantly smaller for Zhao et al., 2022, close to 45 km²), with the values
536 predicted by Eq. (5) by Malamud et al. (2004) for each event. For 2010, we applied this relationship to
537 the three observed values indicated in the first row and by using the N_{LT} , predicted respectively by
538 Havenith et al. (2016) and Malamud et al. (2004). Among all total landslide surface area values predicted
539 for the 2010 event, it can be seen that the one based on the Havenith et al. (2016) N_{LT} estimate produces
540 the best fit (=20.55 km²) when compared with the observed value of 24.86 km². For 2021, the respective

541 predictions all underestimate the observed total landslide surface area value, A_{LT} , by a factor of at least
542 two, even when the highest N_{LT} estimate (using Eq. 1) by Havenith et al. (2016) is used. Using the
543 preceding information, it is also useful to compare the density values (here, expressed in %) of landslide
544 areas within the maximum extent surface area, which correspond to 0.5% and 2%, respectively for the
545 2010 and 2021 events. Within the green rectangle (zone with highest landslide density) shown in Fig; 4
546 above, even 20% of all the area is covered by landslides. Possible explanations for the much larger total
547 area (and the higher density) of landslides triggered in 2021 compared with 2010 will be provided in the
548 discussion.

549 The fourth and fifth rows show that the smallest landslide mapped by Harp et al. (2016) has a surface
550 area of 0.5 m² and their inventory contains 6587 landslide polygons smaller than 100 m² while our
551 inventory for 2021 only includes one landslide with a surface area smaller than this value. This
552 comparison also confirms that our inventory is likely to be incomplete for such small landslides, as there
553 is no physical reason why there would be much fewer smaller landslides triggered in 2021 than in 2010.
554 On the other hand, the largest landslide mapped for the 2021 event (>400,000 m²) has almost twice the
555 size of the largest one that occurred in 2010, when actually only 2 landslides larger than 100,000 m² had
556 been triggered; in 2021, we could outline more than 100 landslides larger than this value. And, for these
557 larger landslides we can be sure that we mapped them all and outlined them correctly, without
558 amalgamating distinct slope failures.

559 Finally, Table 1 provides information about the distribution of the 2010 and 2021 landslides with respect
560 to the blind fault rupture projected on the surface (near the EPGF outline). As already introduced above,
561 a much larger number of landslides occurred in the north of the latter in 2021 (=4678, ~66% of all
562 landslides) compared to 2010 (=2548, at least for onshore slope failures); for 2021, Zhao et al. (2022)
563 even mapped 89.4% of all landslides (7548 landslides as indicated in Table 1) in the north of the activated
564 fault. This higher proportion of landslides in the north of the fault compared to ours can also partly be
565 explained by the fact that Zhao et al. (2022) did not map any distant soil slides in the south of the fault
566 rupture. Consequently, more landslides occurred in 2010 in the south of the respective blind fault rupture.
567 As the total number of mapped landslides is much larger for the 2010 event (which also means that only
568 the relative proportions should really be considered), the difference between those numbers is very high:
569 21,019 occurred in the south of the fault rupture in 2010 (about 90% of all landslides) and only 2420 in

570 the south of the respective fault rupture in 2021 (about 35%). However, when the total surface area
571 affected by landslides is considered, the 2021 event affected more zones both in the south and the north
572 of the fault rupture than the 2010 event. Still, the distribution of landslides for each event with respect to
573 the fault rupture remains the same also when considering the affected surface areas: they are much larger
574 in the south of the fault rupture for the 2010 event but larger in the north for the 2021 event. The main
575 explanation for this difference has already been provided above: the fault segment that ruptured in 2010
576 is located close to the coast, with limited onshore surface areas being exposed to landslide activity in the
577 north of the respective fault rupture, while the location of the fault rupture in 2021 is more central with
578 respect to the shorelines of the southwestern peninsula of Haiti.

579

580 **Table 1: 2010 and 2021 landslide inventory characteristics – where not specified for the 2010 event, using the**
581 **Harp et al. (2016) inventory. The largest values for each specific observation/estimate (if more than 1 indicated)**
582 **are bold.**

| Landslide inventory parameters/predictions | 2010, Mw=7.0 | 2021, Mw=7.2 |
|---|--|---|
| Observed number of landslides, N_{LT} | >4490 ^a / 23,567 ^b / 30,828^c | 7091 /4893 ^d /8444 ^e |
| Havenith et al. (2016) N_{LT} prediction 1 | 6694 | 13,476 |
| Malamud et al. (2004) N_{LT} prediction 2 | 2399 | 4345 |
| Area of region potentially affected by landslides, A_{Lext} (km ²) | 4100 | 4400/2700 ^e |
| Havenith et al. (2016) A_{Lext} prediction 1 | 3124 | 6470 |
| Keefer and Wilson (1989) A_{Lext} prediction 2 | 3467 | 5495 |
| Total surface area of landslides, A_{LT2} (km ²) | 24.86 | 84.38/45.6 ^e |
| Malamud et al. (2004) A_{LT} prediction : | | |
| for the observed N_{LT} | 13.8 ^a / 72.3 ^b / 94.6^c | 21.8 |
| for the N_{LT} prediction 1 | 20.55 | 41.4 |

| / south (S) of the fault rupture | S= 21,019 | S= 2420/896 ^e |
| Total surface area of landslides in the N / S of the fault rupture (km ²) | N= 2.45 S= 22.41 | N= 58.31 S= 26.07 |

583 ^a Number of landslides observed for the 2010 event by Gorum et al. (2013), ^b by Harp et al. (2016), ^c by
584 Xu et al. (2014), and, for the 2021 event, ^d by Martinez et al. (2021) and ^e by Zhao et al. (2022).

