## Abstract. ~~For~~

20 To what extent an individual or group will be affected from the damage of a hazard depends not just on their exposure to the event, but on their social vulnerability – that is, how well they are able to anticipate, cope with, resist, and recover from the impact of a hazard. Therefore, for mitigating disaster risk mitigation planeffectively and for building a society more disaster-resilient society to natural disasters hazards, it is essential to understand the factors that are related to social vulnerability as that policy-makers develop an important dimension to understanding of social riskvulnerability. This study aims to propose an optimal predictive model that allows decision-makers to identify the associations between households with high social vulnerability by using a number of easily accessible household variables. In order to develop such a model, we rely on a large

25 ~~dataset comprising a household survey (n=41,093) that was conducted to generate a social vulnerability index (SoVI). In this study, we assessed the predictive ability of socio-economic and socio-demographic household characteristics, and earthquake related housing conditions on the household level social vulnerability using survey data collected from 41,093 households in Istanbul. Machine through machine learning models, namely: logistic regression, We used classification tree (CART), random forest (RF), support vector machine (SVM), naive bayes, Bayes (NB), artificial neural network, and K (ANN), k-nearest~~  
30 ~~neighbours, were employed (KNN), and logistic regression to classify households according with respect to their social vulnerability status level, which was used as the outcome of these models. Due to the disparity of class size for the outcome variable variables, subsampling strategies were applied for dealing with imbalanced data. Artificial Neural Network (ANN) Among these models, ANN was found to have the optimal predictive performance for discriminating households with low and high social vulnerability when random majority under-sampling was applied (Area Under the Curve (AUC): 0.813).~~  
35 ~~The results from the ANN method indicated that not having lack of social security, living in a squatter house and having high risk of job loss after an earthquake insecurity were among the most important predictors for increasing of social vulnerability risk to hazards. Additionally, the level of education, the ratio of elderly persons in the household, owning a property, household size, ratio of income earners, and having savings of the household were found to be associated with social vulnerability. An open access R-shiny web application was developed to visually display the performance of ML methods, important variables~~  
40 ~~for the classification of households with high and low social vulnerability risk classification and the spatial distribution of the variables across Istanbul neighbourhoods. The machine learning methodology and the findings that we present in this paper can serve as a guidance for guide decision-makers in identifying social vulnerability effectively and prioritising action hence let them prioritise actions towards target vulnerable groups to reduce their vulnerability risk in terms of needs prior to earthquakes an event of a hazard.~~

## 45 **1 Introduction**

~~The United Nations Office for Disaster Risk Reduction describes disasters as events that exceed the capacity of states and/or communities to cope with the consequences of a hazard (UNISDR, 2009). However, not all hazards result in a disaster. The evolution of an earthquake event into a disaster is typically studied through the lenses of geoscientists, civil engineers and earthquake engineers, since the most tangible results or causes of a disaster are physical. However, it is often forgotten or~~

50 ignored that the human consequences of disasters are in part derived from the composition of the population and society prior to the event. Therefore, we posit that a more comprehensive understanding of disasters is possible by looking at both physical and social aspects.

Istanbul, which is the 13<sup>th</sup> most populated city in the world with a population of more than 15 million (WUP, 2021), is exposed to earthquake hazards due to the North Anatolian fault which lies across the southern border of the city. Historical records show that in approximately every 100, 250 and 500 year periods, a severe earthquake hits Istanbul and causes significant casualties and damage to infrastructure. A recent study suggests that Istanbul and other nearby areas in the Marmara region are at a significantly high risk of devastating earthquakes, with magnitudes between 7.1 and 7.4 (Lange et al., 2019). It is estimated that an earthquake with a magnitude of 7.5 in the North Anatolian Fault across Istanbul would cause tens of thousands of deaths, and catastrophic damage to buildings and infrastructure (IMM and KOERI, 2019), leading to the destruction of human life and wellbeing, along with economic and social devastation.

There are various studies in the fields of earthquake engineering and geosciences that address the earthquake hazard and the physical vulnerability of infrastructure and buildings in the Istanbul metropolitan area (IMM and KOERI, 2019; Parsons et al., 2000; Parsons, 2004; JICA and IMM, 2002; Erdik et al., 2003; Ersoy and Koçak, 2016). Such studies are important for interpreting the possible consequences of earthquakes and they support decision makers and public authorities in developing strategies and policies for disaster response. Nevertheless, developing robust and concrete disaster risk reduction measures requires consideration of social aspects as well as physical ones. Among the social aspects, that of “social vulnerability” has become an increasingly popular topic in natural disaster research (Shen et al., 2018). Social vulnerability differs from physical vulnerability in that it does not regard the number of possible injuries or fatalities that may occur due to, for example, the collapse of buildings. It is, rather, a measure of the capacity of an individual or household to anticipate, cope with, resist, and recover from the impact of an earthquake (Blaikie et al., 2014; Wisner et al., 2012). Additionally, social vulnerability increases the social risks of different social groups in relation to a set of socioeconomic conditions and is needed to be determined before a particular hazard hits the society (Cannon, 2008). Social risk refers to expected human and economic losses resulting from a particular natural hazard in a given time and place (Cutter, 1996). Hence, assessing the possible social risks of vulnerable groups can perform a predictive role towards improved preparedness and ability to recover from natural disasters (Ogie and Pradhan, 2019). The identification of the factors that contribute to social vulnerability is therefore crucial for effective disaster risk management and for building a more resilient society (Aksha et al., 2019).

In the literature, there are many different aspects to the assessment of social vulnerability, and they can be based on the location of the research, the hazard type, the scale, and the temporal focus. One of the first studies that describes vulnerability from a social perspective is Cutter’s research (Cutter, 1996) that focuses on social aspects of the vulnerability concept based on a detailed “vulnerability” literature review. Another study by Cutter et al. (2003) is analytical and includes county scale social vulnerability analysis from census data. Social vulnerability is assessed based on 42 different variables that were reduced to 11 significant indicators to construct a social vulnerability index. Various studies thereafter, assessed the indicators that could be used to measure the social vulnerability for a certain location and time frame (Holand et al., 2011;

Bergstrand et al., 2015; Fatemi et al., 2017; Rufat et al., 2019; Spielman et al., 2020; Rahman et al., 2022). It can be suggested that there is almost a consensus between those studies where social vulnerability is defined as a function of gender, health status and access to healthcare, poverty, age, ethnicity, property ownership, and socio-economic indicators (Kalaycioglu et al., 2006). In addition to such individual characteristics, space-related metrics such as rural/urban status (Cutter et al., 2000; Cova and Church, 1997; Mitchell, 2000) and population density (Cutter et al., 2000; Morrow, 1999; Puente, 1999) as well as public service-related indicators, such as infrastructure quality and the proximity of healthcare facilities (Cutter et al., 2000; White, 2000; Bolin and Stanford, 1991; Duzgun et al., 2011), are used to form different types of approaches for assessing the social vulnerability on larger scales such as across a district or a city. Measuring social vulnerability on a regional scale can give important insights into the variation within and overall vulnerability of a country, region or population group. Nevertheless, it may still be informative to measure vulnerability at a household level, using all dimensions and indicators, to represent better individual vulnerabilities (Debesai, 2020).

Numerous studies have examined the factors relating to social vulnerability in the event of an earthquake, which have used either descriptive statistics (Yücel and Görün, 2010; Walker et al., 2019), or traditional data analysis tools, such as linear or logistic regression (Noriega and Ludwig, 2012; Syed and Kumar Routray, 2014; Llorente Marrón et al., 2020). While the former lacks the incorporation of the relationships between the vulnerability indicators, the latter relies heavily on data assumptions. In contrast, machine learning (ML) algorithms allow for a larger number of predictors, can handle complex interactions between predictors, can model nonlinear relationships and they do not make any distributional assumptions regarding the data (Ryo and Rillig, 2017). Due to these advantages, there is an emerging interest in using ML methods for making predictions or classifications for large scale survey data (Buskirk et al., 2018). A relatively small number of researchers have opted to use ML methodology over regression techniques in vulnerability research (Dwyer et al., 2004; Alizadeh et al., 2018; Yoon and Jeong, 2016; Abarea Alvarez et al., 2019), and indeed a detailed model-based assessment of the predictors of social vulnerability to earthquakes is lacking.

Several applications of machine learning methods that relate to social vulnerability in natural hazards are present in the literature. Dwyer et al. (2004) used decision tree methodology for identifying individuals at social risk to natural hazards in Perth City, Australia, and found 11 decision rules that determine high social vulnerability to natural hazards. By collecting data with questionnaires, they investigated the relative importance of 13 indicators related to demographic and economic household attributes in contributing to the prediction of social vulnerability. Other studies were based on larger sampling units such as districts, neighbourhoods or communities, in contrast to our study which was based on household survey data. Alizadeh et al. (2018) used Artificial Neural Networks (ANN) for deriving a social vulnerability to earthquake map in the Tabriz city, Iran, for detecting the most and the least vulnerable zones from a spatial perspective. Yoon and Jeong (2016) assessed the vulnerability to natural disasters at a community level in South Korea using 12 vulnerability variables including social, economic, natural environment and built environment aspects. They examined the important vulnerability indicators by the use of traditional linear regression as well as two machine learning techniques, Random Forests and Cubist. They showed that machine learning techniques have better model performances compared to traditional regression methodology. In another

vulnerability study, Abarea-Alvarez et al. (2019) identified deprived areas that are more prone to social vulnerability in Andalusia using decision trees. They used variables related to socio-demography, socio-economy, community, and public infrastructure. Their dataset was taken from the Andalusian Population Census available at a regional scale. All three aforementioned studies are related to the idea of comparing different and larger settlement units for social vulnerability to natural hazards (Alizadeh et al., 2018; Yoon and Jeong, 2016; Abarea-Alvarez et al., 2019).

In this study, we attempt to give further contribution to social vulnerability research in natural disasters by identifying the most important factors that contribute to the prediction of social vulnerability of households in Istanbul in the event of an earthquake.

The impacts of hazards are increasing at an unprecedented rate as the exposure of communities and individuals increases and climate change amplifies the intensity of the hazards (UNDRR, 2022). Moreover, urban expansion and population growth are expected to be mostly in low and middle-income countries (Mesta et al., 2022; Schipper et al., 2016) where vulnerabilities to hazards are significantly high due to a lack of proper urbanization practices (e.g., construction codes, infrastructure quality and availability) and socioeconomic characteristics (e.g. poverty, lack of access to livelihoods, low level of education attainment) (Dodman et al., 2013).

In this research, we focus on the socioeconomic aspect of the vulnerability phenomenon, which will be named “social vulnerability” hereafter. Based on the vulnerability definition: “The conditions determined by physical, social, economic and environmental factors or processes which increase the susceptibility of an individual, a community, assets or systems to the impacts of hazards” by UNDRR (2022); we look at specific social factors that may increase the level of adverse impacts due to a hazard. Social vulnerability increases the risks of different social groups in relation to a set of socioeconomic conditions and needs to be determined before a particular hazard hits society (Cannon, 2008). Therefore, identification of the factors that contribute to social vulnerability is crucial for building a more resilient society (Aksha et al., 2019). In doing so, some characteristics of various layers of society come to the fore in explaining the concept of social vulnerability.

There is a critical need to assess vulnerabilities for improved preparedness and ability to recover from hazards at different scales, however, only a few studies assessed vulnerability at the individual household level in developing countries (Debesai, 2020). Within this frame, we aim to understand the factors that influence social vulnerability by utilising machine learning (ML) techniques which gives us the chance to deal with big household databases. By that our target is to provide an efficient approach that can be adopted within different spatial contexts for comprehending the determinants of social vulnerability based on easily accessible databases. ML techniques are capable of handling interactions between variables, thus the proposed approach considers interactions between factors to reflect the multidimensional and complex nature of social vulnerability. We demonstrate this approach to the Istanbul case study area in which we benefit from a previous social vulnerability study to test our methodology at household level. For building ML models, we rely on a large dataset of a previous study comprising a household survey (n=41,093) and pre-constructed social vulnerability index (SoVI) of these households. We consider the SoVI scores as an indication of the social vulnerability level for each household, and our focus in this study is to assess to what

150 extent the pre-constructed SoVI (and hence the social vulnerability of the households) can be predicted with machine learning techniques using household data that are available within databases of various institutions and public authorities.

