13
14 **Abstract**

15 The inner shelf and coastal region of the Yellow Sea along the Korean peninsula are frequently
16 impacted by Typhoons. The Mokpo coastal region in South Korea was significantly affected
17 by typhoon Soulik in 2018, the deadliest typhoon strike to the southwestern coast since Maemi
18 in 2003. Typhoon Soulik overran the region, causing extensive damage to the coast, shoreline,
19 vegetation, and coastal geomorphology. Therefore, it is important to investigate its impact on
20 the coastal ecology, landform, erosion/accretion, suspended sediment concentration (SSC) and
21 associated coastal changes along the Mokpo region.

22 In this study, net shoreline movement (NSM), normalized difference vegetation index
23 (NDVI), fractional vegetation coverage (FVC), coastal landform change model, normalized
24 difference suspended sediment index (NDSSI), and SSC-reflectance relation have been used
25 to analyze the coastal morphodynamics over the typhoon periods. We used pre-and post-
26 typhoon Sentinel-2B MSI images for mapping and monitoring the typhoon effect-and recovery
27 status of the Mokpo coast through short and medium-term coastal change analysis. The
28 findings highlighted the significant impacts of typhoons on coastal dynamics, wetland
29 vegetation and sediment resuspension along the Mokpo coast. It has been observed that
30 typhoon-induced SSC influences shoreline and coastal morphology. The outcome of this
31 research may provide databases to manage coastal environments and a long-term plan to restore
32 valuable coastal habitats. In addition, the findings may be useful for post-typhoon emergency
33 response, coastal planners, and administrators involved in the long-term development of human
34 life.

35
36 **Keywords:** Typhoon Soulik, Coastal changes, NDVI, FVC, Suspended sediment movement,

38 **1. Introduction**

39 Typhoons are one of the most destructive natural calamities. Strong winds that accompany
40 typhoons ~~during landfall~~ damage the environment, coastline, wildlife, people, and public and
41 private properties in coastal and inland areas during landfall (Shamsuzzoha et al., 2021; Xu et
42 al., 2021; Mishra et al., 2021a; Nandi et al., 2020; Sadik et al., 2020; Sahoo and Bhaskaran,
43 2018; Hoque et al., 2016). Many coastal and near-coastal countries are plagued by typhoon-
44 induced storms, flooding, deforestation, and increased soil salinity (Rodgers et al., 2009).
45 Typhoons (tropical cyclones) have caused 1,942 disasters in the past 50 years, resulting in
46 779,324 fatalities and USD 1,407.6 billion in economic losses worldwide (WMO, 2020),
47 demonstrating their effects on both the global and regional economies (Bhuiyan and Dutta,
48 2012; Mallick et al., 2017). The effects of typhoons include saltwater intrusion, soil fertility
49 depletion, reduced agricultural productivity, life losses, coastline erosion, vegetation damage,
50 and massive economic disasters (Mishra et al., 2021b).

51 According to instrumental data collected since 1904, typhoon intensity on the Korean
52 peninsula has grown during the previous 100 years (Yu et al., 2018; Cha et al., 2021). A total
53 of 188 typhoons, about three annually, have affected the coastal region from 1959 to 2018
54 (KMA, 2018). Among past Typhoons, RUSA (2002), MAEMI (2003), NARI (2007), and
55 SOULIK (2018) heavily affected the southwestern coast, causing extensive damage to lives
56 and properties (KMA, 2011; 2018). Furthermore, people living in these regions have faced
57 serious coastal floods caused by these events for more than a half-century (Moon et al., 2003).
58 Mokpo coastal region, located in the southwest coast of South Korea, has been hit by 58
59 typhoons since 1980, with most occurring in the July to October period (Kang et al., 2020; Lee
60 et al., 2022). The rapid growth of coastal economies and populations in recent years has made
61 these areas more susceptible to typhoon disasters. Therefore, the increasing frequency of
62 typhoons on the southwestern coasts is a significant issue for disaster management.

63 Several studies (Halder and Bandyopadhyay, 2022; Wang et al., 2021; Shamsuzzoha et
64 al., 2021; Kumar et al., 2021; Sadik et al., 2020; Konda et al., 2018; Parida et al., 2018; Zhang
65 et al., 2013; Yin et al., 2013; Li and Li., 2013; Rodgers et al., 2009) have been carried out in
66 South Asia using various techniques to map the hazard, vulnerability, risk and effects of
67 typhoon disasters. Remote sensing and geospatial technology play a crucial role in monitoring
68 a variety of natural disasters (Wang and Xu, 2018; Mishra et al., 2021b; Charrua et al., 2021).

69 The majority of studies on typhoon-induced coastal dynamics rely on passive optical remote
70 sensing and identify natural disaster damage using changes in landuse data, vegetation indices,
71 and geospatial techniques (Mishra et al., 2021a; Xu et al., 2021; Nandi et al., 2020). The post-
72 typhoon damage assessment research in South Korea mostly focused on property loss,
73 economic losses, and casualties (Yum et al., 2021; Kim et al., 2021; Hwang et al., 2020).
74 However, the coastal morphodynamics along the Mokpo coast over the typhoon period ([such](#)
75 [as short and medium term](#)) have not been investigated in detail. Thus, this study's primary focus
76 is to determine the effects of typhoon Soulik on coastal ecology, landforms, erosion/accretion,
77 suspended sediment movement and associated coastal changes along the Mokpo coast.

78 The normalized difference vegetation index (NDVI) and variations in NDVI (Δ NDVI)
79 have been used to map the extent of vegetation destruction and details on the degree of damage
80 after the typhoon (Wang et al., 2010; Datta & Deb, 2012; Zhang et al., 2013; Kumar et al.,
81 2021; Xu et al., 2021). Vegetation damage can be seen by the negative change in NDVI values
82 between the post-and pre-typhoon period (Mishra et al., 2021a; Hu and Smith, 2018). On the
83 other hand, fractional vegetation coverage (FVC) is a crucial quantitative indicator of the
84 vegetation cover of the land surface (Zhang et al., 2021; Wang and Xu, 2018; Song et al.,
85 2017). Therefore, FVC has also been used to assess the extent of vegetation damage caused by
86 typhoon Soulik and to analyze its impact on vegetation cover. The coastline movement over
87 the typhoon periods has been analyzed using the Digital Shoreline Analysis System (DSAS)
88 program (Tsai, 2022; Adhikari et al., 2021; Bishop-Taylor et al., 2021; Santos et al., 2021). In
89 order to monitor and protect coastal habitats, we need to understand the distribution and
90 movement of SSC between rivers and coastal waters. Thus, the normalized difference
91 suspended sediment index (NDSSI) (Kavan et al., 2022; Shahzad et al., 2018; Hossain et al.,
92 2010) and the SSC-reflectance algorithm developed by Choi et al. (2014) for the Mokpo coastal
93 region have been used to monitor SSC distribution. Furthermore, to understand the [short and](#)
94 [medium-term](#) morphodynamics of the coastal landform due to the typhoon, a ~~GIS~~[GIS](#)-based
95 coastal change model has been developed. Four coastal landform classes, i.e., tidally influenced
96 land (wetland land, wetland vegetation) and non-tidally influenced land (land and water), have
97 been used for the coastal morphodynamic analysis (Maiti and Bhattacharya, 2011). The change
98 detection technique has been employed to quantify the ~~pre~~[short](#) and ~~post typhoon~~[medium-term](#)
99 coastal changes. This approach focuses on details of morphological changes within the coast
100 and highlights the minor changes caused by the typhoon.