585

586 In addition to the numbers shown in Table 1 and explained above, we also provide two values for the
587 smaller landslide inventory compiled for the period between October 10, 2016 and the end of 2017. For
588 this period, 625 landslide zones have been outlined (see yellow polygons shown on the views and map
589 in Figs. 3 and 4), covering a total surface area of 9.5 km² (located within an area of maximum extent of
590 these landslides of 1770 km² as outlined in yellow, above in Fig. 4) This also means that about 0.5% of
591 the area within the maximum extent was covered by landslides. Highest concentration of landslides can
592 be observed within the green rectangle shown in Fig. 4, where 3% of the total area is covered by
593 landslides. However, we must indicate that these values represent approximations as only 50% of the
594 potentially affected area is covered by cloud-free imagery on GEPPro for this period, most of which
595 actually covers the short period between October 10 and 28, 2016 (just after Hurricane Matthew event).
596 Post-2017 imagery was not used as we could observe that many landslides identified shortly after Oct.
597 10, 2016, had already ‘disappeared’ in 2018-2020 due to revegetation of the affected area (see, above,
598 the comparison between GEPPro views of October 2016 and February 2020 in Fig. 3).

599 **Table 2: Factors contributing to the total number and surface area of landslides triggered by the 2010 and the**
600 **2021 earthquakes, according to the prediction proposed by Havenith et al. (2016). The minimum and**
601 **maximum values proposed by Havenith et al. (2016) are also indicated, the latter with information on the**
602 **event – region, to which this maximum factor value was attributed.**

| Haiti Events/ Factors | Shaking Intensity, I | Fault Factor, F (type, FT) | Topographic Energy, TE | Climatic Background, CB | Lithological Factor, LF | Hypocentral Depth, D (km) |
|---------------------------------|-------------------------|-------------------------------|---------------------------|----------------------------|----------------------------|------------------------------|
| 2010 | 0.74 | 2.25(1.5) | 2 | 1.5 | 2 | 10 |
| 2021 | 1 | 2.25(1.5) | 2 | 1 | 2 | 10 |
| min. values | 0.1 | 0.75 | 1 | 0.5 | 1 | 10 |

|--|--|-------|-------|-------|----------------|-------|

603

604 4.2.2 Landslide size-frequency statistics

605 We also computed frequency-density values for various landslide surface area classes as shown on the
606 graph in Fig. 6. There are two important parameters to be analyzed for the observed frequency-density
607 distributions, according to Malamud et al. (2004), among others: the first part is represented by the
608 power-law decay (see also introduction in Stark and Hovius, 2001) that appears as a linear decay in the
609 log-log graph below; the second part is the so-called ‘rollover’, which can be observed for a landslide
610 surface area where the exponentially decreasing number of larger landslides turns into a decrease of the
611 number of smaller landslides. Here, we will only focus on the power-law decay that can be observed for
612 the larger landslides, for which we consider both, the 2010 and the 2021, inventories as complete. Fig. 6
613 shows that such a power-law decay can be observed for 2010 landslides larger than 2000 m² and for 2021
614 landslides larger than about 4000 m². This comparison confirms the likely incompleteness of the 2021
615 inventory, even for landslides smaller than 4000 m². The rollover part will not be analyzed here as it
616 occurs for smaller landslides, well below this limit of completeness of our 2021 inventory (referring to
617 estimates by Malamud et al., 2004).

618 For the larger landslides, the comparison between frequency density outputs of the 2010 and 2021
619 landslide inventories presented in Fig. 6 first shows that related values are higher for the latter catalogue.
620 Actually, related frequency density values are three times larger for the landslide size class of 10,000 m²
621 and even twelve times for the one of 100,000 m². And, for those larger landslide classes, the absolute
622 value of the power-law decay is slightly higher (-2.57, for the pink line fitting the 2010 data) for the 2010
623 inventory than for the 2021 one (-2.03, for the red line fitting the 2021 data – to be compared with the
624 equivalent value of -2.47 determined by the Zhao et al., 2022, for their inventory). Thus, the relative
625 smaller decay exponent observed for the 2021 landslide inventory explains why related frequency density
626 values are increasingly (i.e. for larger landslide sizes) higher compared with the 2010 values observed
627 for the same landslide size classes. These different size-frequency characteristics of the 2010 and 2021
628 landslides inventories will shortly be discussed below (considering the constraint of inventory
629 completeness for both events), but the most important information to be retained at this level is that for
630 all landslide classes larger than 4000 m² more landslides have been observed in 2021 than in 2010.