155 This study contributes to disaster risk research in several aspects. First, we propose a methodology to identify the descriptors of social vulnerability, which is generic enough to be adopted for any spatial context. The proposed method extracts representative predictors for social vulnerability which are accessible in most spatial contexts around the world. Second, we introduce ML algorithms into vulnerability assessment practices which is a relatively overlooked aspect as a method in the disaster risk discipline. It is seen that ML algorithms can be used efficiently to overcome the complexity of the social vulnerability concept, particularly with large datasets. Thirdly, since there are only a limited number of studies which assesses vulnerability at the household level (particularly in developing countries) (Debesai, 2020), our method is an attempt to contribute to the literature by bringing in a more precise approach to estimating social vulnerability in a household scale.

160 This paper is structured in four following sections: i) context and motivation for this study, which involves a literature review on the social vulnerability context and the approaches developed to measure it, followed by our motivation on why we chose machine learning techniques as an approach to identify the descriptors of social vulnerability (Sect. 2) ii) the materials and methods applied within our research (Sect. 3) iii) the results that came out as a consequence of our methodology applied (Sect. 4) and iv) conclusions and discussions where we present our findings based on the results and discuss the limitations and rooms for improvement in our approach (Sect. 5).

## **2 Background for Social Vulnerability Assessment**

170 The social, political and economic characteristics of individuals influence their status of being exposed to disasters (Cutter et al., 2009). Therefore, the human dimension has become an increasingly popular topic in disaster risk research for comprehensively assessing and understanding the potential impacts of natural hazards (Shen et al., 2018). In this regard, social science research in the hazard domain is shaped around questions such as “Which factors influence the adoption of individuals to hazards?”, “Why do people prefer to live in hazardous areas?”, and “How the individuals’ risk perception influences their behaviour?” (Burton et al., 2018). Answers to these questions could help to understand social indicators of vulnerability, and in fact, they explain why people with similar levels of exposure may experience very different levels of adverse impact. Social indicators of vulnerability are studied extensively in the literature (e.g., Wang and Sebastian, 2021; Aksha et al., 2019; Fatemi et al., 2017; Cannon, 2008; Cutter et al., 2003). Within these studies, social vulnerability expands over a diverse range of social, individual, and sometimes spatial characteristics.

180 Just to mention a few, disability, for example, is one of the most common indicators within social vulnerability literature, in which it is emphasised that disabled people are more disadvantaged in terms of coping against the implications of hazards compared to non-disabled individuals. It is also empirically known that the death rate of disabled people is higher in large-scale disasters such as earthquakes, floods, and tsunamis (Stough and Kelman, 2018; Peek and Stough, 2010). Within

185 demographical components, gender is also one of the most commonly used ones as women are considered more vulnerable to hazards compared to men (e.g., Llorente-Marrón et al., 2020; Martins et al., 2012; Fekete, 2009). With respect to the age dimension, it is acknowledged that children and especially elderly people over 65 who live alone are age groups that can be more affected by any disaster (e.g., Fatemi et al., 2017). The responses of children, the elderly, the disabled, and patients to a hazard may not be the same as those of young, healthy people (Chou et al., 2004).

190 Besides demographic properties, the characteristics that determine the socioeconomic level such as income, employment status, social security, and household size, have an influence on the level of vulnerability (e.g., Chen et al., 2013; Holand et al., 2011; Evans and Kantrowitz, 2002). Enarson et al. (2018) show that the distribution of labour affects the impact of disasters on mortality and morbidity. It must also be noted that socioeconomic status is mostly accompanied by “education level” which denotes the highest education degree a person has. In several studies, it is implied that higher education level leads to more ability to cope and/or resist hazards, as higher education level enables higher-income jobs and wealthier life (e.g., Wisner and Luce, 1993; Armaş, 2008).

195 In addition to socioeconomic and demographic properties, in some studies, the physical environment is also considered an indicator of social vulnerability, where the infrastructure quality, availability and access to public resources such as transportation, education and health facilities are incorporated within the concept (e.g., de Oliveira Mendes, 2009; Cutter et al., 2000; Holand and Lujala, 2013). It is assumed that the lack of those opportunities increases the social vulnerability of the individuals within the area of interest.

200 In this context, it is seen that descriptors for social vulnerability to hazards are mainly grouped under 3 dimensions: i) demographics, ii) socioeconomics, and iii) the physical environment. More detailed reviews on social vulnerability indicators can be found at Nor Diana et al. (2021), Fekete, (2009), and Fatemi et al. (2017).

205 Although there is more or less a consensus on the indicators of social vulnerability, measuring it is challenging due to the complexity of the concept and its latent nature (Birkmann and Wisner, 2006). To quantify social vulnerability as a single metric value, three main statistical modelling approaches are employed: inductive, deductive and hierarchical. Inductive models combine a set of large indicators into latent factors, and then sum these factors to construct a single index score for social vulnerability. Deductive models contain fewer indicators which are normalized and summed to construct the index score. Hierarchical designs aggregate indicators into groups (sub-indices) that share an underlying dimension of vulnerability. These sub-indices are then aggregated to construct a vulnerability index. The methodological comparison of these designs and various approaches to constructing a social vulnerability index are reviewed by various authors, such as Tate (2012), Rufat et al. (2019), and Bakkensen et al. (2017).

210 Among these approaches, the social vulnerability index (SoVI) developed by Cutter and her colleagues (2003) has been one of the most commonly used tools to quantify vulnerability (6663 citations according to Google Scholar by 24th December 2022). In the aforementioned study, SoVI was constructed by factor analysis based on principal components analysis (PCA)

215 in U.S. County scale based on 42 vulnerability variables. In Cutter et al. (2003), where the data from areal divisions (U.S. Counties) are used, a total of 11 factors were obtained which explains 76.4% of the variance in social vulnerability in the U.S. counties. The SoVI scores were calculated by summing the raw metrics for each county, where the higher and lower scores represent high and low social vulnerability, respectively. Various studies thereafter assessed the indicators that could be used to measure social vulnerability for a certain location and time frame (Holand et al., 2011; Bergstrand et al., 2015; Fatemi et al., 2017; Rufat et al., 2019; Spielman et al., 2020; Mahbubur Rahman et al., 2022). It can be suggested that there is almost a consensus between those studies where social vulnerability is defined as a function of gender, health status and access to healthcare, poverty, age, property ownership, and socio-economic indicators (Kalaycioglu et al., 2006). For the SoVI which was constructed in İstanbul in 2018 similar variables and categories were used with reference to Cutter et al. (2003) but the data was collected via a household survey (for more information on variables see Sect. 3 and Supplementary File 1).

225 The inductive factor analytic framework proposed by Cutter et al. (2003) to measure social vulnerability has been widely adopted in many studies (e.g., Aksha et al., 2019; Chen et al., 2013; Rabby et al., 2019; Guillard-Gonçaves et al., 2015; Krishnan et al., 2019; Roncancio et al., 2020; Wang et al., 2022). SoVI is a valuable tool not only for academics but also for policy-makers and governmental bodies as it allows making spatial assessments, that enables comparison of different spatial entities such as counties, districts, and neighbourhoods with respect to their social vulnerability level (e.g., Spielman et al., 2020; U.S. Environmental Protection Agency, 2015; Emrich et al., 2014; Dunning and Durden, 2011; Flanagan et al., 2011). Although SoVI is used in many studies, the vulnerability research which assesses household-level social vulnerability are limited (Liu and Li, 2016; Wilson, 2019; Tasnuva et al., 2021).

235 Although the common usage of SoVI and its advantages, various studies showed that the prediction of social vulnerability can be enhanced by empirical modelling utilising historical event data and intensity measures for the given hazard (Wang and Sebastian, 2021; Wang et al., 2021; Bjarnadottir et al., 2011). Relying on empirical data can be considered a more realistic approach in estimating the social vulnerability of a given entity (compared to SoVI); but the high dependence on data may become an obstacle, particularly for contexts where data scarcity is in place or data sharing protocols are missing. Another drawback of such an approach is that hazard occurrence can be very rare which decreases the chance to use historic data and relate it with the social context for a specific hazard event. For example, in İstanbul – Turkey, the historical records show that the return period of a major earthquake (over 7.0 Mw) is approximately 100 years (Parsons, 2004; Utsu, 2002). As a result, there is no temporal correlation between urban development pace and the hazard occurrence in İstanbul which makes it impossible to use empirical data to evaluate social vulnerability. Therefore, it is not possible to use such a method in the İstanbul context.

240 In this respect, SoVI scores are commonly used as a proxy of social vulnerability, which is independent of empirical data, which enables to develop a more generic methodology that can be applied in different contexts. Within this scope, there are numerous studies that have examined the factors relating to social vulnerability in a hazard, by using either descriptive statistics

245 (e.g., Yücel and Görün, 2010; Walker et al., 2019), or traditional data analysis tools, such as linear or logistic regression (e.g.,  
Fekete, 2009; Noriega and Ludwig, 2012; Syed and Kumar Routray, 2014; Llorente-Marrón et al., 2020; Mtintsilana et al.,  
2022). While the former lacks the incorporation of the relationships between the vulnerability indicators, the latter relies  
heavily on data assumptions. In contrast, machine learning (ML) algorithms allow for a larger number of predictors, can handle  
complex interactions between predictors, can model nonlinear relationships and do not make any distributional assumptions  
250 regarding the data (Ryo and Rillig, 2017). In quantitative social research, particularly with large-scale survey data where  
relationships between socio-demographic and socio-economic variables cannot be ignored, there is an emerging interest in  
using ML methods for making predictions (Buskirk et al., 2018).

A relatively small number of researchers have opted to use ML methodology over traditional statistical techniques in  
vulnerability research (Table 1), and indeed a detailed model-based assessment of the predictors of social vulnerability to  
255 hazards seem lacking. The few studies that employ ML techniques were based on larger sampling units such as districts,  
neighbourhoods, or communities, in contrast to our study which was based on a household scale. Due to the low number of  
studies and significant variation in their methodology, scale level and outcome type, it is difficult to make model-based  
recommendations. Moreover, the performance of various ML methods is rarely compared in terms of their predictive accuracy  
for social vulnerability in hazards (Yoon and Jeong, 2016).

### 3 Materials and Methods

In our study, we attempt to contribute to social vulnerability research by identifying the most important factors that contribute to the prediction of social vulnerability of households by using ML approach. In this regard we address the following research questions: (1) What is the best performing ML method for classifying the risk status prediction of social vulnerability? (2) What are the most influential predictors associated with social vulnerability? We posit that, when large data sets are available at the application of a broad conceptual model, household level, the models developed based on ML algorithms, leads have the potential to a better understanding of households that would be predict socially vulnerable in the event of an earthquake, households with high accuracy.

The research presented in this paper acts as an addition or phase two of a previous study. The first phase covers the calculation of the social vulnerability score for more than 40,000 households in Istanbul, as explained in Menteşe et al. (2019).

290 It considers the concept of social vulnerability as a state that arises from intrinsic characteristics of society, such as the  
perception of risk and the measures taken against risk, as well as cultural values and socio-economic status. Then, in the second  
phase, presented in this paper, we assessed to what extent household characteristics can predict the severity of social  
vulnerability risk via ML methods. The predictors we use in this study have been restricted to quantifiable variables as they  
present tangible information for modelling and measuring social vulnerability. This type of household information is available  
295 in metropolitan / district municipalities, neighbourhood mukhtars, city governorship and from Address Based Population  
Registration System. At present, such data has not been used for risk reduction policies by public decision makers. Hence, our  
model can serve as guidance for the decision makers for identifying and prioritising action towards target groups in the interests  
of risk mitigation.

300 The layout of the paper is as follows. First, the household survey data is introduced. Secondly, ML methods including  
subsampling strategies for the imbalanced class variables are explained, along with the model assessment criteria. Then we  
train, validate, and compare predictive performances of ML models for social vulnerability and find the best performing ML  
model. Finally, the importance of the predictors and their effects on the response for estimating social vulnerability were  
discussed for the best performing model.