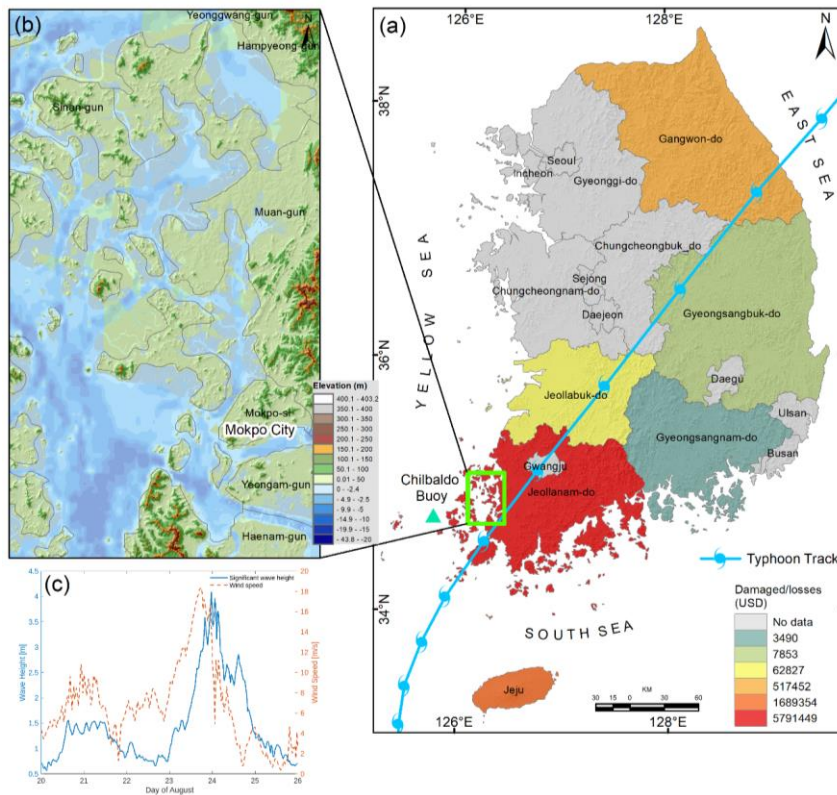

101 This study uses Sentinel-2 MSI images as a primary data source to examine the

102 morphodynamics and effects of Typhoon Soulik on coastal ecology. Accordingly, the
103 objectives of this study are to (i) quantify and mapping of coastal landform dynamics prior to
104 and after the typhoon, (ii) examine shoreline movement and assess coastal erosion and
105 accretion, (iii) assess the degree of typhoon damage to vegetated land, and (iv) analyze changes
106 in SSC and the response of sediment dynamics over the typhoon period. Coastal managers can
107 use this study to develop and implement appropriate strategies and practices to protect natural
108 ecosystems and post-disaster rehabilitation.

109 **2. Study Area**

110 The Mokpo coast is located in the southwestern part of South Korea and is characterized by
111 muddy flats with wide tidal ranges (Choi et al., 2007; Kang et al., 2007), as depicted in Figure
112 1. The inner part of the coast includes harbor and industrial complexes, a large residential area,
113 and a wastewater treatment plant. Mokpo coast is most frequently hit by typhoons, which cause
114 the most significant amount of property damage and loss of human lives (Kang et al., 2020;
115 Lee, 2014). According to storm surge records, the Mokpo coastal region has experienced the
116 highest number of typhoons (58) since 1980 due to its geographical location (Lee et al., 2022;
117 Kang et al., 2020). The tidal range has been observed to be broader, with the extreme high tide
118 60cm higher and the extreme low tide 43cm lower in the Mokpo coast (Lee et al., 2022; Kwon
119 et al., 2018). This fluctuation resulted in significant flooding during the typhoon period. High
120 water and waves severely damage the coastal structures and environment, especially during
121 surges (Tsai et al., 2006). The Mokpo coastal region is characterized by a strong ebb dominant
122 pattern because of its complex bathymetry, scattered islands and extensive tidal flats (Byun et
123 al., 2004; Kang and Jun, 2003; Kang, 1999).

124 The vast tidal flat of the Mokpo coast serves as a habitat for many different species, has
125 a large production capacity, and is highly regarded for its role in cleaning up pollution and
126 controlling floods and typhoons (Lee et al., 2021; Na, 2004). Furthermore, the powerful storm
127 has affected the coastal wetlands (mudflats) that serve as the primary spawning and nursery
128 grounds for fish and other marine life. However, Choi (2014) observed that tidal flat systems
129 in the Korean peninsula are actively responding to various phenomena, such as tides, waves,
130 and typhoons. The wetland, coastal vegetation and coastline along the Mokpo coastal region
131 have been disturbed due to the extreme climatic events. It has been observed that most typhoon
132 passages severely impacted the tidal flat environment and caused morphodynamics along the
133 Mokpo coast.