631

632 **Figure 6: Frequency density graphs developed for the 2010 (in pink, by Harp et al., 2016) and the new 2021**

633 **landslide inventories (in dark red), with related power-law decays outlined.**

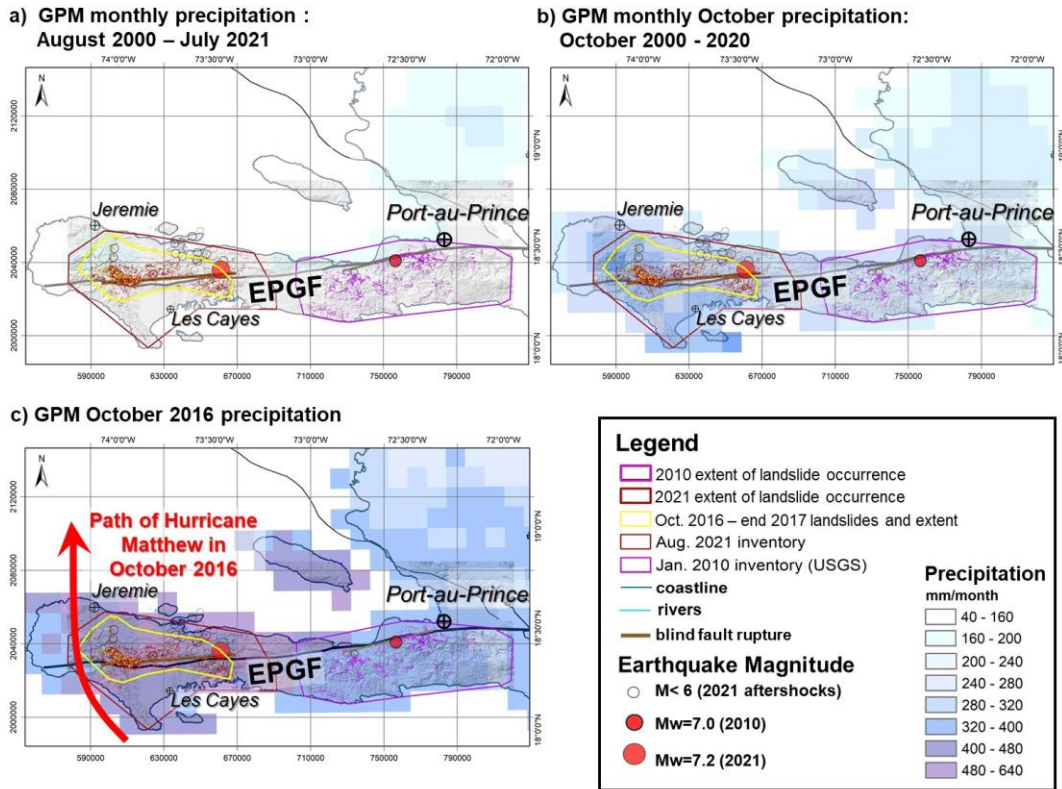

634 4.3 Climatic (pre- and post-seismic) conditioning of slope instability

635 The climatic influence on landslide occurrence (in 2021) has been introduced above, by considering the
 636 possible impacts of hurricanes on slope failure occurrence, marked both by preconditioning of slope
 637 instability and by post-seismic intensification. We first start analyzing the last effect, by considering the
 638 potential impact of Hurricane Grace on post-seismic landslide intensification, on August 16-17, 2021
 639 (when it had crossed the target region and was actually classified as tropical depression at that stage). A
 640 possible effect of related rainfalls on landslide occurrence has already been highlighted, for instance, on
 641 the AGU Landslide blog (by Petley, D., 2021, on blogs.agu.org/landslideblog). This effect could be
 642 confirmed when we compared Sentinel-2 imagery collected right after the earthquake (2h after the main
 643 shock) with images remotely sensed after August 17, 2021. As indicated above and shown in Fig. 4, an
 644 intensification of denudation could indeed be observed after the tropical storm Grace event. However,
 645 one important limitation has to be highlighted: this comparison could only be completed for about 10%
 646 of the area potentially hit both by the earthquake and by Grace, due to the intense cloud cover present in
 647 the target region during that period. Furthermore, another effect could have contributed to slope failure
 648 intensification after the main shock on August 14, the one related to the aftershocks (see empty circles

649 shown in all maps above). However, analyzing this effect would require a refinement of the satellite
650 image analysis both in space and time, which is hardly possible considering the extensive cloud cover
651 present in the target area when all those seismic shocks occurred. Here, we will focus on the possible
652 climatic influence, which can better be outlined when comparing the landslide distribution with actual
653 precipitation maps. Therefore, we used the aforementioned Global Precipitation Measurement Mission
654 (GPM) data. Fig. 7 presents the three following types of GPM maps: average monthly precipitation maps
655 for the whole period of 2000 – July 2021, for all months of October between 2000-2020, and for October
656 2016, when Hurricane Matthew had crossed the island. Additionally, we compare in Fig. A4 the first and
657 third map with the precipitation map produced for August 2021, when Hurricane Grace had affected the
658 target area.