## **2 Materials and Methods**

### **2.1 Social vulnerability survey**

305 As an indication of hazard-related social vulnerability, we have adopted SoVI that was previously constructed in Istanbul in  
2017 (IMM, 2018; Mentese et al., 2019). In this paper we do not intend to discuss the SoVI scores or the methodology of this  
previous study; but instead, we consider the SoVI scores as a proxy of social vulnerability state for each household. We  
assessed to what extent the pre-constructed SoVI (and hence social vulnerability of the households) can be predicted with  
machine learning techniques using quantifiable household variables data (such as socio-economic and socio-demographic  
310 characteristics and housing conditions) that are assumed to be available within publicly accessible databases provided by  
statistical institutes of central government agencies or local public authorities. Thus, we aimed at presenting an approach which  
can reduce the time and economic burden that decision-makers can spend collecting data and modelling to identify households  
with high social vulnerability.

### **3.1 Study Area**

315 We used household survey data from Istanbul, Turkey which was collected to assess earthquake-related social vulnerabilities  
of the households in Istanbul. Turkey is in a region that is prone to natural hazards where a large-scale disaster happens every  
seven to eight years (Baris, 2009). Istanbul, which is the 13th most populated city in the world with a population of more than  
15 million (WUP, 2021), is exposed to earthquake hazards due to the North Anatolian fault which lies across the southern

border of the city under the Marmara Sea. It is estimated that an earthquake with a magnitude of 7.5 Mw in the North Anatolian Fault across Istanbul would cause thousands of deaths, and catastrophic damage to buildings and infrastructure (IMM and KOERI, 2019), leading to the destruction of human life and well-being, along with economic and social devastation. In addition to earthquakes, it is also known that there are other hazards in the city, such as flooding, landslides, tsunami and extreme weather events (Menteşe et al., 2022).

### 3.2 Data source: Social vulnerability research in Istanbul in 2017

#### 3.2.1 Survey sampling method and application

To provide a basis for the social vulnerability analysis, a large-scale household survey was carried out by the Directorate of Earthquake and Ground Research of Istanbul Metropolitan Municipality ~~between the period of 2017 and 2018, after approved by institutional review board (IMM) in 2017.~~ The authors of this study were given the permission to use this survey data after the data were fully anonymized. ~~N=~~The exact number of surveys is 41,093 households ~~in~~covering 955 sub-districts/neighbourhoods, with residential occupation ~~covering~~ ~~expanding over~~ the whole jurisdiction boundaries of the metropolitan municipality of Istanbul, ~~were included in the study of social vulnerability (IMM, 2018) (IMM, 2018).~~ The households were randomly selected from the Address Based Population Registration System Database of the Turkish Statistical Institute using the proportionate stratified sampling method. All 955 neighbourhoods within 39 districts of Istanbul were taken as strata, then households were randomly selected from each neighbourhood. The number of households in each neighbourhood taken is proportional to the neighbourhood population.

The survey ~~data~~ was ~~obtained~~ ~~conducted~~ via face-to-face interviews with one household member, ~~who is~~ ~~ages~~ between 18 and 70 ~~years and capable~~ of ~~age and who is able to give~~ ~~giving~~ relevant and accurate information about the household. The verbal and written informed consents were obtained from the participants during the data collection stage. ~~The survey included questions related to socio-demography, socio-economy, duration lived in an urban environment, access to health services, social solidarity, risk perception, actions taken to reduce risk and cultural beliefs.~~

#### 3.2.2 Assessment Construction of SoVI

SoVI scores of the selected households were calculated using Cutter's factor analytic framework (Cutter et al. 2003) in the social vulnerability ~~-research funded and being used by IMM, as explained in Menteşe et al. (2019) and Supplementary File 1.~~ To date, this work by IMM has been the most comprehensive study for assessing the social vulnerability of households in the event of a hazard, which was originally constructed for earthquakes as the most probable major hazard for Istanbul. It considers the concept of social vulnerability as a state that arises from the lack of capacity of society and individuals to cope with natural

350 hazards, such as the perception of and preparedness for risk and the measures taken against risk, as well as cultural values and socio-economic status. For constructing SoVI, 53 indicators within 7 variable clusters (socio-demography, socio-economy, access to health services, social solidarity, risk perception and actions taken to reduce risk and values) were used as they are regarded to be related to social vulnerability. The indicators and variable clusters were selected following extensive literature reviews and expert judgement with a specific focus on earthquake hazard (IMM, 2018).

355 ~~In the first phase of the study, a social vulnerability index score was calculated for each household from the survey data (IMM, 2018; Menteş et al., 2019). The households were then defined in clusters as households with “severe risk of social vulnerability” and all others as “non-severe risk of social vulnerability”, by dichotomising the vulnerability score using the established cut-off points. Thus, a binary variable (with an imbalance ratio of 1/5 in favour of non-severe risk) was generated as an indication of risk of social vulnerability level, which in turn was used as the primary outcome for all the further analyses presented in this paper. The three main reasons for defining the social vulnerability as a binary outcome were: (1) To find out the key vulnerability predictors that discriminates between the households that requires the most urgent action and all others, (2) to increase the accuracy of predictions obtained by machine learning methods, and (3) to ease the interpretation of the results.~~

### **2.3 Selection of predictors and data preparation**

365 ~~Using the social vulnerability risk level as the binary outcome, household characteristics were taken as predictors to build a model. The predictors chosen have been selected following extensive literature reviews, discussions with experts and with the aim of exploring quantitative variables in predicting the risk of social vulnerability of a household in the event of an earthquake.~~

370 ~~Prior to model development, the predictors were prepared in terms of data representation, standardization and feature selection. As the predictors represent household characteristics, they were sought at household level. As made clear by Akhanli and Hennig (2020), data representation is about enabling better interpretation of the relevant information. Therefore, the predictors which are measured at household level, such as the number of women, men, <5 years olds, >65 years olds and the number of income earners were taken in proportion to the given household’s size (HhS). Then, in order to make the variation of continuous variables comparable, these variables were standardized into the same scale with unit variance standardization (Hennig and Liao, 2013). For the final step, we used feature selection prior to process the data and we identified the predictors with near zero variance, as the predictors which take only one value may cause numerical problems during resampling (Kuhn, 2008). The set of 26 variables used for model building are presented in Table 1, along with their relevance in relation to the objectives of our study.~~

380 Here we note that it is quite challenging to access/find quality empirical information regarding disaster-related topics, in Turkey as in many developing countries and the global south context. Information related to historical data on disaster

impact/losses/recovery is mostly not in place for smaller regional units in Turkey, then even if it is there (gathered by related institutions), it is not shared. Therefore, Cutter et al.'s (2003) index-based methodology to represent social vulnerability was opted for constructing SoVI in the previous study by IMM.

### **3.3 Outcome of the machine learning models: Household-level social vulnerability**

In this study, we relied on the pre-constructed SoVI as an indication of the social vulnerability of the households. By that, we used SoVI as the outcome of the machine learning (ML) models we tested. SoVI score does not have any unit and rather than its absolute value, its importance lies within its comparative value across various households (Cutter and Finch, 2008). Various authors dichotomised social vulnerability index scores in their research for both ease of interpretation and to identify those most vulnerable (e.g., Dwyer et al., 2004; Abarca-Alvarez et al., 2019; Basile Ibrahim et al., 2021; Mtintsilana et al., 2022). In this research, we also aimed to discriminate between the most vulnerable households and all others. Therefore, we defined households with high social vulnerability (SV) as those with SoVI scores +1 standard deviation from the mean which corresponds to 17.2% of the households, whereas the rest of the households were deemed as low SV. Thus, a binary variable (with an approximate imbalance ratio of 1/5 in favour of low SV) was generated as an indication of social vulnerability level, which in turn was used as the primary outcome for all the further analyses presented in this paper. Further, from the statistical point of view, we preferred to dichotomize the outcome rather than using it as a multi-category variable, as the available performance metrics for a multi-class confusion matrix are limited compared to a binary classification problem and the complexity of analysis increases with the increase in number of classes (Markoulidakis et al., 2021). Therefore, in accordance with our motivation and for interpretive reasons we used SoVI as a binary outcome.

### **3.4 Predictors of the machine learning models and data pre-processing**

We have restricted the variables that are used in the ML models as input variables to quantifiable predictors which can be obtained from various institutional databases without requiring a household-based survey that is costly and time intensive. These quantifiable predictors are related to the socio-demography and socio-economy of the households as well as housing information. The list of related institutions from which the variables were used in this study is given in the Supplementary File 2. Here we note that, although the household data used in the IMM study (2018) to construct SoVI is focused on earthquakes; the indicators used for social vulnerability classification in the present study can be implemented in a more generic way to assess the possible impact of social vulnerability to other hazards as well.

Prior to model development, the predictors were prepared in terms of data representation, standardisation and feature selection. As the predictors represent household characteristics, they were sought at the household level. As stated by Akhanli and Hennig (2020), data representation is about enabling better interpretation of the relevant information. Therefore, the predictors which are measured at the household level, such as the number of women, men, <5 years olds, >65 years old, and the number of income earners were taken in proportion to the given household's size (HhS). Then, in order to make the variation of continuous

variables comparable, these variables were standardized into the same scale with unit variance standardization (Hennig and Liao, 2013). For the final step, we used feature selection prior to processing the data and we identified the predictors with near zero variance, as the predictors which take only one value may cause numerical problems during resampling (Kuhn, 2008). The set of 26 variables used for model building is presented in Table 2, along with their relevance in relation to the objectives of our study.

**Table 12.** Predictors used in ML model building for ~~the classification of prediction household level~~ social vulnerability-risk.

Themes	Variable	Definition of a variable or survey question
Socio-Demographic	Household size	Number of people living in the house (HhS) (Range: 1-14)
	Average age	Average age of the household members in years (Range: 8.8-85)
	Number of women/HhS	Ratio of women in the household (Range:0-1)
	Number of men/HhS	Ratio of men in the household (Range:0-1)
	Number of <5 year olds/HhS	Ratio of <5 years old children in the household (Range:0-0.67)
	Number of >65 years of age/HhS	Ratio of over 65 years old individuals in the household (Range:0-0.1)
	Average education	Average years of education of the household members who are over 15 years old (Range:0-17)
	Social security	Are there any household members with social security? (yes/no)
Health	Health insurance	Are there any household members with health security or insurance? (yes/no)

	Disability	Are there any disabled or elderly persons who needs care in the Hh? (yes/no)
	Health access	Do you have any <del>healthcare facilities nearby</del> hospital/health centre within close proximity to your <del>home</del> house? (yes/no)
	Number of income earners/HhS	Ratio of the number of income earners in the household (Range:0-2)
	Regular salary income	Are there any household members who have regular salary income? (yes/no)
	Pension income	Are there any household members who earn pension income? (yes/no)
	Rent income	Are there any household members who earn income from rent? (yes/no)
	Income support from public authorities	Are there any household members who receive income support from public authorities? (yes/no)
	<del>Risk of job loss</del> Job Insecurity	Are there any household members <del>with the risk of</del> who have job loss in an earthquake? <del>insecurity? i.e., unregistered informal work, unemployment</del> (yes/no)
Socio-Economic	House ownership	Do any of the household members own the house of your residence? (yes/no)
	Type of the house	What is the type of the home of your residence? (apartment flat, squatter house, detached house, gate keepers lodge)
	Natural gas heating	Do you have natural gas heating at the home of your residence? (yes/no)
	Own house in Istanbul	Are there any household members who own a house in Istanbul, other than the home of residence? (yes/no)
	Own land in Istanbul	Are there any household members who own land in Istanbul? (yes/no)
	Own house out of Istanbul	Are there any household members who own house outside Istanbul? (yes/no)
	Own land out of Istanbul	Are there any household members who own land outside Istanbul? (yes/no)
	Saving	Are there any household members who have savings to use for emergency situations? (yes/no)
	<del>Dept</del> Debt	Are there any household members who have debt to banks (inc. credits, bank loans, etc.)? (yes/no)

#### 435 **2.43.5 Machine learning methods**

We developed models for the classification of households in terms of their social vulnerability ~~risk~~ in the event of an earthquake using ~~seven~~six supervised machine learning (ML) algorithms: ~~logistic regression (LR)~~, classification and regression tree (CART), random forest (RF), artificial neural network (ANN), support vector machine (SVM), ~~Naïve Bayes (NB)~~, ~~K-Nearest Neighbours (KNN)~~, naïve Bayes (NB), k-nearest neighbours (KNN). The predictive performances of these ML models are

440 compared to that of the logistic regression model, which is a traditional statistical technique used for binary classification.  
Supervised ML adopts an algorithm to learn the mapping function from the input variables to the output variable and it is  
suited well to classification problems. Models were developed using the variable set in Table 42 as the input variables, while  
a binary indicator of the social vulnerability ~~risk status~~ level of each household was the output variable. We developed a  
prediction model using 90% of the ~~social vulnerability dataset~~ data set to train the underlying algorithm, while 10% ~~of the~~  
445 ~~dataset~~ was held back as independent testing data for evaluating the performance of the models. We note that these algorithms  
have different tuning parameters. For different tuning parameter alternatives, the choice of the optimal tuning parameter was  
determined by the largest area under the curve (AUC) value of the receiver operating characteristic (ROC) curve- using the  
automated grid search. The details regarding the machine learning models and R software packages used for the analysis are  
provided in Supplementary File 3. The workflow for the model building is shown in Fig. 1.