134
 135 Figure 1. (a) Typhoon Soulik passage passed through the Mokpo coastal region on 23rd August
 136 2018 (Typhon track data were downloaded from [https://www.ncdc.](https://www.ncdc.noaa.gov/ibtracs/)
 137 [noaa.gov/ibtracs/](https://www.ncdc.noaa.gov/ibtracs/)), while the background shades represent province-wise recorded
 138 damaged/loss distribution reported by Member Report (2018), (b) Topography
 139 variation of the Mokpo coastal region (elevation data acquired from NGII (2018),
 140 <https://www.ngii.go.kr/>), and bathymetry data downloaded from GMRT,
 141 <https://www.gmrt.org/>), and (c) Variation of significant wave height and wind speed
 142 from August 20 to 25, 2018 recorded by Chilbaldo Buoy Station (located near the
 143 landfall area) during the typhoon Soulik (Data source:
 144 <http://wink.kiost.ac.kr/map/map.do#>).
 145
 146
 147

2.1 Typhoon Soulik

148 The southwestern coast of the Korean peninsula was ravaged by the strong intensity
 149 typhoon Soulik, which hit the Mokpo coast on 23rd August 2018 (Ryang et al., 2021). On 16th
 150 August, it developed near Palau as a tropical depression. Subsequently, it strengthened into a
 151 tropical storm before intensifying into a typhoon (Lee et al., 2022). It moved into the East China

152 Sea on 20th August with a maximum intensity of 950 hPa (44 m/s) and lasted until 22nd August.
153 The Korea Meteorological Administration (KMA) issued typhoon warnings, and national and
154 local authorities took preventative measures to limit potential damage. On 23rd August, around
155 14 UTC, Typhoon Soulik made landfall close to Mokpo city, located on Korea's southwest
156 coast. The typhoon remained on the mainland for an additional 12 hours before moving to the
157 East Sea, where it underwent a transformation and became an extra-tropical cyclone. A peak
158 sustained wind speed of 30.2 m/s was recorded at Gageodo in South Jeolla Province, while the
159 central pressure of the typhoon was measured at 975 hPa (Member Report, 2018). Meanwhile,
160 the strongest gust was observed at Mt. Halla, with a peak gust of 62 m/s. It also dumped
161 tremendous rain (Kang and Moon, 2022; Kang et al., 2020; Yu et al., 2018; Cha et al., 2021).
162 The buoy station near Jeju Island has recorded extreme sea surface conditions, including a
163 maximum wave height of 15m, gusts of 35 m/s, and a drop in water temperature of 10°C. (Kang
164 et al., 2020; Yoon et al., 2021). Figure 1(c) illustrates the variations in sea surface parameters
165 between August 20 and August 25, 2018, in the vicinity of the landfall region (Chilbaldo buoy),
166 including wind speed and significant wave height. It was observed that a significant wave
167 height, i.e., 4-6 m, was recorded at Chilbaldo Buoy station. According to the Ministry of the
168 Interior and Safety (MOIS), typhoon Soulik caused various damages and disruptions across
169 various regions in the country. One woman was reported missing in the coastal area of Jeju,
170 and three people sustained injuries. A total of 362 facilities were damaged. In addition, the
171 typhoon resulted in power outages for 26,830 houses and flooding that affected over 3,063
172 hectares of farmland (Member Report, 2018). Furthermore, the typhoon destroyed extensive
173 vegetation with strong gusts and damaged non-residential structures along the Mokpo coast. A
174 province-wise breakdown of the damage and losses caused by the typhoon is depicted in Figure
175 1(a). The total damage caused by Typhoon Soulik in South Korea was \$45 million (KMA,
176 2018).

177

178 **3. Data and Methods**

179 **3.1 Data Sources and pre-processing**

180 Typhoon-induced coastal dynamics along the Mokpo coast have been studied using the
181 pre-and post-event Sentinel-2 MSI images. A multispectral instrument (MSI), Sentinel-2,
182 consists of two polar-orbiting satellites, Sentinel-2A and Sentinel-2B, launched in June 2015
183 and March 2017, respectively (ESA, 2020). The Sentinel 2 MSI has a 290 km wide field of

184 view, a minimum revisits period of five days, 13 spectral bands ranging from visible to
185 shortwave infrared (SWIR), and spatial resolution of 10m (4 bands), 20m (6 bands), & 60m (3
186 bands) (ESA, 2020). The Sentinel-2 User Manual describes the MSI's radiometric, spectral,
187 and spatial characteristics (ESA, 2020).

188 The cloud-free Sentinel-2 MSI level 1C satellite images with a relatively fine spatial
189 resolution (10m) for the pre-and post-typhoon period have been downloaded from the
190 Copernicus Scientific Data Hub (<https://scihub.copernicus.eu/dhus/>) as depicted in Figure 2.
191 Level 1C is a 12-bit radiometric product that was presented the top of the atmospheric
192 reflectance value (Phiri et al., 2021). The open-source software SNAP (Sentinel Application
193 Platform) has been used to process the Sentinel-2 MSI images such as masking, band
194 visualization, atmospheric correction etc. We used SANP's iCOR tool (image correction for
195 atmospheric effect) for atmospheric correction of the Sentinel 2 MSI data over the land and
196 water (Tian et al., 2020; Keukelaere et al., 2018). After that, satellite remote sensing reflectance
197 (R_r) images were used to monitor ~~the~~ short and medium-term coastal dynamics in the Mokpo
198 coastal region ~~over the typhoon period.~~

200 Figure 2: Pre (a) and post-typhoon (b) standard false color composite of reflectance image of
 201 the Mokpo coastal region (Sentinel-2 MSI level 1C satellite images are downloaded
 202 from <https://scihub.copernicus.eu/dhus/>). The arrows indicate extensive vegetation
 203 damage due to typhoon Soulik.
 204

205 On the other hand, to exclude the impact of tidal changes, satellite images have been
 206 chosen during low tide conditions (Maiti and Bhattacharya, 2009). The tide height has been
 207 computed using the WXTide32 program (Hopper, 2004). Several researchers have discussed
 208 the significance of low tide satellite data for coastal mapping and dynamics modeling (Nayak,
 209 2002). The details of pre- and post-typhoon satellite data used in the study are listed in Table
 210 1. In addition, the coastal morphology was also investigated using high-resolution (5m×5m)
 211 topography data (i.e., LiDAR DEM) provided by the Korean National Geographic Information
 212 Institute (NGII) and bathymetry data obtained from GMRT (<https://www.gmrt.org>) (Fig. 1b).

213 Table 1. The details of Sentinel-2 MSI data used for coastal dynamic modeling.

Periods	Date of acquisition	Sensor	Cloud cover (%)	Tidal Height (m)
Pre-typhoon	2018/08/01	Sentinel-2B MSI	1.3464	0.77
Post-typhoon	2018/10/15	Sentinel-2B MSI	0.6548	1.01
	2019/10/20	Sentinel-2B MSI	2.8444	1.02

214

215 3.2. Typhoon-induced coastal dynamic modeling

216 ~~This study aims to analyze the typhoon Soulik induced coastal dynamics and associated~~
 217 ~~coastal changes along the Mokpo coastal region. The present study addresses the typhoon~~
 218 ~~Soulik-induced morphodynamics over the Mokpo coast region, specifically examining short~~
 219 ~~and medium-term coastal changes. Short-term coastal erosion refers to the rapid erosion~~
 220 ~~processes and coastal alterations that occur immediately after typhoons or over short durations,~~
 221 ~~typically within days, weeks, or months. Contrarily, medium-term coastal change refers to~~
 222 ~~erosion processes and coastal changes that take place over a period of time ranging from a few~~
 223 ~~months to a few years. It involves the restoration and stabilization of coastal land surfaces after~~
 224 ~~the typhoon.~~ Figure 3 depicts an integrated flowchart of the impact of a typhoon on a coastal
 225 system. The outline of the study is divided into four sections: (a) coastal vegetation disturbance
 226 mapping, (b) coastal landform mapping and change analysis, (c) suspended sediment
 227 concentration variation modeling, and (d) coastal erosion and accretion analysis. The details
 228 methodology of each objective has been discussed in the subsequent section.