659 While comparing the average monthly precipitation rates between 2000 and 2021 (Fig. 7a) with the one
660 of October 2016 (Fig. 7c) we can see that, for the latter month, a peak of intensity of 626 mm can be
661 observed for the area between Gran Rivière De Nappe and Petite-Rivière-de-Nippes, situated
662 immediately in the north of the epicentral area of the 2021 main shock. Actually, the whole area
663 potentially affected by the August 2021 earthquake had been exposed to clearly higher precipitation rates
664 of more than 400 mm in October 2016, while, according to the GPM, average precipitation recorded in
665 October between 2000 and 2020 varies typically between 200 and 320 mm (as shown by the map, in Fig.
666 8b). For October 2016, those values were also the highest ones compared with the rest of the country and
667 are also larger than those obtained for August 2021 (max. 320mm) for the target zone, when Hurricane
668 Grace had crossed this region. This clearly indicates that the precipitation values must be related to a
669 specific (and even exceptional) climatic event, which can easily be identified as Hurricane Matthew that
670 had crossed the western peninsula (including the region hit later by the August 2021 earthquake) on
671 October 4-5, 2016. And, precisely for this region that had been exposed to abnormal precipitation rates
672 in October 2016, we could outline 625 landslides triggered after the Hurricane Matthew event, and before
673 the end of 2017 (yellow polygons shown above in the maps in Figs 1, 2, 3 and 4 and below in Fig. 7).
674 Additionally, most of these October 2016 – end of 2017 landslide zones (at least 90% of them) are located
675 within those mapped for the August 2021 seismic event (which are still marked by a much higher level
676 of denudation compared to the October 2016 activation). In the discussion, we will analyze how such
677 Hurricane Matthew might have preconditioned slope instability in the region hit by the August 14, 2021,

678 earthquake. We will also consider a general influence of tropical storms on the wide distribution of the
 679 landslides triggered in 2010 (and also for those triggered in 2021, in addition to the Hurricane Matthew
 680 effect).

681

682 **Figure 7: Monthly © Global Precipitation Measurement Mission (NASA) maps (0.1° resolution, values in**
 683 **mm/month) for southwestern Haiti, (a) for all months between August 2000 and July 2021, (b) for the month**
 684 **of October between 2000 and 2020, and (c) for October 2016 (marked by the Hurricane Matthew event).**

685 By comparing equivalent data (not shown here) of the merged satellite-gauge precipitation estimate for
 686 August 2021 with the monthly precipitation map averaged for all months of the previous 20 years, we
 687 can clearly see that August 2021 was indeed marked by a higher precipitation rate, which is most likely
 688 related to the Grace event. However, the most intense precipitation did not affect the region hit by the
 689 2021 earthquake but the eastern part of the peninsula, roughly covering the same region as the one
 690 affected by the 2010 event (note, we did not check any landslide reactivation after Grace for that area).
 691 The region hit by the 2021 earthquake was not affected by much higher monthly precipitation rates than
 692 usual: for the central seismically affected zone, in the north of Les Cayes, about 240-280 mm had been