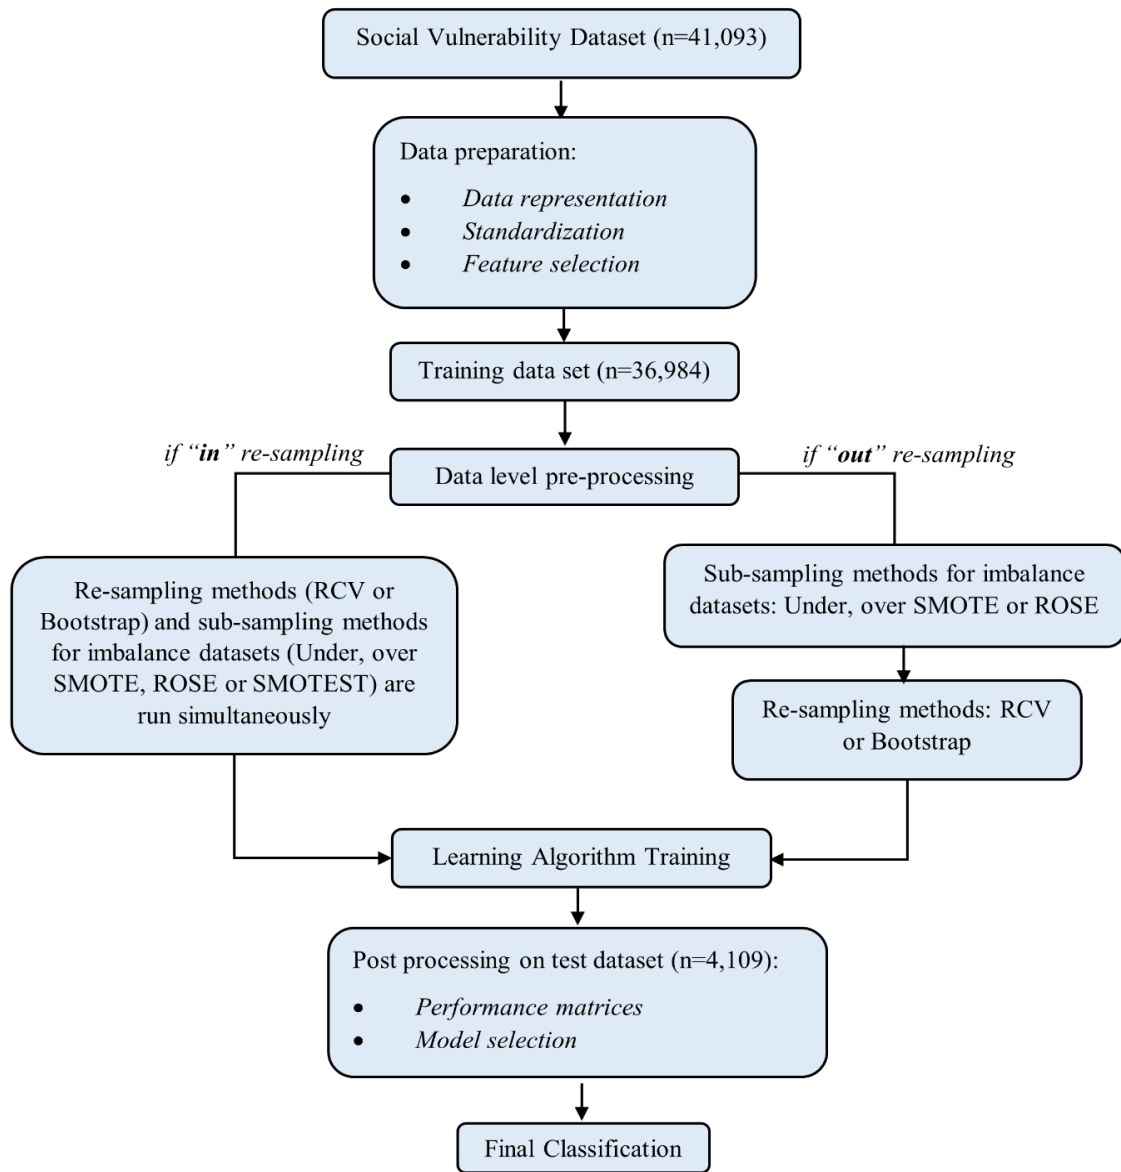

~~Fig 1. Machine learning flowchart for data processing and model development.~~

## **2.53.6 Data level pre-processing**

### **2.53.6.1 Resampling techniques**

455

Repeated cross-validation (RCV) and bootstrap resampling procedures were used to draw multiple subsamples from the original data to build machine learning models on the training data and to validate the models, in each instance, on the data that were excluded from the subsample. The tuning parameters were selected as 5-fold with 4 repetitions for repeated cross-validation and 20 repetitions for bootstrap, resulting in the same amount of resampling. The number of resampling repetitions was kept low to diminish the computational time burden for large data sets.

**Fig 1.** Machine learning flowchart for data processing and model development.

### 2.53.6.2 Subsampling for the imbalanced class variables

A ~~dataset~~ data set is said to be imbalanced when the classification categories are not represented equally (~~Lin and Nguyen, 2020~~)(Lin and Nguyen, 2020). In our study, the social vulnerability data set consists of imbalanced class variables, in which the “~~severe risk of social vulnerability~~high SV” class has a lower frequency compared to the “~~non-severe~~low SV” class. The imbalance ratio of these two classes was approximately 1/5. The main challenge of the imbalance problem in

standard machine learning algorithms is that the minority classes can be overlooked and weighed down by the majority one (Ramyachitra and Manikandan, 2014). (Ramyachitra and Manikandan, 2014). In order to address this issue, we used various subsampling approaches during the data pre-processing steps as explained below:

470 (i) *Random majority under-sampling (Under)*: Under-sampling randomly samples from the majority class and returns a sub-sample which has the same size as the minority class, thus ensuring the majority class prevalence is equal to that of minority one for subsequent modelling (Batista et al., 2004) (Batista et al., 2004). For instance, assume a binary class variable in which 90% of training set samples belongs/belong to the majority class, while the remaining 10% are in the minority class. Under-sampling will randomly sub-sample from the majority class such that its prevalence is 10%. As a result, only 20% of the total training set will be used for the classification model. While balancing the class variable, however in some cases this approach may remove many important or otherwise influential data points prior to modelling.

480 (ii) *Over-sampling*: Three different over-sampling strategies were applied:

~~*Random minority over sampling (Over)*: It aims to balance the distribution of the class variable by taking random replicates of the minority class (Batista et al., 2004). Although it helps to improve the accuracy of classification in imbalanced datasets, it is prone to overfitting and computational problems when the data set is large (Maheshwari et al., 2017).~~

485 ~~*Synthetic Minority Over sampling Technique (SMOTE)*: It creates artificial minority examples by interpolating between randomly selected examples of the minority class and their nearest neighbours (Chawla et al., 2002). It attempts to avoid overfitting problem by using new synthetic minority class examples instead of replicating minority samples.~~

490 ~~*Random Over Sampling Examples (ROSE)*: It generates artificial balanced samples according to a smoothed bootstrap approach and aids in the phases of estimation and accuracy evaluation of a classification algorithm in the presence of an imbalanced class variable (Menardi and Torelli, 2014).~~

495 ~~*Random minority over-sampling (Over)*: It aims to balance the distribution of the class variable by taking random replicates of the minority class (Batista et al., 2004). Although it helps to improve the accuracy of classification in imbalanced data sets, it is prone to overfitting and computational problems when the data set is large (Maheshwari et al., 2017).~~

~~*Synthetic Minority Over-sampling Technique (SMOTE)*: It creates artificial minority examples by interpolating between randomly selected examples of the minority class and their nearest neighbours~~

500 (Chawla et al., 2002). It attempts to avoid the overfitting problem by using new synthetic minority class examples instead of replicating minority samples.

Random Over-Sampling Examples (ROSE): It generates artificial balanced samples according to a smoothed bootstrap approach and aids in the phases of estimation and accuracy evaluation of a classification algorithm in the presence of an imbalanced class variable (Menardi and Torelli, 2014).

505 The above procedures are independent of resampling methods such as ~~the~~ repeated cross-validation and ~~the~~ bootstrap. On the other hand, these subsampling procedures can also be performed for the resampling techniques, so that subsampling is conducted inside of resampling. In this paper, when subsampling procedures are performed outside of resampling techniques it is referred to as “out sampling”, otherwise it is expressed as “in sampling”.

510 One could also consider creating a custom-made subsampling procedure. In this respect, we also apply the transformed version of SMOTE that use 10 nearest neighbours instead of the default of 5 by adopting a simple wrapper function, which we call ~~as~~ the “SMOTEST”. Note that the SMOTEST function is only performed inside of the resampling (~~Kuhn and Johnson, 2013~~)(Kuhn and Johnson, 2013).

### **2.63.7 Statistical analysis and model performance assessment**

515 The characteristics of the study population ~~was~~were summarised using descriptive statistics. Pearson’s chi-square tests were used to compare categorical variables, and independent samples t-tests or non-parametric Mann Whitney U tests were used to compare continuous variables between the ~~non-severe~~high and ~~severe-risk~~low SV groups depending on the data distribution. In studies with large sample sizes, in addition to p-values, it is also relevant to provide effect sizes as it can help ~~deciding whether the difference found is meaningful or not (Bakker et al., 2019).~~decide whether the difference found is meaningful or not (Bakker et al., 2019). Thus, we have reported effect sizes in the univariate comparisons that ~~measures~~measure the strength of the relationship between two variables along with the p-values to assess whether the effect of a variable is real and large enough to be useful or not. Cohen’s *d* statistic with sample size adjustment was used for normally distributed continuous variables, Cohen’s *r* value which is calculated by dividing the z value obtained from the Mann Whitney test ~~to~~by the square root of the sample size was used for non-normally distributed variables, and Cramer's *V* is used for categorical variables (Fritz ~~et al., 2011~~et al., 2012).

525 For various machine learning applications confusion matrices were generated. Sensitivity, specificity, and accuracy with 95% Confidence Intervals (CIs) were calculated for LR and each ML algorithm using different resampling and subsampling techniques. The models were fitted with two different resampling strategies and eight subsampling techniques. In addition, we fitted the models to the raw data without any subsampling, and thus we obtained results for 18 combinations of various sampling strategies for each ML algorithm.