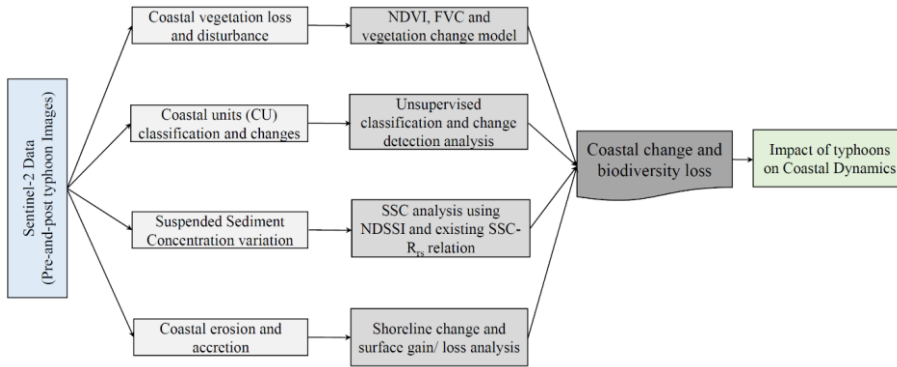

Figure 3. Geospatial-based approach for typhoon-induced coastal dynamics ~~due to a typhoon analysis~~.

3.2.1 Analyses of coastal vegetation loss and disturbance

Vegetation damage severity mapping (VDSM) has been performed using pre-and post-event satellite images. NDVI and FVC are widely used techniques for measuring vegetation density, health status, regional vegetation condition, and detecting vegetation disturbances (Xu et al., 2021; Mishra et al., 2021b; Wang et al., 2010; Yang et al., 2018, Wang and Xu, 2018; Carlson and Ripley, 1997). Subsequently, numerous studies (Xu et al., 2021; Mishra et al., 2021a; Charrua et al., 2021; Shamsuzzoha et al., 2021; Kumar et al., 2021; Nandi et al., 2020; Wang and Xu, 2018; Konda et al., 2018; Zhang et al., 2013; Rodgers et al., 2009) have shown that the NDVI and FVC is a reliable indicator of post-typhoon damage detection. Therefore, in this study, the vegetation damage due to typhoon Soulik has been determined using the NDVI and FVC approach. The NDVI has been calculated by using the following Eq. (1) (Rouse et al., 1974; Filgueiras et al., 2019):

$$NDVI = \frac{\rho_{NIR} - \rho_{RED}}{\rho_{NIR} + \rho_{RED}} \quad (1)$$

where ρ_{NIR} and ρ_{RED} are the spectral reflectances corresponding to the eighth (832.8–832.9nm) and fourth (664.6–664.9nm) Sentinel-2 MSI bands, respectively (Xu et al., 2021). In general, NDVI values range from -1.0 to 1.0; the higher the NDVI value, the better the conditions for vegetation development, and extremely low values indicate the presence of water. Furthermore, the NDVI value above 0.4 indicates vegetated surfaces, and those between 0.25 and 0.40 signify soils with the presence of vegetation (Charrua et al., 2021). The vigor of the vegetation increases as the NDVI values come closer to 1.00 (Rouse et al., 1974). Numerous

252 studies have established the NDVI threshold for vegetated land (e.g., Xu et al., 2021; Wong et
253 al., 2019; Liu et al., 2015; Eastman et al., 2013; Yang et al., 2012; Sobrino et al., 2004). Most
254 researchers noted that the NDVI threshold value for vegetation cover typically ranges from
255 0.15-2.0 (Xu et al., 2021; Eastman et al., 2013; Sobrino et al., 2004). Therefore, the vegetated
256 pixels (e.g., NDVI threshold > 0.20) present in pre and post-typhoon NDVI images have been
257 used for vegetation severity analysis. The NDVI threshold is considered to reduce the
258 ~~influenceeffect~~ of land cover change from the pre-typhoon (2018-08-01) to post-typhoon
259 (2018-10-15) periods.

260 The degree of vegetation damage has been determined by comparing the NDVI values
261 of the pre-and post-typhoon periods. Various researchers have frequently used the direct
262 difference of NDVI to determine the damage severity caused by typhoons to naturally
263 vegetated land (Wang and Xu, 2018; Konda et al., 2018). It has been calculated on a cell-by-
264 cell basis by subtracting the pre-typhoon NDVI image from that of the post-typhoon in ArcGIS
265 software using map algebra (Zhang et al., 2013; Cakir et al., 2006). The following equation is
266 used to calculate the $\Delta NDVI$ (Wang and Xu, 2018),

$$267 \quad \Delta NDVI = NDVI_{post-typhoon} - NDVI_{pre-typhoon} \quad (2)$$

268 The difference in NDVI (i.e., $\Delta NDVI$) illustrates the change in natural vegetation, while a
269 negative $\Delta NDVI$ value indicates the damage inflicted by a typhoon to the vegetation cover (Xu
270 et al., 2021).

271 The relative change in NDVI value has been used to investigate the geo-ecological
272 impact on the forest area (Mishra et al., 2021b). The relative vegetation changes ($NDVI_r$) after
273 Soulik have been determined by using the following Eq. (3) (Kumar et al., 2021),

$$274 \quad NDVI_r = \frac{\Delta NDVI}{NDVI_{pre-typhoon}} \times 100 \quad (3)$$

275 where the negative $NDVI_r$ value indicates vegetation loss caused by typhoons, and the positive
276 $NDVI_r$ value shows vegetation gain. The $NDVI_r$ value has been classified into three categories
277 corresponding to pixels with decreased, no change, or increased vegetation cover.