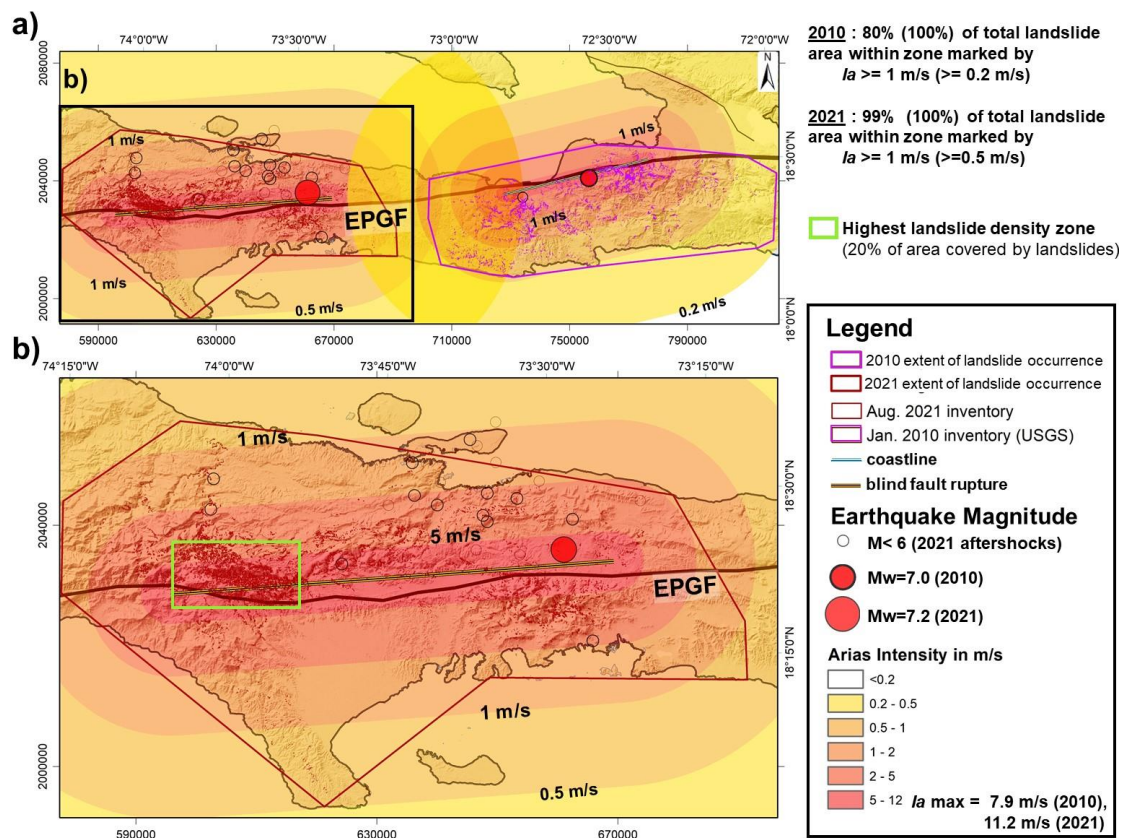

693 recorded in August 2021, against a monthly average of 200 mm. Thus, just by considering these data,
694 one would not expect an important climatic contribution to slope failure occurrence in the region affected
695 by the 2021 earthquake. Still, an influence could be observed and this is likely to be related to the
696 concentration of most of the ‘monthly precipitation’ of August 2021 within the two days (Aug. 16 and
697 17) of the Grace tropical storm event, just two days after the 2021 main shock. As indicated above, we
698 estimate that related precipitation has resulted in an increase of landslide surface areas of about 10-15%.
699 Due to the limited extent of zones where this check can be made (only considering the cloud-free areas
700 on the Sentinel-2 image of August 14, 2021), it was decided to map all areas covered by landslides after
701 August 14, 2021, also those which are likely to have been (re)activated by rainfall. The total effect of the
702 latter can barely be controlled and quantified outside the 10% of cloud-free zones visible on the image
703 collected right after the main shock. The only ‘correction’ that can be made is to reduce the total surface
704 area mapped as landslides by those 10-15% to estimate the one that was actually affected by co-seismic
705 slope failures: thus, instead of considering the value of 84 km², it is possible that co-seismic landslides
706 covered a total surface area of ‘only’ 75-78 km² – which is still three times more than the total surface
707 area covered by 2010 co-seismic landslides (close to 25 km²).

708

709 **4.4 Shaking intensity maps**

710 Above, we first analyzed the possible climatic influence on seismically induced slope failures as it could
711 affect the landslide distribution and thus has to be taken into consideration when assessing and
712 interpreting the seismic effect on landslide occurrence. The latter will only be analyzed here at regional
713 scale. Therefore, we compare the landslide distributions observed for the 2010 and 2021 events with the
714 respective estimated Arias Intensity (Ia) attenuation maps, computed by applying Eq. (7b) introduced
715 above, as recommended by Wilson and Keefer (1985) and also by later studies (e.g., Harp and Wilson,
716 1995, among many others). The map in Fig. 8a presents the 2010 and 2021 mainshock Ia attenuation
717 values, with a maximum shaking intensity of 11.2 m/s computed for the 2021 event and 7.9 m/s for 2010
718 (respective maps are partly overlapping in the central region, but not summed up, keeping the individual
719 values). This map shows that all 2010 and 2021 landslides are included within a zone marked by an Ia
720 threshold of 0.2 m/s (close to the one proposed by Keefer and Wilson, 1989, for disrupted slides and

721 falls). Actually, for 2021, 99% of the total landslide surface areas are even located within a zone marked
 722 by I_a values larger than 1 m/s; however, only 80% of the total surface areas of the 2010 landslides are
 723 included within the respective $I_a \geq 1$ m/s zone. Thus, the latter mass movements appear as more
 724 ‘dispersed’ with respect to the estimated seismic intensity attenuation than the 2021 ones. The 2021
 725 landslides are indeed most concentrated, as indicated above, within the green rectangle (see Fig. 8b,
 726 marked by I_a values of 4-11 m/s) with an area of 200 km² that contains 40 km² of landslide-covered
 727 zones (=20% of total area).
 728 Notwithstanding the relative dispersion of 2010 landslides, and the overlap of I_a values larger than 0.2
 729 m/s in the central zone between the two blind fault ruptures of 2010 and 2021, not a single landslide of
 730 2010 seems to have been reactivated in 2021. This observation raises the question if the central ‘landslide
 731 gap’ is due to an overestimation of the I_a values in this central zone (as this zone is marked by I_a values
 732 above the aforementioned minimum threshold of 0.2 m/s, for both events, and thus should have been
 733 affected by landslides both in 2010 and 2021, according to the shaking intensity prediction parameter),
 734 or if this zone is simply less susceptible to (seismic) slope failures.

735

736

737 **Figure 8: a) Arias Intensity (I_a) attenuation maps computed (by using Eq. 7b, by Keefer and Wilson, 1989)**
738 **for the 2010 and 2021 main shocks in Haiti; see also indication of % of total surface area of landslides observed**
739 **for different I_a thresholds. b) Focus on the respective map computed for the 2021 event.**

740

741 To answer this and other related questions, a full landslide susceptibility analysis has been completed
742 and will be presented in another paper. Here, only the possible links between landslide distribution the
743 aforementioned seismotectonic and climatic factors will be discussed.

744 **5 Discussion**

745 **5.1 Discussion about landslide distribution characteristics**

746 From the comparison of the two landslide catalogues (2010 and 2021), we could first infer that apparently
747 not a single landslide triggered in August 2021 occurred within the zone previously impacted by the 2010
748 event. There is a gap of about 10 km between the westernmost 2010 and the easternmost 2021 landslide
749 (see gap between the general outlines of the maximum extent of landslides triggered in 2010 and in 2021
750 shown on the map in Fig. 4a). Thus, we assume that there was no obvious preconditioning of landslide
751 generation in 2021 by the 2010 event, while landslide studies completed in other parts of the World (e.g.,
752 by Parker et al., 2015, for events in New Zealand) could outline an influence of previous earthquakes on
753 landslide occurrence during later events. The absence of this influence by the 2010 earthquake is
754 probably due to the long distance (the ‘gap’) of about 60 km between the fault segments that ruptured in
755 2010 and in 2021. However, by citing Saint Fleur et al. (2020), Stein et al. (2021) hint at an older event,
756 of 1770, with an assumed magnitude of 7.5 and an epicenter located precisely in the gap between the
757 2010 and 2021 blind fault ruptures, which could also have affected the region hit by the 2021 earthquake.
758 At present, we cannot exclude that this older event had preconditioned some slopes (by soil weakening,
759 rock fracturing) affected by some larger landslides in 2021; however, very shallow slope failures initiated
760 in 1770 are unlikely to have stayed in place over such a long period of more than 250 years, as they

761 would have been ‘washed’ away by the next tropical rains.