In line with the objective of the study, we compared the methods in terms of their success in identifying the households with ~~severe risk of high~~ social vulnerability, which is the minority class with a smaller prevalence in our study. Therefore, we used sensitivity (true positives / (true positives + false negatives)) as the primary measure for assessing the model performance and balanced accuracy ((sensitivity + specificity) / 2). We identified the best performing method as the one with the highest sensitivity and balanced accuracy, provided that the AUC of the ROC curve is greater than 0.7 and ~~model could be considered as acceptable to discriminate households with severe risk from those with non-severe risk (Hosmer et al., 2013); the model could be considered acceptable to discriminate households with high SV from those with low SV (Hosmer et al., 2013).~~

The sensitivity and specificity of the best ~~performing method with those of other methods were compared with pairwise comparisons using McNemar's chi-square test (Kim and Lee, 2017). In addition, AUC comparisons were performed using DeLong chi-square statistics (DeLong et al., 1988). Bonferroni adjustment was applied in these pairwise comparisons of ML methods and  $\alpha < 0.05/7 = 0.007$  was considered as an indication of performing method with those of other methods were compared with pairwise comparisons using McNemar's chi-square test (Kim and Lee, 2017). In addition, AUC comparisons were performed using DeLong chi-square statistics (DeLong et al., 1988). Bonferroni adjustment was applied in these pairwise comparisons of ML methods and  $\alpha < 0.05/7 = 0.007$  was considered as an indication of a statistically significant difference in terms of performance metrics between two methods.~~

For the final step of the analysis, the important variables of each model were assessed. The identification of the important predictors is either based on the contribution of each variable to the model, or ~~by an~~ a ROC curve analysis conducted on each predictor ~~(Kuhn, 2008); (Kuhn, 2008).~~

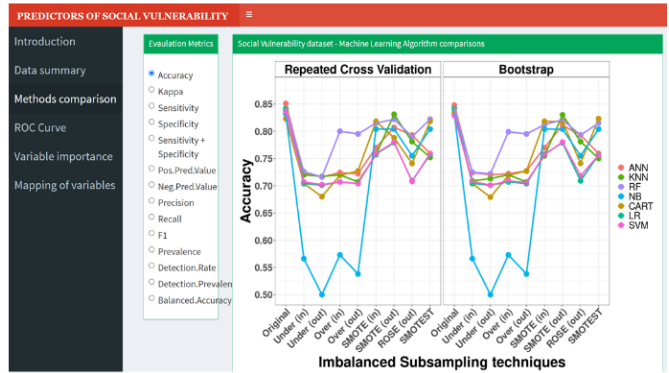

### **2.73.8 Open-access R-shiny web application**

An open-access R-shiny web application was created for visualising summary statistics and predictive performances of the LR and ML methods for the classification of households in terms of their social vulnerability risk level. Users are able to examine the distribution of the characteristics of the households with ~~severe high~~ and ~~non-severe risk of low~~ social vulnerability, compare the performances ML and subsampling methods based on ~~a user-~~ a user-defined evaluation criteria, assess variable importance rankings for each ML method and obtain the area-based calculations of the variables in the Istanbul map. The R-shiny web application is freely available online and can be accessed at [https://oyakalaycioglu.shinyapps.io/Social\\_Vulnerability/](https://oyakalaycioglu.shinyapps.io/Social_Vulnerability/). The components of this R-Shiny application are presented in ~~detailed detail~~ in Fig. 2. All analyses were performed in the statistical programming environment R version 4.0.3 ~~(R Core Team, 2013); (R Core Team, 2013)~~ and the machine learning model development was carried out using the R caret package ~~(Kuhn, 2008). The spatial distribution of the important predictors within the city scale were expressed via the 3.10 version of QGIS software (QGIS, 2021); (Kuhn, 2008). The spatial distribution of the important predictors within the city scale was expressed via the 3.10 version of QGIS software (QGIS, 2021).~~

(can be accessed from [https://oyakalaycioglu.shinyapps.io/Social\\_Vulnerability/](https://oyakalaycioglu.shinyapps.io/Social_Vulnerability/)-[https://oyakalaycioglu.shinyapps.io/Social\\_Vulnerability/](https://oyakalaycioglu.shinyapps.io/Social_Vulnerability/)). The left side commands allow the user to choose which analysis to activate. (A) Summary statistics of the variables are visually compared across social vulnerability risk-groups. Box plots and bar plots were used for continuous and categorical variables, respectively. (B) The performance metric ROC Curve chosen by the user (y-axis) in comparison to subsampling method (x-axis). The ML methods are displayed in different colours. Two separate plots are generated for RCV and bootstrap resampling techniques. (C) For the chosen subsampling method, LR and ML methods are compared in terms of the AUC of the ROC curve. Different coloured lines represent different ML-methods. (D) For the chosen ML method and subsampling techniques, variable importance plots are displayed.

## 34 Results

### 34.1 Descriptive statistics

The prevalence of households that were identified as having a severe risk of with high social vulnerability to a possible earthquake in Istanbul was 7,052 (% 17.2) among 41,093 households. The median household size was 3, with values ranging from 1 to 14 residents, and the median of the average age of the households varied between 8.8 to 85 years with the median

being 35.5. The median of the average education was 8 years (Range: 0-17 years) in the entire survey sample, while it was 8.8 years (Range: 0-17 years) in those households with non-severe risk/low SV and 6 (Range: 0-16.3 years) in those households with severe risk/high SV. Additional comparisons between social vulnerability risk groups/levels in terms of socio-demographic, health and socio-economics/socioeconomic information are demonstrated in Table 2. In particular, households 3. Households with severe risk/high SV were often overcrowded, less educated, older, had a low number of income earners, had low levels of savings, and had less access to social security and health insurance compared to the non-severe risk/low SV group. The statistically significant variable with the largest effect on social vulnerability was the average education of the household (Cohen's  $d = 0.947$ ), followed by the ratio of income earners (Cohen's  $d = 0.366$ ) and the ratio of over 65 years olds/old in the household (Cohen's  $r = 0.120$ ), having social security (Cramer's  $V = 0.211$ ), having health security or insurance (Cramer's  $V = 0.226$ ), having natural gas heating at home (Cramer's  $V = 0.152$ ), the presence of anyone with a disability or who is elderly and needs care at home (Cramer's  $V = 0.142$ ) and having savings for emergency situations (Cramer's  $V = 0.135$ ).

**Table 23.** Univariate analysis of the study population characteristics.

Variables	Risk of Social Vulnerability Level		Effect size (Cohen's $d^a$ or Cohen's $r^b$ or Cramer's $V^b$ )	P

### **34.2 Comparison of machine learning methods**

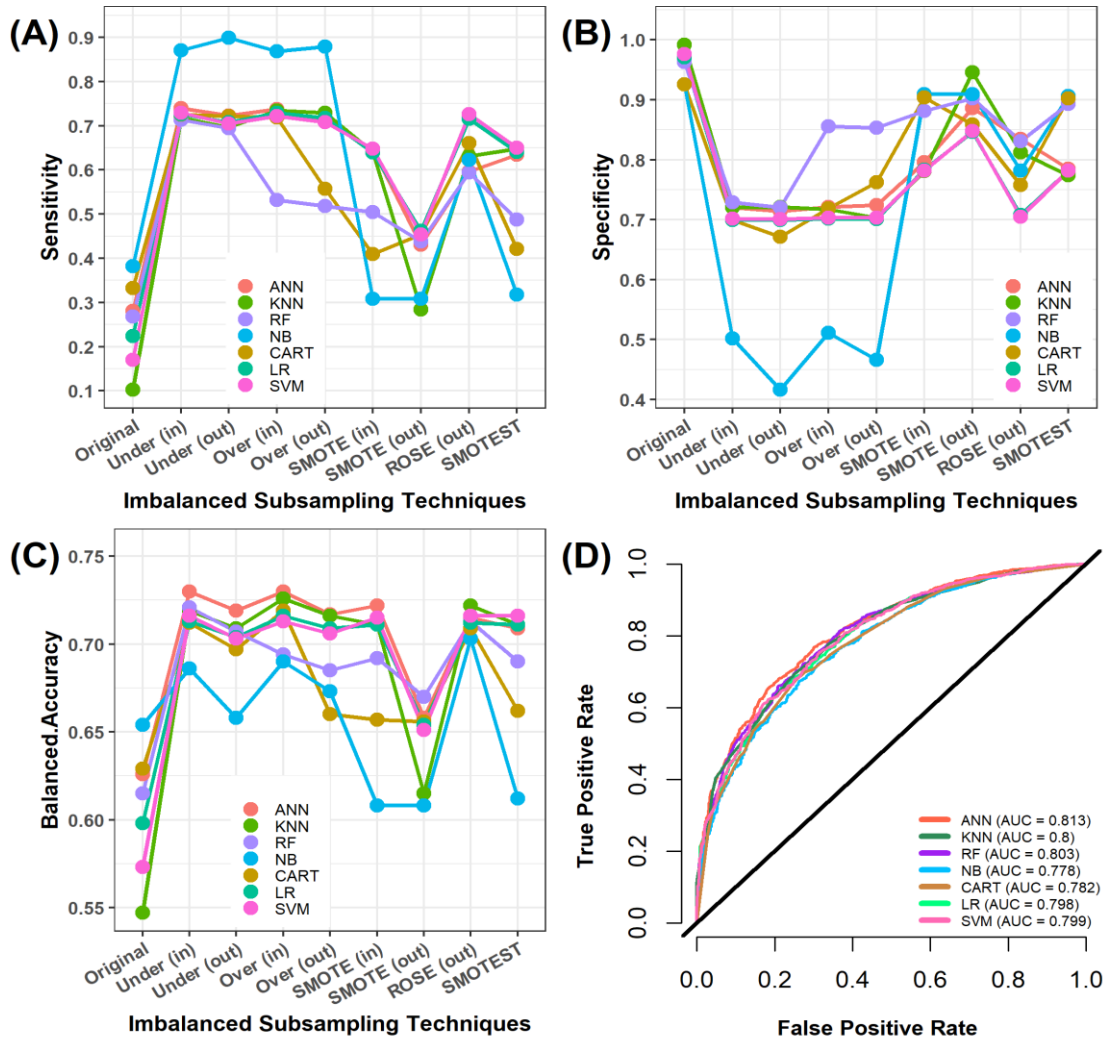

The comparison of the machine learning models in terms of their sensitivity, specificity, balanced accuracy, and AUC under different subsampling methods are presented in Fig. 3. The additional comparisons of models using other evaluation metrics (e.g., ~~pos~~ positive prediction value, negative prediction value, accuracy, F1 score, Recall, Precision, etc.) can be found in the R-shiny application Within these comparisons, no substantial differences were observed in the model performance indicators of LR and different ML strategies between RCV and bootstrap resampling methods. Therefore, we present the results that were obtained with 5-fold cross-validation.

**Fig 3.** Model performance comparisons. ML methods are visualized in different colours in all figures. (A) Sensitivity (y axis) in comparison to subsampling technique (x axis). (B) Specificity (y axis) in comparison to subsampling technique (x axis). (C) Balanced accuracy ((sensitivity + specificity) / 2) (y axis) in comparison to subsampling technique (x axis). (D) Using the under(in) imbalanced subsampling technique, ML methods are compared in terms of the AUC of the ROC curve.

605 As mentioned earlier, the data set suffered from imbalanced class variables, particularly the outcome variable, and as such significant differences were observed when subsampling strategies were applied. Using the standard algorithm without subsampling (referred as “Original”) resulted in poor sensitivity (Fig. 3A), but inflated specificity (Fig. 3B) rates. Based on the criteria that  $AUC > 0.7$ , overall, the methods fitted with under subsampling inside the resampling procedure (referred as under(in)) performed better in terms of model performance metrics when compared to other subsampling methods. The highest

610 balanced accuracy for each method was also obtained with under(in) subsampling (Fig 3C).

**Fig 3.** Model performance comparisons. LR and ML methods are visualized in different colours in all figures. (A) Sensitivity (y-axis) in comparison to subsampling technique (x-axis). (B) Specificity (x-axis) in comparison to subsampling technique (y-axis).

axis). (C) Balanced accuracy  $((\text{sensitivity} + \text{specificity}) / 2)$  (x-axis) in comparison to subsampling technique (y-axis). (D) Using the under(in) imbalanced subsampling technique, ML methods are compared in terms of the AUC of the ROC curve.

In Table 34, all ML methods using under(in) subsampling were compared to their counterpart using the original data without imbalanced subsampling. When the subsampling strategy was not employed, all ML methods had inflated specificity due to the imbalance present in the studied study sample, where the negative class is dominant. Here we remind the reader that the priority in this study was to assess the performance of the models in terms of their success in identifying the households with ~~severe-risk-of-high~~ social vulnerability, which is the minority class, but therefore also the positive class. Using under(in) subsampling strategy demonstrated superior sensitivity and balanced accuracy rates compared to using original data and other subsampling strategies. Therefore, the results obtained with under(in) subsampling are considered for further comparisons between ML methods. Classification results for the ML models using under(in) subsampling are presented with ROC curves in Fig. 3D. The ROC curves for all other subsampling strategies with all other methods can be found in the [R-shiny-webR-shiny web](#) application.