278 On the other hand, we analyze FVC in conjunction with NDVI, which provide
279 additional insights into vegetation conditions and damage severity. Numerous researchers
280 (Wang and Xu, 2018; Song et al., 2017; Bao et al., 2017; Chu et al., 2016; Amiri et al., 2009)
281 used FVC to analyze vegetation damage, restoration, recovery, and inter-annual variability. In
282 the present study, FVC was calculated before and after the typhoon using the derived NDVI

283 data (Wang and Xu, 2018). It is expressed as a percentage and can range from 0 to 100%. The
284 formula of FVC is as follows (Wang and Xu, 2018; Amiri et al., 2009; Carlson and Ripley,
285 1997),

$$286 \quad FVC = [(NDVI - NDVI_m)/(NDVI_{max} - NDVI_m)]^2 \quad (4)$$

287 where, $NDVI_m$ and $NDVI_{max}$ represent the $NDVI_{min}$ and $NDVI_{max}$ values calculated using
288 equation (1) (Zhang et al., 2021; Ge et al., 2018). The calculated FVC values vary between 0
289 and 1. After that, the FVC values were converted to percentages to fit the actual FVC
290 classification scheme (Wang and Xu, 2018), which consists of five classes: high (80-100%),
291 medium-high (60-80%), medium (40-60%), medium-low (20-40%), and low (0-20%). Further,
292 the difference in FVC values between the pre-and post-typhoon images was used to calculate
293 the extent of vegetation damage using the following equation,

$$294 \quad \Delta FVC = FVC_{post-typhoon} - FVC_{pre-typhoon} \quad (5)$$

295 where, ΔFVC denotes the difference between the pre and post-typhoon FVC. The ΔFVC value
296 represents alterations in vegetation conditions and damage intensity, while a negative value of
297 ΔFVC indicates the extent of damage caused by a typhoon to vegetation cover (Wang and Xu,
298 2018).

299

300 **3.2.2 Coastal landform classification and change analysis**

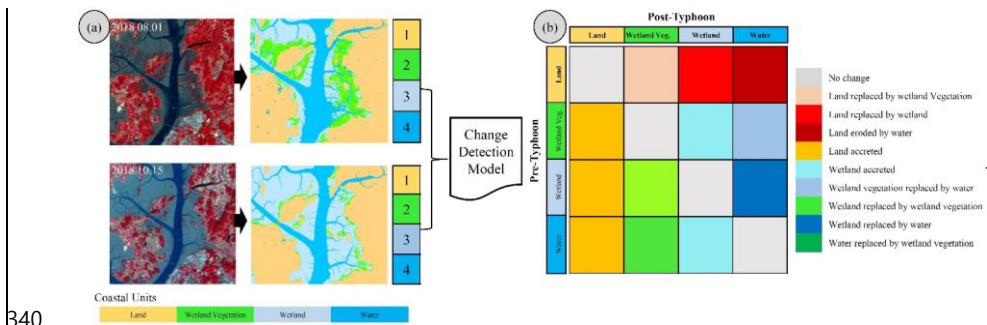

301 Typhoons have adversely affected the coastal landform and ecology of the south and
302 west coasts of the Korean peninsula every year. Therefore, a [GIS](#)-based coastal change
303 model has been developed to understand the morphodynamics of coastal landforms during
304 typhoons. In the present study, we considered four coastal landform classes, i.e., wetland,
305 wetland vegetation, land, and water, for the coastal morphodynamic analysis (Maiti and
306 Bhattacharya, 2011). The method consists of two algorithms, i.e., (a) the ISODATA algorithm
307 used to classify the coastal landform with four main classes, i.e., water, wetland, wetland
308 vegetation, and land, and (b) the change detection technique used to quantify the [pre-short-](#)
309 [term](#) and [post-typhoon-medium-term](#) coastal changes. In this approach, we accentuate in-depth
310 morphological changes and emphasize minor changes along the Mokpo coast caused by
311 typhoon Soulik.

312 The pre-and post-typhoon Sentinel-MSI images have been classified using the
313 unsupervised classification technique to distinguish among different coastal landforms of the
314 study region. This approach is used to determine which types of coastal landforms were
315 adversely affected by Typhoon Soulik and which of them have recovered more quickly than

316 others. ERDAS Image software has been used to run the unsupervised classification algorithm
 317 (ERDAS, 1997). Based on the k-means algorithm, this technique reduces variability within
 318 pixel clusters (Charrua et al., 2021; Aswatha et al., 2020; Bhowmik et al., 2013). Finally, pre-
 319 and post-typhoon Sentinel-2 MSI images have been classified into four coastal landform
 320 classes: land, water, wetland, and wetland vegetation.

321 The accuracy assessment is a commonly used method to determine how closely the
 322 classified map matches the reference data (Congalton, 1991). In the present study, the classified
 323 data (i.e., coastal landforms maps) have been derived through an unsupervised classification
 324 technique, while 550 random samples collected from different parts of the Sentinel- 2MSI
 325 standard false-color image are considered reference data. Thereafter, a confusion matrix was
 326 developed based on the reference and classified data to evaluate accuracy statistics (Story and
 327 Congalton, 1986). The *kappa* coefficient (*k*) has been used to determine the quantitative
 328 accuracy of the classified map (Landis and Koch, 1977). The assessment is quantified using
 329 three different statistics: overall accuracy, producer accuracy, and user accuracy (Story and
 330 Congalton, 1986). The model's precision is classified into five categories based on the *k* values:
 331 near perfect ($k > 0.8$), substantial ($0.6 < k < 0.8$), moderate ($0.4 < k < 0.6$), fire ($0.2 < k < 0.4$),
 332 and poor ($k < 0.2$) (Landis and Koch, 1977).

333 The land transformation model based on mutual spatial replacements has been applied
 334 during the post-classification stage, as shown in Figure 4. The classified coastal landform
 335 classes, such as land, wetland, wetland vegetation, and water, have been spatially replaced in
 336 order to create coastal-change units. For example, the coastal landform class of wetland
 337 vegetation in the pre-typhoon period replaced by water in the post-typhoon period indicates the
 338 change class of wetland vegetation replaced by water. A total of nine coastal-change classes
 339 have been derived, as illustrated in Figure 4(b).

342 classes.