762 Second, none of the two earthquakes triggered very massive landslides, such as deep-seated rockslides
763 with a volume of more than $10 \cdot 10^6 \text{ m}^3$ (while extensive areas are covered by layered and weathered
764 limestone that could also produce massive slope failures; but this aspect will not be further discussed
765 here as the related geological influence on landslide occurrence will be analyzed in the landslide
766 susceptibility paper presently under preparation). Such massive failures have been observed after many
767 M7+ events in other mountainous regions of the world: see Fan et al. (2018) for the 2008 Mw=7.9
768 earthquake in China, or Havenith et al. (2015) for a series of M>7 events that hit Central Asian mountain
769 regions during the last 120 years. This is partly due to the fact that the regions hit by the two earthquakes
770 in Haiti are represented by mountains of limited elevation changes, typically less than 1000 m – while,
771 for instance, the Longmenshan Mountains hit by the 2008 Wenchuan earthquake, present elevation
772 changes of up to 3000 m over relatively short (<6 km) distances (Fan et al., 2018). This fact, combined
773 with the higher magnitude of the Wenchuan earthquake (Mw=7.9), could partly explain the much larger
774 number of massive rockslides triggered by the latter event in China. However, we have also to consider
775 some counterexamples of regions marked by mountainous relief that did not produce any very massive
776 rockslides during high-magnitude earthquakes (just like the 2010 and 2021 Haiti events), such as the part
777 of the Himalayas hit in 2015 by the Gorkha earthquake (see Lacroix, 2016). Thus, this problem related
778 to the more or less likely occurrence of massive rockslides in regions hit by high-magnitude earthquakes
779 is relatively complex, and cannot purely be approached by spatial analysis, as the one presented here.
780 More extensive numerical simulations would actually be necessary (but are definitely not the target of
781 our studies in Haiti) to assess the potential of seismically induced rockslides, such as those presented in
782 Gischig et al. (2015) or Lemaire et al. (2021).

783 Third, considering the values presented in Table 1, we still have to explain why the total surface area
784 covered by landslides in 2021 is much larger than the one covered by the 2010 landslides. We estimate
785 that this fact is likely to be related to (a combination of some of) the four following points: a) the first
786 likely physical reason for the larger area hit by mass movements in 2021 is the higher triggering
787 earthquake magnitude of the last event (this effect is also analyzed by comparing the influence of shaking
788 intensity on landslide distribution); b) another physical reason could be the possibly higher susceptibility
789 to mass movements of the western part of the peninsula hit by the 2021 event, compared to the eastern

790 part (this factor has to be analyzed on the basis of landslide susceptibility maps, considering also the
791 geological influence, which have been computed and will be presented in a follow-up paper); c) a third
792 reason for the larger area affected by landslides in 2021 could be related to the aforementioned ‘hurricane’
793 effects that will be further discussed below; d) and fourth, the more central location of the fault segment
794 activated in 2021 with respect to the coasts of the peninsula certainly also explains parts of the larger
795 total surface areas of (subaerial) slope failures triggered during the last event within the wider onshore
796 hanging wall part, as already introduced above.

797 In this regard, we also highlighted the fact that the 2010 event triggered most landslides in the south of
798 the activated fault segment, while in August 2021 about 2/3 of all landslides were triggered in the north
799 of it. Considering the oblique slip character along the fault ruptures of 2010 and 2021 dipping to the
800 north, the hanging wall is located on the northside of the blind fault rupture projected on the surface -
801 (according to the fault mechanism provided by the USGS Earthquake Hazard Program page,
802 earthquake.usgs.gov). In this regard, the Wenchuan earthquake has clearly marked the effect of the
803 hanging wall on the landslide distribution: about 90 % of all landslides were triggered on top of the
804 reverse fault dipping towards the west-northwest, only a minor portion occurred on the more ‘stable’ foot
805 wall (Gorum et al., 2011; Fan et al., 2018). The ‘hanging wall effect’ on landslide triggering can be
806 explained by stronger upward oriented shaking that contributes to a higher surface acceleration and more
807 intense slope failures; additionally, all (or most of the) aftershocks occurred within the hanging wall,
808 increasing the seismic shaking intensity cumulated over the active seismic period in the related surface
809 area, which could have contributed to prolonged landslide activity as well (to be added to the climatic
810 effect introduced above and discussed below). This effect may thus also be at the origin of the more
811 widespread landslide occurrence in the north of the 2021 blind fault rupture. The reduced number of
812 ‘subaerial’ landslides induced on the hanging wall side of the 2010 fault rupture can be explained by the
813 relative proximity of the respective fault rupture to the coast in the north and the absence of high and
814 steep slopes (onshore) on this side. Actually, a few known massive landslides occurred near the coast,
815 but are mostly located on submarine slopes in the 2010 hanging wall zone. Three of them reportedly also
816 caused tsunami waves (see Olson et al., 2011, among others) – a phenomenon that was not observed for
817 the 2021 event, as the coasts are located farther away from the seismic source zone.