630 \*Diff sens: The difference in sensitivity between the same ML method with and without subsampling strategy for imbalanced  
635 problem. ~~Same~~The same superscript letters indicate statistically significant difference in a performance measure between two  
640 methods, at  $\alpha < 0.05/7 = 0.007$  significance level. CI: Confidence Interval. NA: Not Applicable.

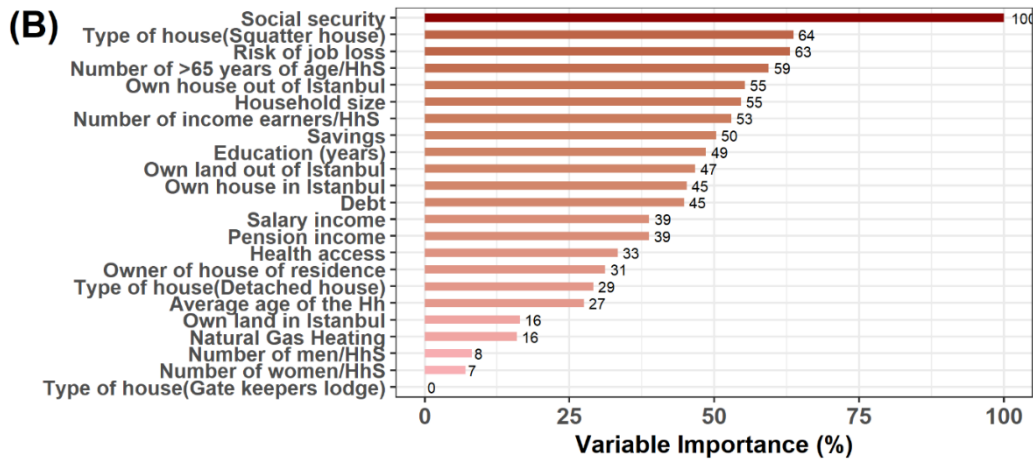

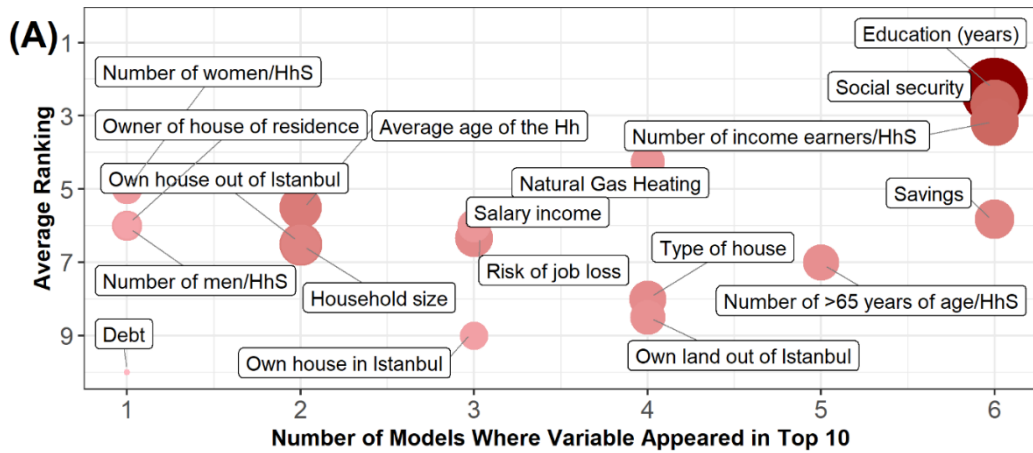

The best performing method in terms of AUC, accuracy, balanced accuracy<sub>2</sub> and sensitivity was artificial neural network  
635 (~~ANN~~) using under(in) subsampling strategy (AUC: 0.813 (0.800-0.826), Accuracy: 0.724 (0.710-0.737), Balanced accuracy  
640 : 0.730 (0.790-0.752), Sensitivity: 0.740 (0.706-0.772), Specificity: 0.720 (0.705-0.735)). The sensitivity + specificity was  
equal to 1.46 for ANN using under (in) and is considered to be in an acceptable range as the value is halfway between 1, which  
is useless, and 2, which is perfect (~~Power et al., 2013~~)-(Power et al., 2013). Naïve Bayes (NB) also produced a high sensitivity  
rate of 0.871 (0.843-0.894), however it resulted in significantly lower specificity (0.502 (0.485-0.519)) and overall accuracy  
0.566 (0.550-0.581) compared to ANN (p=0.003 and p<0.001, respectively). While ANN balances sensitivity (0.740) and

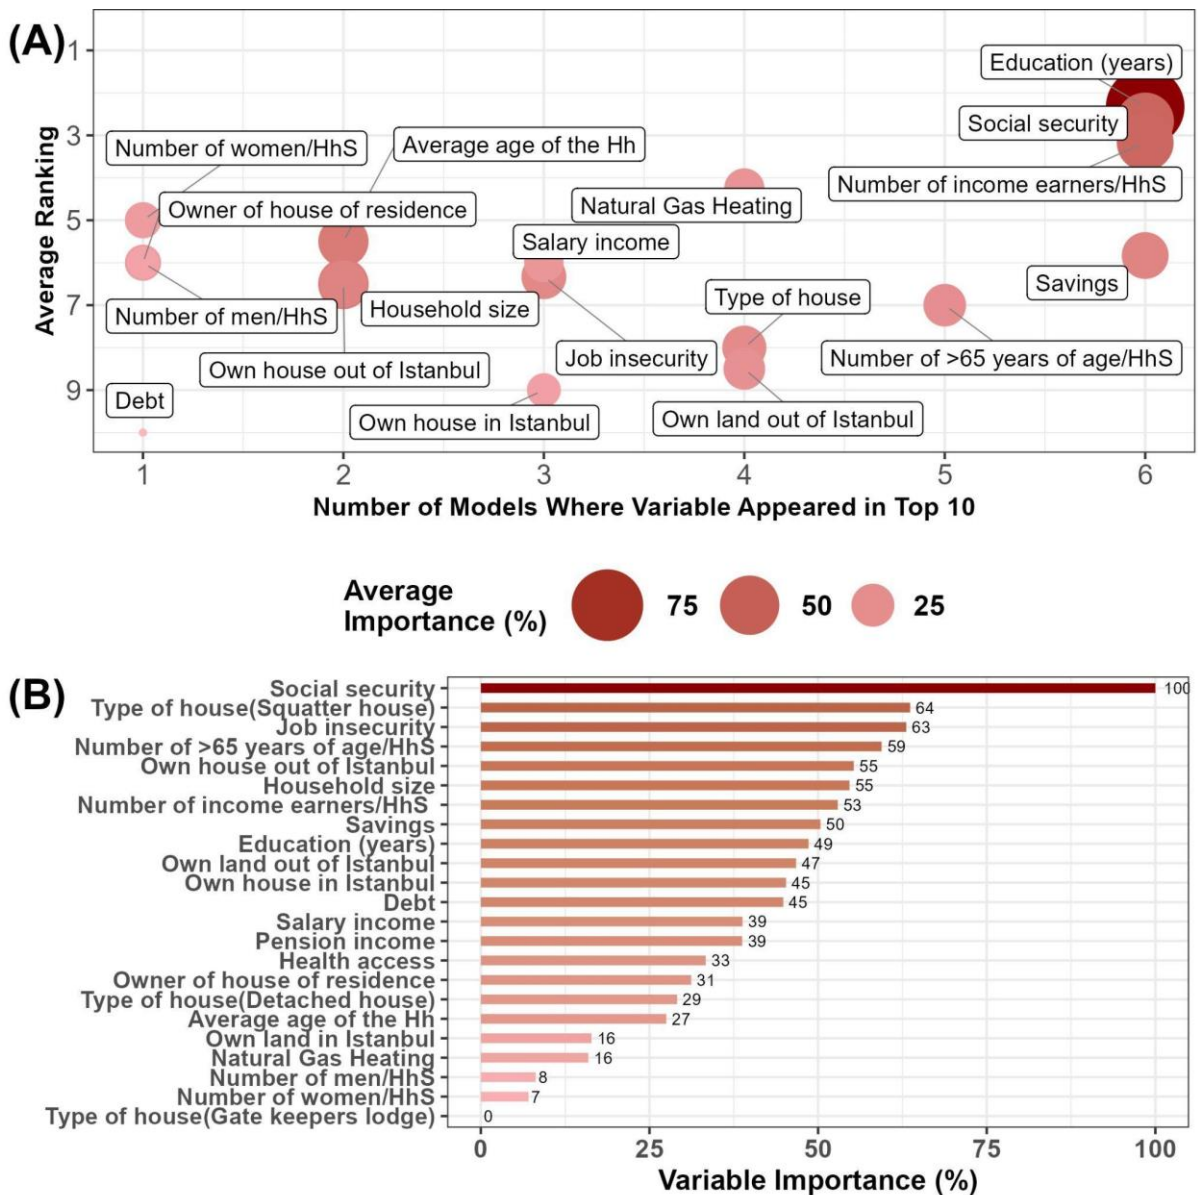

specificity (0.720), NB emphasizes sensitivity (0.871) over specificity (0.502). All other methods using under(in) sampling provided similar sensitivity rates between the range of 71.9% and 72.9%, and specificity rates between 69.9% and 72.4%. When AUC was considered, CART was also significantly worse than ANN (0.782 (0.768-0.796) vs. 0.813 (0.800-0.826),  $p = 0.005$ ). Logistic regression, random forest, support vector machine and k-nearest neighbours did not show significant differences from ANN in terms of performance metrics.

### **34.3 Important predictors for the machine learning methods**

In Fig. 4, a visual summary of the average relative importance of the predictors as indicated by the ML methods using under(in) sampling is presented. The most important variable for every model is given a score of 100%, followed by the next important variable which takes a relative value between 0 and 100. The variables which appeared in top ten most influential variables in all seven models were education, having social security, the ratio of income earners in the household and having savings for emergency situations (Fig. 4A). Of these variables, the variable with the highest average importance was education.

**Fig. 4.** Important predictors for the assessment of social vulnerability. (A) the average relative importance of the predictors obtained with ML methods using under(in) sampling. Average ranking of the predictor across all models (y-axis) in comparison to a number of models that the predictor appeared in the top ten most important variables (x-axis). (B) Variable importance for the ANN-under(in) model