343

344 **3.2.3 Suspended sediment concentration modeling**

345 The suspended sediment concentration (SSC) distribution in coastal regions is a
346 significant indicator of changes in the marine environment caused by typhoon-induced storm
347 surges, strong waves, and subsequent coastal flooding (Min et al., 2012; Gong and Shen, 2009).
348 In a short period, a typhoon may drastically influence the water column structures (Souza et
349 al., 2001), change the transport and deposition of sediment (Li et al., 2015), and affect the
350 distribution of nutrients and biological production in the affected seas (Wang et al., 2016).
351 Extreme storms or typhoons can modify suspended sediment distribution in coastal areas,
352 which can significantly change marine habitats (Chau et al., 2021; Lu et al., 2018; Li ~~landand~~
353 Li, 2016). Due to strong typhoon wind stress, the concentration of suspended particles in the
354 seawater column and sediment resuspension may increase dozens of times before and after the
355 event (Lu et al., 2018; Bian et al., 2017). Thus, typhoons significantly affect suspended
356 sediment movement in the coastal region (Zhang et al., 2022; Li and Li, 2016; Goff et al.,
357 2010). The spatiotemporal distribution of SSC can be impacted by variations in tidal phase,
358 runoff, and wind speed (Tang et al., 2021). Furthermore, the resuspension of sediment can
359 cause numerous problems in ocean engineering and change the region's ecology (Kim, 2010).
360 The amount of material delivered to and advected across the shelf by typhoons is considerably
361 larger than that of winter storm systems (Dail et al., 2007). The southern and western part of
362 the Korean peninsula is affected by an average of three typhoons annually passing through the
363 Yellow Sea (KMA, 2018; Altman et al., 2013). Some studies on SSC distribution impacted by
364 artificial construction along the coastal region of the Yellow Sea have been undertaken by
365 several researchers (i.e., Lee et al., 2020; Eom et al., 2017; Min et al., 2012, 2014; Choi et al.,
366 2014). However, the effects of typhoons on the sedimentary environment in the Mokpo coastal
367 region have not yet been investigated. Therefore, it is imperative to carry out regional-scale
368 SSC mapping and coastal modifications to reveal changes in the marine environment and
369 sediment transport mechanisms over the typhoon period.

370 Remote sensing has long contributed to the advancement of water quality studies
371 (Hossain et al., 2021). In the present study, we attempted to calculate both the qualitative and
372 quantitative SSC in the inner-shelf region of the Mokpo coast using Sentinel-2B MSI data. The
373 relative suspended sediment concentration has been calculated from pre- and post-typhoon

374 Sentinel-2B MSI images using the NDSSI. NDSSI has been used in various water quality
 375 research (Kavan et al., 2022; Hossain et al., 2010). Further, many studies (Shahzad et al., 2018;
 376 Arisanty & Saputra, 2017) have successfully used Landsat and Sentinel-2 data to calculate
 377 NDSSI. This index determines the relative concentration of suspended sediment, with values
 378 ranging from -1 to 1, where -1 indicates the highest concentration and +1 indicates the lowest
 379 (Hossain et al. 2010). The NDSSI has been calculated by using Eq. (6).

$$380 \quad NDSSI = \frac{\rho_{Blue} - \rho_{NIR}}{\rho_{Blue} + \rho_{NIR}} \quad (6)$$

381 where ρ_{Blue} and ρ_{NIR} represent the surface reflectances of Band 2 (492.1– 492.4 nm) and
 382 Band 8 (832.8 – 833.0 nm) of Sentinel-2 MSI data, respectively. The NDSSI is based on the
 383 observation that turbid waters reflect more in the NIR band but less in the visible band. The
 384 negative NDSSI value represents that the reflectance of water in the NIR band is greater than
 385 that in the blue band (Shahzad et al., 2018; Hossain et al., 2010). Therefore, the positive values
 386 of NDSSI represent lower SSC or more transparent water, while a negative value indicates
 387 higher SSC. The spatial patterns of relative SSC during the typhoon period have been
 388 determined using the NDSSI.

389 On the other hand, the empirical model has also been used to quantify the suspended
 390 sediment concentration before and after typhoon Soulik. This method is widely used for SSC
 391 mapping and monitoring around the world (Eom et al., 2017; Hwang et al., 2016; Son et al.,
 392 2014; Min et al., 2012; Lee et al., 2011; Choi et al., 2014). For this purpose, we reviewed the
 393 existing relations between the in-situ SSC (SSC, g/m³) and remote sensing reflectance (R_r)
 394 developed by various researchers for the southern and western coasts of South Korea, as
 395 illustrated in Table 2. In the present study, the SSC algorithm developed by Choi et al. (2014)
 396 for the Mokpo coastal region based on the in-situ SSC and a spectral ratio of water reflectance
 397 around 660nm has been used to quantify the SSC distribution. The atmospheric corrected
 398 sentinel-2 MSI image (Red band) has been used to calculate the SSC.

399

400 Table 2. Relationship between the remote sensing reflectance (R_r) and suspended sediment
 401 concentration (SSSSC, g/m³).

Authors	Relation	Region	Wavelength (nm)

402

403 3.2.4 Coastal erosion and accretion analysis

404 The shorelines (i.e., land and water boundary) of the Mopko coast for ~~pre-short~~ and
405 ~~post-typhoon~~medium periods have been extracted using a semi-automatic technique (Maiti and
406 Bhattacharya, 2009). Here, we used the normalized difference water index (NDWI) and manual
407 digitization approach to separate the land and water boundary. The technique is widely used
408 for dividing land and water boundary (Santos et al., 2021; Dai et al., 2019). By using Sentinel-
409 2 imagery, NDWI can be achieved with the following formula (McFeeters, 1996),

$$410 NDWI = \frac{\rho_{Green} - \rho_{NIR}}{\rho_{Green} + \rho_{NIR}} \quad (7)$$

411 where ρ_{Green} is the green band, and ρ_{NIR} is the near-infrared band of Sentinel-2 MSI data.

412 The extracted land and water boundary of the Mokpo region are then converted into
413 polygons, and the shoreline has been determined using ArcGIS software. The shoreline change
414 statistics have been calculated using the DSAS program (Thieler et al., 2009). The extracted
415 shoreline for pre-and post-typhoon periods has been merged, and a 10m interval transect
416 perpendicular to a baseline has been created (Santos et al., 2021). ~~Thereafter~~After that, the
417 NSM method was used to calculate the total shoreline movement (in meters) between the pre-
418 and post-typhoon shoreline positions of each transect (Kermani et al., 2016).

$$419 NSM = sh_{post} - sh_{pre} \quad (8)$$

420 where sh_{post} and sh_{pre} represent the post and pre-typhoon shoreline positions, respectively.

421 On the other hand, the back-shore surface area changes due to shoreline movement
422 (retreat/advance) over the typhoon period has also been calculated using the geo-statistical
423 analyst tool. Several researchers (Awad and El-Sayed, 2021; Deabes, 2017; Karmani et al.,
424 2016) have also previously mapped the surface changes of the backshore region. To create the
425 surface area-change map, we first generated two polygon layers based on the extracted
426 shoreline, one for the pre-and one for the post-typhoon periods. Next, we utilized the
427 Symmetrical Difference tool in ArcGIS software to compute the difference between these
428 polygon layers during the period affected by the typhoon. Finally, two feature classes have
429 been derived, one for erosion and another for accretion. In addition, the attribute table contained
430 in each zone illustrates the magnitude of spatial changes (amounts of erosion and accretion)

431 during the typhoon period.