818 5.2 Discussion about landslide size-frequency characteristics

819 Above, we clearly outlined the incompleteness of our 2021 inventory, for landslides smaller than about
820 3000 m²; thus, it is likely that thousands of smaller landslides could not be mapped from the medium-
821 resolution Sentinel-2 imagery (10 m) and the higher resolution imagery (0.5 – 1 m) available on GEP
822 for 50% of the target area before the end of 2021. To refine our landslide mapping in future, higher
823 resolution imagery must be used for the whole area affected by the 2021 event, and automatic landslide
824 identification techniques shall be applied by combining image analysis and machine learning as proposed
825 by Amatya et al. (2021). Actually, the ‘manual’ mapping applied now would take too much time to outline
826 the many thousands of very small landslides that have not been identified so far. Those would contribute
827 to the increase of the weight of the smaller landslides in the 2021 inventory, especially of those smaller
828 than 3000 m². It can be assumed that Zhao et al. (2022) have identified a larger number of smaller
829 landslides or have mapped separate landslides where we had considered them as merged larger mass
830 movements, as they obtained a larger absolute value of the decay exponent ($=2.47$, compared to ours,
831 being 2.03). In addition, the total area affected by landslides mapped by Zhao et al. (2022) is clearly
832 smaller than ours. From the combination of both observations, we may conclude the following: either we
833 have over-mapped landslide areas or, by splitting coalescent mass movements, Zhao et al. (2022) have
834 under-mapped failed slopes. Providing an answer to this question would require a more detailed analysis
835 of both inventories, which is not possible here. For our inventory we may just say that its likely
836 incompleteness limits its use for size-frequency analyses. By comparing related statistics with those made
837 for the 2010 landslide inventory, we can just say that the last event has triggered numerous larger
838 landslides than the one in 2010 (based on ‘landslide size’ classes, for which the 2021 inventory can be
839 considered as complete). Actually, landslides triggered in 2010 mainly consisted of narrow slides and
840 flows in weathered limestone rocks, while the 2021 earthquake also induced landslide processes over
841 wider slope areas – as clearly shown by the 2021 and 2010 landslide zone views presented in Fig. 5; in
842 the *Ravine du Sud*, even entire slope units had failed in August 2021 (but the failed parts were typically
843 not very thick, less than 10 m).

844 5.3 Discussion about climatic pre-conditioning effects

845 We estimate that the different climatic conditions observed before the respective events may partly
846 explain the more widespread occurrence of larger landslides related to the 2021 event. In this regard we
847 indicated that the climatic contribution to landslide activity in 2021 might be twofold: first, some post-
848 seismic intensification of slope failures could be observed after the tropical storm Grace event that had
849 crossed the earthquake region on August 16-17, two days after the main shock. However, related effects
850 cannot really be quantified as only 10% of the total surface area potentially affected by the earthquake
851 appeared as cloud-free on imagery available right after the August 14 main shock and before August 16
852 (Grace event). For those limited areas, we estimate that storm Grace caused a widening of about 10-15%
853 of all slope failures with respect to the purely earthquake-induced landslide activation. Second, by
854 comparing the 2016-2017 landslide distribution with the one observed after August 14, 2021, it can be
855 seen that most of the October 2016 – end 2017 landslides occurred within the same region as the 2021
856 ones and most were clearly reactivated by the seismic shaking in August 2021 (while also many of them
857 had been revegetated in between). Above we could show that Hurricane Matthew had crossed the western
858 part of the peninsula in October 2016, producing an abnormal amount of precipitation precisely over the
859 area that was later hit by the earthquake (see GPM maps in Fig. 7), and where also hundreds of landslides
860 had occurred just after mid-October 2016. Therefore, it is very likely that this climatic event has triggered
861 many (and probably most) of the 625 mapped pre-seismic (October 2016 - pre-2018) landslides, which
862 preconditioned slope instability all over the area hit by the 2021 earthquake. Preconditioning of the
863 August 2021 slope failures could have been related to rock weakening and fracturing, and removal of the
864 protective vegetation cover during the 2016 Matthew event. Indeed, practically all 625 mapped October
865 2016 – pre-2018 landslide zones (at least 90% of them – and, considering that only for 50% of the entire
866 potentially affected area in 2016 landslide could be mapped over cloud-free zones) are located within the
867 landslide areas mapped for the August 2021 seismic event (which are still marked by a much higher level
868 of denudation compared to the October 2016 activation). The double hurricane effect (by Matthew in
869 2016 and by Grace just after the 2021 main shock) observed in the area hit by 2021 earthquake could be
870 responsible for the proportionally larger size of the 2021 landslides (estimating that the 2016 event, due
871 to its extreme intensity, made the strongest contribution) compared with the 2010 ones. In addition, we
872 have to consider that the 2010 earthquake had not been preceded by any particular hurricane event during
873 the previous ten years, at least not by any storm that had caused abnormal precipitation amounts (similar