655

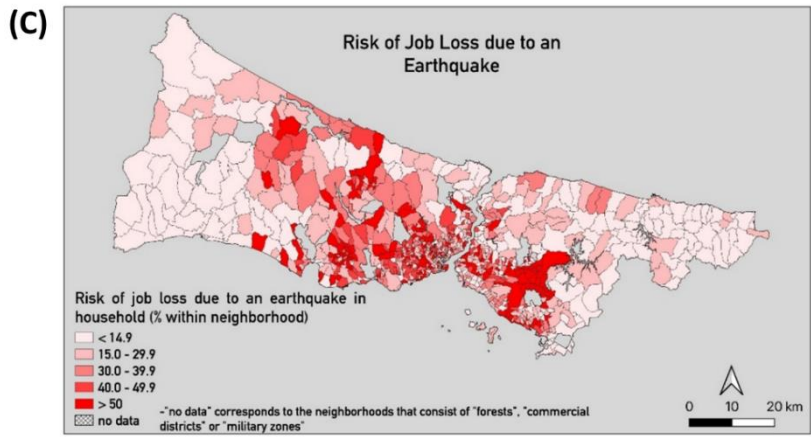

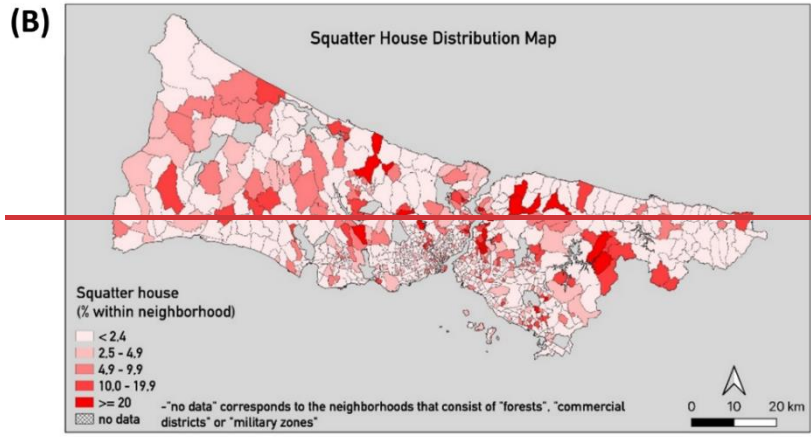

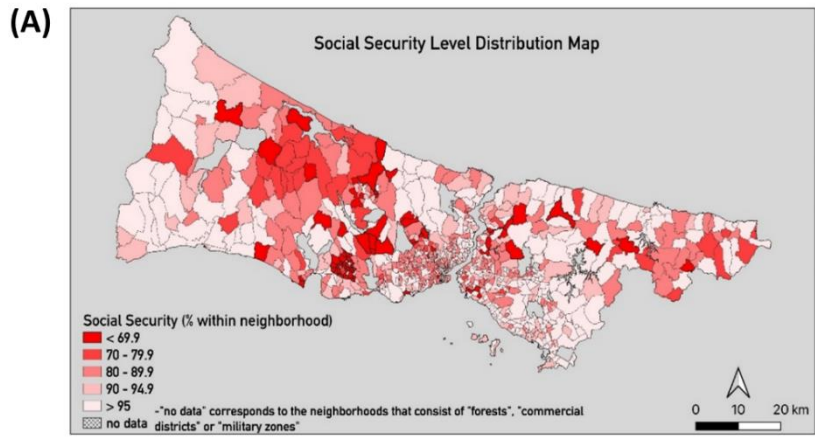

660

In Fig. 4B we investigated the relative importance of the independent variables within the top-performing model, ANN-under(in), using the approach suggested by ~~(Garson, 1991)~~(Garson, 1991). Based on this model, the most important variable for the classification of households' social vulnerability appeared to be having social security. The other predictors with over 50% of relative importance were a mixture of demographic and economic variables including living in a squatter house, ~~risk of job loss in a possible earthquake~~job insecurity, ratio of the over 65-year-olds in the household, owning a house outside of Istanbul, household size, ~~the~~ ratio of income earners in the household and having savings for emergency situations.

#### **3.4.4 Spatial distribution of the important predictors of the ANN model**

—Based on the variable importance analysis with the top-performing model, ANN-under(in), we performed area-based calculations to compare the neighbourhood characteristics in Istanbul. For categorical variables, the prevalence in the neighbourhood was calculated, while neighbourhood averages were used for the continuous variables. The three most important predictors of social vulnerability ~~level~~ were subsequently displayed as a five-category map in Fig. 5.

For Fig. 5A, the areas represented with dark red colours, below 70%, ~~indicates~~indicate those neighbourhoods with the lowest social security and these areas are prevalent in the outer regions of the metropolitan area. On the other hand, those neighbourhoods close to the central region mostly cover households with ~~a~~ higher prevalence of social security benefits. The number of neighbourhoods with high-density of squatter housing (>20%) was 27 (Fig. 5B). These neighbourhoods are scattered throughout the city and are not concentrated in any specific region. The households ~~in which persons at risk of losing their jobs in a possible earthquake live~~with job insecurity, are mainly located in the central region of the city (Fig. 5C). The distribution of all other variables across neighbourhoods of Istanbul can be found ~~in~~ the R-shiny web application.

**Fig. 5.** The five-category neighbourhood map of the three most important predictors of social vulnerability. (A) Neighbourhood prevalence of having social security (B) Neighbourhood prevalence of living in squatter houses (C) Neighbourhood prevalence of risk of job loss/insecurity of any household member in a possible earthquake.

## 45 Discussion

### 45.1 The selection of the optimal ML method

For many decades, data analysis in the social sciences has focused on identifying causal links between a set of empirically derived variables (Di Franco and Santurro, 2020). Based on our classification results, the best-performing ML method for identifying households with severe risk-high social vulnerability was ANN using under-sampling within the resampling procedure to address the problem of class imbalance (sensitivity: 0.740, balanced accuracy: 0.740, AUC:0.813). An AUC of 0.813 for ANN model indicated a good ability to discriminate households with severe risk-of-high social vulnerability in thea hazard event of-an-earthquake in Istanbul from those with non-severe risk. ~~For many decades, data analysis in the social sciences has focused on identifying causal links between a set of empirically derived variables (Di Franco and Santurro, 2021). Interrelated~~ low social vulnerability. That means interrelated social relations between the variables in our data set may be best handled by ANN.

The methodology of the ~~Artificial Neural Network~~ artificial neural network drew inspiration from networks of biological neurons found in the nervous system ~~(McCulloch and Pitts, 1943)~~ (McCulloch and Pitts, 1943). For modelling purposes, it is often represented as interconnected groups of nodes (i.e., the predictors), in which subsequent processing between the nodes occurs according to their interconnections. This structure enhances the capacity for handling complex nonlinear relationships between dependent and independent variables in large data sets ~~(Hornik et al., 1989)~~ (Hornik et al., 1989). In quantitative social research, relationships between socio-demographic and socio-economic variables cannot be ignored ~~(Meade et al., 1970)~~ (Meade et al., 1970). The use of ANN is therefore an effective tool for identifying hidden nonlinear relationships that arise in social research ~~(Di Franco and Santurro, 2021)~~ (Di Franco and Santurro, 2020). We note that apart from CART and NB, all methods provided similar AUC results with no significant differences. There was no significant difference between ML methods except with NB in terms of the performance of identifying households at-risk-of-severe with high social vulnerability (i.e., sensitivity).

### 45.2 The importance of subsampling for imbalanced class ~~variable~~ variables

An important aspect of our study was to find the most viable solution for the imbalance problem in our ~~dataset~~ data set, as the imbalance ratio between the ~~two~~ high and low SV groups was around 1/5. When no subsampling strategy was applied ~~for~~ to the imbalance problem, we obtained poor sensitivity rates. A 39.3% to 61.7% gain in sensitivity was achieved when under(in) subsampling was applied, and therefore the imbalance was being addressed, compared to using the original raw data without subsampling.

In our study, when ML models without subsampling strategies were used, the overall accuracy ~~were~~ was higher due to the inflated specificity compared to the models using subsampling strategies. -ML models are trained to ~~maximize~~ maximise the

715 overall accuracy and therefore, if trained on imbalanced data they are prone to over-predict the class with higher frequency, (Esposito et al., 2021) which is ~~non-severe~~ low vulnerability ~~risk~~-group in our data set (Esposito et al., 2021). Therefore, the models based on the original imbalanced data failed to identify households with ~~severe risk of~~ high social vulnerability, and they failed to meet our aims in ~~this~~ the study.

720 Among subsampling methods, the random majority under-sampling approach resulted in the best performance for all ML methods. This method discards data points from the majority class at random until a more balanced distribution is reached. Our data set was sufficiently large not to be negatively affected by the discarding of data. Our results obtained with random under-sampling are consistent with the ML literature, in the sense that if the size of the ~~dataset~~ data set is large, then it is better to employ an under-sampling method (~~Durahim, 2016~~) (Durahim, 2016).

### 4.5.3 Important variables and their theoretical implications

725 A favourable property of ML methods is that the importance of the independent variables in the models can be obtained. This can be done by two means: by computing the contribution of the variable to the model, as per the standard regression model, or by computing its contribution to the AUC of ROC curve. The variable importance rankings tend to differ between different ML models, as they use a different algorithm or weighting scheme. ~~Saarela and Jauhainen (2021)~~ Saarela and Jauhainen (2021) compared the variable importance measures obtained by different ML methods used for classification and showed that the most important features differ depending on the technique. In ~~the present~~ our study, performance measures were not very different between ML methods, so first we averaged the rankings of the variables across seven ~~ML~~ models using under(in) subsampling. On average, education was found to be the most important variable in all ~~ML~~ methods, followed by having social security, the ratio of the income earners in the household and having savings to be used in emergency situations. When we discuss these results based on socio-urban conditions in Turkey; first, we can easily comprehend that education and social security are interrelated factors, as more educated citizens tend to work in jobs with social security. Secondly, income and savings are both representing the economic power of households to cope with hazards.

730

735

~~When we assessed~~ Within the top performing model, which was ANN, the most important variable was found to be social security, followed by living in a squatter house and ~~risk of job loss in a possible earthquake;~~ job insecurity. Social security, ~~meaning means~~ the right to have the guarantee of unemployment benefits, retirement pensions ~~and~~, public protection from job injuries, and access to public health coverage, which is gained through regular work and employment. (The Republic of Turkey Ministry of Labour and Social Security, 2021). The lack of social security and of insurance, particularly in a demonstrably unstable economy, increases vulnerability to many kinds of crises, including disasters and health emergencies such as pandemics. For our research, having social security actually means being able to get different kinds of socio-economic and health support in sudden shocks which also covers the aftermath of a hazard as the individual is registered

740

745 in the public health system. In Turkey, the rate of unregistered labourers who are not affiliated with social security  
institutionthe Social Security Institution in total employment was recorded as 27.4% (~~Turkish Statistics Institute,~~  
2021)(Turkish Statistics Institute, 2021), while the most unregistered ~~sectors~~ labourers are found in agriculture and service  
(~~Ocal and Senel, 2021~~)-sectors (Ocal and Senel, 2021). Unregistered employment means that no social insurance  
750 premiums will be paid by the employer, thus the employees cannot have the benefits of social security (~~Turkoglu,~~  
2013)-(Turkoglu, 2013). On the other hand, people in agriculture are mostly self-employed and do not have social security  
since they cannot regularly afford to pay ~~the~~ social security premiums. Hence the map we have presented on social security  
indicates the significance of having social security in the case of Istanbul households, also representing  
the general situation in Turkey (Turkoglu, 2013). The different social security status of neighbourhoods towards  
the with respect to the household survey indicates the North-West of Istanbul represent mostly agricultural areas as  
755 well as households with lower social security- which may be due to a large amount of agricultural areas in that region. On  
the other hand, those neighbourhoods close to the centre of the Istanbul metropolitan area ~~cover~~ are mostly inhabited by people  
employed in the services and industrial sectors, significantly in registered employment and thus having a higher prevalence of  
social security benefits. Having social security is a significant indicator of social welfare and for the guarantee  
of general well being of citizens, as explained above. The lack of social security and of insurance,  
760 particularly in a demonstrably unstable economy such as Turkey, increases vulnerability to many kinds  
of crises, including natural disasters and health emergencies such as pandemics. In Moreover, in the data  
presented, the prevalence of social security in the severe risk-low vulnerability group is around 72% whereas in the non-  
severe risk group it is as high as 91% in the households with high vulnerability.

765 Based on our findings, living in a squatter house was found to be the second most important variable in increasing  
the risk of social vulnerability using the ANN method. Squatter housing comprises houses that are assembled quickly and that  
do not conform to technical and legal standards, and as such represent grave vulnerability in the event of an earthquake and  
are more likely to result in building collapse. However, previous academic studies of earthquake engineers for Istanbul inform  
that a large proportion of buildings in Istanbul are not earthquake resistant (IMM and KOERI, 2019; Parsons, 2004; JICA and  
IMM, 2002; Erdik et al., 2003; Ersoy and Koçak, 2016). In particular, squatter houses are very low quality buildings, when  
770 taken together with the poor socio-economic characteristics of their residents, represent high social vulnerability for these  
households. Hence the building type indicator representing the illegal construction (with a distinct value called “gecekondu”  
as the Turkish name for poor squatter settlements) can be used for representing at high risk buildings, in the event of an  
earthquake, as they have not been built to withstand such an event. A study by Abarca Alvarez et al. (2019) in Andalusia,  
which used a decision tree analysis, showed the importance of dwelling variables on social vulnerability, such as average age

775 of constructions and the density of housing buildings in a census section urban area. In our study, age of the buildings was not available, however, the type of the house was found to be an important predictor of social vulnerability.