432

433 4. Result and Discussion

434 4.1 Vegetation damage severity mapping (VDSM) before and after ~~typhoon~~ Typhoon

435 4.1.1 VDSM based on the NDVI and FVC analysis

436 The VDSM shows the degree of vegetation damage due to typhoons. The comparison
437 of pre-and post-typhoon NDVI and FVC distribution shows a significant loss of vegetated land
438 as the number of no-productivity and low-productivity pixels increases in the post-typhoon
439 NDVI and FVC image.

440 Figure 5 depicts the spatial distribution of pre and post-typhoon NDVI images. Further,
441 to determine the severity of vegetation damage, the pre-and post-typhoon NDVI image has
442 been classified into six categories, namely non-vegetation (-1.0-0.0), low-vegetation (0.0-0.2),
443 medium-low vegetation (0.2-0.4), medium vegetation (0.4-0.6), medium-high vegetation (0.6-
444 0.8) and high vegetation (0.8-1.0). The pre and post-typhoon mean NDVI values were observed
445 to be 0.159 and 0.143, respectively, indicating a mean NDVI value decline of 0.016 after the
446 typhoon.

447

448 Figure 5. Status of vegetation greenness based on the NDVI data for the (a) pre-Soulik (01st
449 August 2018) and post-Soulik (15th October 2018) period.
450

451 Table 3 depicts the area changes for each NDVI category over the typhoon period. It
452 has been observed that the high NDVI values (>0.8) have changed drastically after typhoon-
453 Soulik. The area changes in the low and non-vegetation categories along the Mokpo coastal
454 region revealed that the wetland (mudflat) had accreted after the typhoon. On the other hand,
455 the post-typhoon image was acquired two months after typhoon Soulik, which suggests that
456 the grasses and crops have recovered well. This recovery is reflected in Table 3 from medium-
457 low to medium-high NDVI levels.
458

459 Table 3. NDVI distribution over the study area before and after the typhoon.

NDVI levels	Pre-typhoon (km ²)	Post-typhoon (km ²)	Change (km ²)
Non-vegetation (-1 to 0)	673.7	647.6	-26.2
Low (0 to 0.2)	430.4	415.2	-15.2
Medium-low (0.2 to 0.4)	141.6	243.3	101.6
Medium (0.4 to 0.6)	132.5	225.3	92.8
Medium-high (0.6 to 0.8)	283.7	294.4	10.7
High (0.8 to 1.0)	183.6	19.8	-163.8

460
461 On the other hand, the physical presence of vegetation has also been measured using
462 FVC analysis. In general, NDVI provides information on the health and productivity of
463 vegetation, while FVC provides information on the physical presence and distribution of
464 vegetation. Figure 6 depicts the pre- and post-typhoon FVC map of the Mopko coast. The area
465 of each FVC category is illustrated in Table 4. The results reveal that the typhoon caused a
466 substantial decrease in FVC in the area, with the average FVC reducing significantly from
467 33.43% to 23.64% after the typhoon. It was observed that the medium-high to high FVC area
468 decreased from 485.4 km² to 211.9 km², while the medium-to-low FVC area increased from
469 1359.8 km² to 1633.3 km². The high FVC vegetation category was more severely affected and
470 decreased considerably after the typhoon. These results indicate that the typhoon significantly
471 impacted the wetland vegetation in the region.

472
473 Figure 6. Status of vegetation based on the FVC analysis for the (a) pre-Soulik (01st August
474 2018) and post-Soulik (15th October 2018) period.
475

476 Table 4. Summary of FVC classes before and after the typhoon.

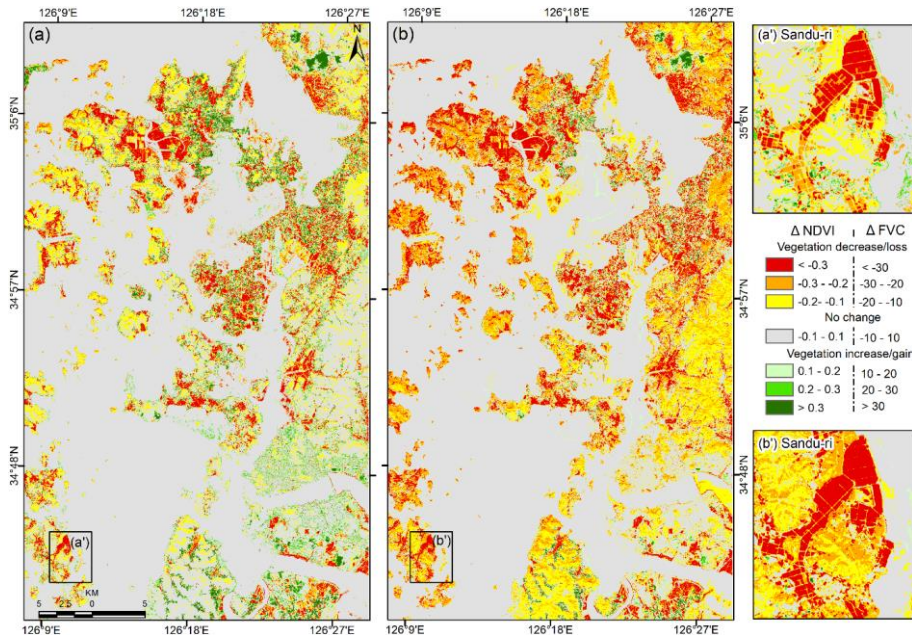

FVC levels (%)	Pre-typhoon (km ²)	Post-typhoon (km ²)	Change (km ²)
Non-vegetation (<20)	890.3	1053.3	162.943
Medium-low (20-40)	327.4	319.6	-7.811
Medium (40-60)	142.4	260.6	118.205
Medium-high (60-80)	206.1	211.5	5.365
High (80-100)	279.4	0.7	-278.671

477
478 In order to determine the damaged vegetation areas along the Mokpo coast, we
479 compared pre-and post-typhoon NDVI images. A decrease in Δ NDVI is one of the most
480 distinctive features of abrupt canopy modifications detectable by optical remote sensing (Xu et
481 al., 2021). Thus, we can only determine vegetation deterioration from the two NDVI images.
482 Subsequently, an NDVI threshold of 0.2 has been used to extract only vegetation features from
483 the pre-and post-typhoon NDVI images. The threshold value has been manually adjusted to

484 achieve the highest accuracy of vegetation pixels. The extracted vegetated pixels have been
485 compared with reference samples randomly collected from the original high spatial resolution
486 images to determine the accuracy (Schneider, 2012; Xu et al., 2021). The two extracted
487 vegetation images obtained within six or seven weeks of typhoon Soulik's (i.e., before the
488 damaged vegetation had recovered) exhibits an overall accuracy of 95.7 % for pre-typhoon and
489 94.5% for the post-typhoon period.