874 to those caused by Hurricane Matthew) within the region hit by the 2010 earthquake.
875 Furthermore, the combined seismic and climatic influence could also explain the very different spatial
876 landslide distribution characteristics of the 2010 and 2021 catalogues: the relative dispersion of
877 landslides observed after the 2010 event could thus be partly related to the spatially highly variable effect
878 of tropical storms and hurricanes on landslide activity (acting over a longer period, with an influence that
879 could last over tens of years), partly overprinting the more concentrated seismic effect (resulting in
880 clusters of mass movements near the seismic source zone). The same dispersion might also have been
881 observed for the 2021 event if the central part of the seismically affected area had not been hit by that
882 major climatic event just five years before – doubling the landslide concentration effect in that area
883 (specifically for the 2021 event). However, we acknowledge that a quantification of these opposite effects
884 of climatic events, both on landslide dispersion and on their concentration, requires a more detailed
885 analysis. The latter should also include some studies focused on specific sites, by completing numerical
886 simulations of mass movements affected by variable climatic (modelling changing groundwater level)
887 and seismic influences (including the effect of rock structures and types of lithologies and morphologies
888 on shaking polarization and amplification). A related landslide spatial distribution analysis should then
889 also consider the influence of extensive deforestation on slope destabilization, all over the country of
890 Haiti. Actually, deforestation is responsible for the decrease of 90% of the primary forest over the last
891 few tens of years, especially in the southern regions of Haiti where the two earthquake events had
892 occurred (see Hedges et al., 2018). As mostly shallow landslides occurred in 2010 and 2021, the effect
893 of deforestation on the destabilization of shallow soils and weathered rock cover must be taken into
894 consideration for landslide occurrence prediction. Such an extensive study would thus require the
895 creation of an integrated seismotectonic-morpho-geological-climatic-soil cover model allowing us to
896 fully understand changing landslide activity in Haiti – which is not the target of the present analysis (but
897 will be partly approached in the follow-up paper).

898 **5.4 Discussion about the regional seismic shaking influence on landslide distribution**

899 As for the climatic part, here, we only present regional data to outline some general seismic influences
900 on landslide activity induced by the 2010 and 2021 earthquakes. Related maps (Fig. 8) show that the
901 aforementioned gap of landslides between the areas affected by the earthquakes in 2010 and 2021 would

902 indeed be marked both by a lower shaking intensity (but showing values that are still larger than the
903 threshold Ia values observed elsewhere for landslide occurrence) and lower landslide susceptibility (a
904 result that still has to be published). In the annex (Fig. A1), we also present the shakemaps produced by
905 the USGS for the two events, but we did not compare landslide distributions with these maps as the latter
906 do not seem to be coherent with respect to each other, noting that much larger intensities would have
907 been produced by the lower magnitude event of 2010. Actually, it should be considered that such maps
908 are also influenced by regional site effects (mostly on flat areas) that are not really relevant for landslide
909 trigger mechanisms, and are also depending on ground measurements of seismic intensity that had not
910 been well constrained during the 2010 event due to missing seismic stations in Haiti at that time (a
911 problem that starts to be solved now).

912 **6 Conclusions**

913 In this paper we presented a new landslide inventory created for the Mw=7.2 Nippes earthquake that
914 occurred on August 14, 2021, in Haiti. Related spatial and statistical characteristics have been compared
915 with those of the landslides mapped by others for the previous, Mw=7.0, January 12 (2010), earthquake
916 that had occurred along the same fault zone (EPGF zone) but more to the East. Considering a series of
917 uncertainties affecting the landslide statistics (related to the mapping technique, including the uncertain
918 number of particularly small landslides triggered in 2021) and the environmental information (including
919 some general climatic and geological conditions), this comparison allowed us to highlight the following
920 points: 1) the 2021 earthquake triggered clearly bigger landslides than the one in 2010, and also the sum
921 of all landslide areas is much larger than the one computed for the 2010 event; 2) a climatic
922 preconditioning of slope instability could be outlined for the 2021 event, mainly in connection with the
923 impacts of recent hurricanes in the 2021 affected region, which could also partly explain the more
924 extensive landslide activity observed in 2021; 3) the 2010 landslides seem to be more dispersed around
925 the epicentral area than the 2021 slope failures, which could be due to the opposite climatic effect
926 inducing spatially more variable slope destabilization (also as no particular storm had hit the 2010
927 affected region just before or after the seismic event, as it was the case in 2021). This dispersion effect
928 can also be enhanced by the spatially varying deforestation that is locally very intense in the target areas.

929 We estimate that this proof of a likely combined seismic and climatic influence on landslide activity
930 (possibly augmented by morpho-geological and soil cover effects not studied in detail here) opens new
931 avenues for geohazard research, especially for regions like Haiti that are regularly hit both by severe
932 earthquakes and weather events. We also think that preconditioning of slope failures by multiple events
933 over longer terms, including by former earthquakes, should be studied more in detail as this
934 preconditioning could highly contribute to local and regional landslide hazards, both over short and
935 longer terms. A full analysis of such a scenario would require the development of an integrated
936 seismotectonic-morpho-geological-climatic-soil (and vegetation) cover model, combining extensive
937 spatial analyses with detailed numerical simulations, which can only be completed through an extensive
938 international multi-disciplinary collaboration around this target – which is obviously missing for Haiti.
939 Assessment of related risk would further require the involvement of experts in social geography and
940 economy. Also, a closer collaboration between scientists and the population shall be promoted as
941 recommended by Calais et al. (2022) and von Hillebrandt-Andrade and Vanacore (2022). Only when
942 these goals are achieved, we could really work on the prevention of at least parts of another future
943 earthquake disaster in Haiti.

944

945 **Acknowledgments**