780 With the ANN method, the third highest ranked variable was the risk of job loss in a possible earthquake. Here, as mentioned above in social security indicator, the labour market opportunities in Turkey are highly dominated by the informal sector (Ocal and Senel, 2021). A recent study showed that informal employment increases social vulnerability to natural hazards (Mavhura and Manyangadze, 2021). These may be either in the form of casual, seasonal employment or self-employment, where social security and social insurance registrations are not provided by the employers. Most of those working in the informal sector are unregistered within the social security scheme. Most small and self-employed businesses are without security since they could not afford to pay their premiums regularly. These types of employees and small businesses mostly fall below the poverty line even if they may be observed as working (Adaman et al., 2015). These households depending on unregistered labour and small businesses in the informal sector have a high probability of experiencing vulnerability when a disaster strikes. In an earthquake, their workplaces may be damaged or closed which means a vulnerability risk for them due to loss of jobs or income. In the COVID-19 Pandemic, when small workplaces have been required to close or to restrict their services for a long period of time, most of these working people suffered severe job and income losses, hence severe vulnerability emerged (Bartik et al., 2020; Gray et al., 2022). One related factor for job loss is the duration of unemployment. Thus, the persons who live through long period of unemployment are also prone to severe vulnerability. As the third map indicates, the neighbourhoods in the centre of Istanbul are populated with small and informal workplaces, mostly with unregistered employees. When a disaster occurs, these groups living in neighbourhoods close to the city centre are at high risk of severe social vulnerability.

795 The other variables among the top ten most important predictors that contribute to the model performance of the ANN model were a mixture of demographic and economic variables. These included the ratio of over 65-year olds in the household, owning a house outside of Istanbul, household size, the ratio of income earners in the household, having savings for emergency situations, owning land outside of Istanbul, and the level of education of the occupants. It is known that poorer people are more vulnerable to natural hazards as they settle in buildings at higher risk as they are more affordable to them. Furthermore, the associations between income and level of education are strong and consistent; that is children from poorer family backgrounds have a tendency of achieving a lower level of education (West, 2007). Also, the poor have less access to resources that reduce risks and therefore cannot take as many precautions to cope with a disaster when it occurs (Hallegatte et al., 2020).

805 5 LimitationBased on our findings, living in a squatter house was found to be the second most important variable of social vulnerability using the ANN method. Squatter housing comprises houses that are assembled quickly and that do not conform to technical and legal standards, and as such represent a higher vulnerability in the event of an earthquake and are more likely to result in building collapse. Hence the building type indicator representing the illegal construction (called “gecekondü” as the Turkish name for poor squatter settlements) can be used for representing at-high-risk buildings, in the event of an

810 earthquake, as they have not been built to withstand such an event. However, previous academic studies of earthquake  
engineers for Istanbul inform that not only squatter settlements but a large proportion of buildings in Istanbul are not  
815 earthquake-resistant (IMM and KOERI, 2019; Parsons, 2004; JICA and IMM, 2002; Erdik et al., 2003; Ersoy and Koçak,  
2016). Furthermore, the social vulnerability representativeness of squatter housing is not only because of the construction  
standards but also the poor socio-economic household profile that is hidden under this variable. It is known that poorer people  
are more vulnerable to natural hazards as they settle in buildings at higher risk but more affordable to them due to cheap rents  
(Salami et al., 2015). In particular, squatter houses are very low-quality buildings, and when taken together with the poor socio-  
economic characteristics of their residents, they represent high social vulnerability for households. A study by Abarca-Alvarez  
et al. (2019) in Andalusia, which used a decision tree analysis, showed the importance of dwelling variables on social  
vulnerability, such as the average age of constructions and the density of housing buildings in a census section of an urban  
area. In our study, the age of the buildings was not available in the data, however, the type of housing was found to be an  
important predictor of social vulnerability.

820 With the ANN method, the third highest-ranked variable was job insecurity. The spatial distribution of neighbourhoods in  
terms of job insecurity indicates that the centre of Istanbul close to the Marmara Sea is densely populated with households  
with job insecurity representing the possible unemployment figures in those crowded areas. Further, as mentioned above in  
the social security indicator, the labour market opportunities in Turkey are highly dominated by the casual or seasonal  
825 employment opportunities (Ocal and Senel, 2021). Such forms of casual employment are highly fragile since the labourers are  
not in full employment and not registered in the social insurance system. A recent study showed that casual and unregistered  
employment increases social vulnerability to natural hazards (Mavhura and Manyangadze, 2021). These may be either in the  
form of casual, seasonal employment or self-employment, where social security and social insurance registrations are not  
provided by the employers and the employees could not afford to pay their premiums regularly by themselves. These types of  
employees and small businesses mostly fall below the poverty line even if they may be observed as working (Adaman et al.,  
830 2015). Those households which depend on casual, unregistered employment and small businesses have a high probability of  
experiencing vulnerability when a disaster strikes as they may experience loss of any economic means in that situation. There  
is an important difference between job insecurity and social security variables. Job insecurity actually reflects the situation  
where the individual has no regular income, on the other hand, social security is covering all kinds of support and compensation  
mechanisms not only limited to the economic means of regular income. Although not limited to these, there might be several  
835 reasons for the difference between neighbourhoods in terms of these two variables. For example, it may be that in the rural  
areas of North-West Istanbul, the individuals may not have social security, but they own their land and small businesses and  
their jobs are more secure even though they may have a limited income (Acar et al., 2022). In contrast, in the centre of the  
city most of the population is in wage employment where a major group is in regular registered employment besides a  
significant group of unemployed or those working on a daily basis in casual jobs (Acar et al., 2022). Hence, unemployed or  
840 those in daily jobs may suffer job insecurity and high risk of losing employment and/or income if caught by a hazard. Moreover,

845 the individuals working in the service sector, which is common in İstanbul neighbourhoods, may suffer more from the possibility of work closures after a major hazard. For example, during the COVID-19 Pandemic, when small workplaces have been required to close or restrict their services for a long period of time, most working people suffered severe job and income losses, hence high vulnerability emerged (Bartik et al., 2020; Gray et al., 2022). While İstanbul took 41.9% share of the total services sector in Turkey in 2021, the share of the services sector in İstanbul's total gross domestic product was 33.7% (Turkish Statistical Institute, 2021).

850 The other variables among the top ten most important predictors that contribute to the model performance of the ANN model were a mixture of demographic and economic variables. These included the ratio of over 65-year-olds in the household, owning a house outside of İstanbul, household size, the ratio of income earners in the household, having savings for emergency situations, owning land outside of İstanbul, and the level of education of the residents. The demographic variable of having elderly (>65 years) in the household being an important predictor of social vulnerability to hazards is also highlighted in the literature (Chou et al., 2004; Fatemi et al., 2017). High education which lowers social vulnerability is a factor that is both related to having social security, as mentioned before, and with an increase of awareness to take precautions for possible hazard risks. The other significant variables like having property and savings are both related with income, where the property outside the city may give more chances for the households to have a safe shelter after a major hazard. Furthermore, the associations between income and level of education are strong and consistent; that is children from poorer family backgrounds have a tendency of achieving a lower level of education (West, 2007). Also, the poor have less access to resources which may be effective in reducing risks, such as extra savings for preparing their houses to hazard risks or accessing risk preparation information, and therefore cannot take as many precautions to cope with a disaster when it occurs (Hallegatte et al., 2020).

## 860 **6 Limitations and recommendations**

~~We have found that socially~~ Socially, economically, and environmentally vulnerable communities are more likely to suffer disproportionately from disasters- (Cureton, 2011; Hallegatte et al., 2020). However, our analysis was based solely on quantifiable household data, ~~and since~~ variables related to environmental factors, historical hazard data and building infrastructures were not available in our survey-based data set. ~~Furthermore, the predictors in the survey data are specific to earthquake risk but not necessarily relevant to multiple disaster risks.~~ Another important limitation regards the fact that we are using social vulnerability ~~scores that are predefined in the previous survey study (phase one).~~ As the urbanization process is always live index scores that are pre-constructed in a previous social vulnerability research. As we aim to assist the social vulnerability assessment process of local authorities, which is IMM in our case, we do not tend to discuss their scoring scheme as it is part of their official policy-making process, but we try to present them the best possible predictors of social vulnerability according to their variable selection. However, as urban growth and migration are

~~common experiences~~ in a vibrant city like Istanbul, ~~they~~ regeneration and renewal processes ~~in Istanbul may cause possible changes in~~ accelerating the trend, the location of residents ~~and their~~ is continuously changing similar to the change ~~in~~ socio-economic positions ~~of neighbourhoods~~ both upward and downward, ~~which differs according to each urban project scheme.~~ This may result in a continuous change ~~of status~~ and dynamic social vulnerability of households and neighbourhoods which needs to be studied in further research.

~~Although assessing social vulnerability is a complex process that takes many personal and environmental factors into account, our predictors in the ML models were limited to quantifiable household data as our aim in this paper is to present an optimal modelling strategy capable of processing readily available large databases.~~ For future studies, we recommend using household data along with community-level spatial predictors to enhance the predictive ability of the models. In addition, the spatial distribution of social vulnerability ~~risk~~ can further be detected along with the fault lines. We note that we could not perform a validation of the ML models using a separate and independent ~~dataset~~ data set due to the unavailability of such ~~survey~~ household data derived from another source. Although the models were tested using ~~an~~ independent testing data from our survey data, the model predictions may benefit from validation studies which could be conducted using an additional ~~dataset.~~ independent data set.

## 67 Conclusion

This research presents a new and alternative ~~decision making support tool~~ approach for public authorities to develop ideas for future governance mechanisms ~~to cope with social vulnerability~~ based on interdisciplinarity: ~~as a combination of social and statistical science.~~ To address the ~~first research question on determining the best performing social vulnerability predictors by using ML method,~~ we compared ~~seven~~ six different supervised ~~ML~~ machine learning techniques ~~and logistic regression~~ which can be employed for binary classification with imbalanced class variables. We demonstrated that an ANN using majority under-sampling was the optimum method in terms of sensitivity, AUC, and other relevant performance metrics. ~~Results from the variable importance analysis fulfil the second research question regarding the most influential predictors of social vulnerability risk of households.~~ The variable importance results showed that economically deprived households which do not have social security, ~~those that have a high risk of and experience~~ job ~~loss in the event of an earthquake, live~~ insecurity, the ones living in squatter houses and ~~are~~ less educated ~~individuals~~ are ~~at the highest risk of~~ more likely to have a high social vulnerability to ~~earthquakes~~ hazards. We stress strongly ~~and have demonstrated~~ that our research outcomes ~~have~~ and demonstration of employing machine learning with large

household-level data have the potential to support decision-makers to develop more effective policies ~~through prioritising~~  
~~the~~ by making use of quantifiable household data which are available across various institutions and public bodies. More  
900 explicitly, a policy-maker can make use of our proposed final ANN model to discriminate between households with low and  
high social vulnerability, by inputting the variables found significantly important in the study. Thus, the groups with certain  
characteristics which are more vulnerable target groups, understanding the perspective and preference may be  
prioritised by decision-makers in terms of their needs in order to develop new schemes that are specifically targeted for  
reducing disaster related vulnerabilities. This kind of communities, considering urgency and high risk in  
905 exceptional locations and developing more sensitive and effective projects for the needs ~~targeted assistance~~  
is missing in Turkey's local and national disaster risk reduction policies, though it is a part of the people expected to be  
affected. Furthermore ~~Sendai Framework (UNISDR, 2015). Therefore,~~ the local authorities, mainly Municipalities, can  
benefit from the results of this study ~~in accordance with their disaster risk reduction activities in urban~~  
~~transformation processes, training, and~~ to target poor groups to accommodate them in affordable disaster-resistant  
910 housing within urban renewal schemes, for improving social assistance for the elderly, children, youth, and the poor, and for  
increasing awareness ~~raising events-~~ raising events. Also, the central authorities may define new policies for increasing  
access to education and to social security of the poor and the vulnerable groups. This study made use of machine learning  
methodology and assessed their performances on social data based on an interdisciplinary collaboration where the statistics,  
urban planning and sociology disciplines intersect, to understand ~~disaster risk mitigation~~ the significance of assessing  
915 social vulnerability at the household level and how to build a society more resilient to natural disasters.