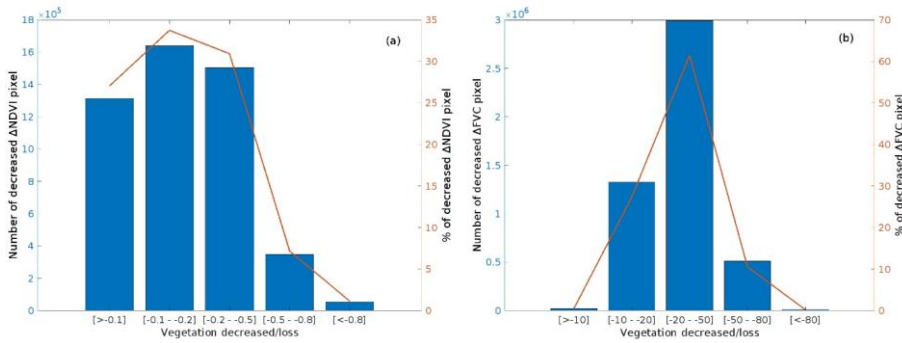

490 Figure 7(a) depicts the spatial distribution of Δ NDVI, where the highest Δ NDVI
491 indicates a region with highly impacted vegetation areas. The negative Δ NDVI is attributed to
492 about 26.7% of the total area (1845.60 km²), which suggests that Typhoon Soulik affected
493 approximately 493.98 km² of vegetated land. The lowest Δ NDVI value is -0.89, which
494 indicates either tree wind throws or a change in land surface cover from vegetation to build-up
495 land or other non-vegetation covers (Zhang et al., 2013). The results showed that wetland
496 vegetation and agricultural land experienced the most significant NDVI changes, with Δ NDVI
497 values below-0.3. This suggests that these two types of land cover were severely affected by
498 typhoon Soulik.

499 On the other hand, Figure 7(b) displays the change map obtained from the difference in
500 FVC (Δ FVC), which reveals areas of altered vegetation after the typhoon. The negative Δ FVC
501 is attributed to about 32.07% of the total area, which suggests that Typhoon Soulik affected
502 approximately 591.89 km² of vegetated land. It has also been observed that the pure vegetation
503 pixels (i.e., NDVI>0.6 and FVC>60%) were drastically changed over the typhoon period. The
504 changed area determined for NDVI and FVC is -153.43 km² and -273.40 km², respectively
505 (Tables 3 & 4). The results obtained from both techniques indicate a significant decrease in
506 vegetation cover after the typhoon. The probable reason for the change is that Typhoon Soulik
507 made landfall close to Mokpo coastal region.

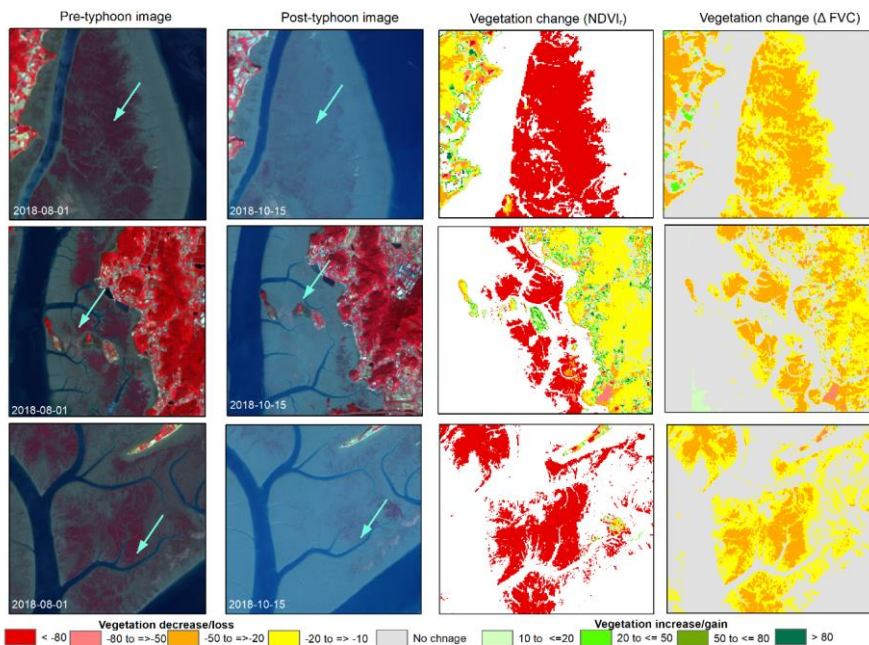

508
 509 Figure 7. Vegetation change map of the Mokpo coastal region derived through two different
 510 methods: (a) Δ NDVI and (b) Δ FVC, whereas zoom boxes show the vegetation
 511 damage of Sandu-ri areas.
 512

513
 514 Figure 8 compares vegetation damage based on the number and percentage of the
 515 decreased pixel of Δ NDVI and Δ FVC. It exhibits decreased pixels in different categories of
 516 vegetation damage, ranging from low damage to extensive damage. The pixels showing the
 517 most significant vegetation damage (i.e., Δ NDVI -0.2 to -0.5 and Δ FVC -20 to -50%) account
 518 for about 30.9% and 61.5% of the total pixels, respectively. On the other hand, the pixels
 519 showing extensive vegetation damage (i.e., Δ NDVI < -0.5 and Δ FVC < -50%) account for only
 520 8.31% and 10.76% of the total pixels. It was observed that the dominant vegetation in the region
 521 is wetland vegetation, which is mainly due to the prevalence of wetlands or mudflats in the
 522 area. Therefore, the significant vegetation damage implies that wetland vegetation was most
 severely impacted during typhoons.

523
 524 Figure 8. Comparison of vegetation damaged represented based on the number and percentage
 525 of decreased pixels of (a) Δ NDVI and (b) Δ FVC.
 526

527 The pre-and post-typhoon Sentinel-2 false-color images and the corresponding relative
 528 change in $NDVI_r$ and Δ FVC values are presented in Figure 9. The standard FCC imagery (left
 529 panel of Fig. 9) for pre and post-typhoon shows that $NDVI_r$ is more effective in detecting areas
 530 of damaged vegetation compared to Δ FVC (right panel, Fig. 9). It was observed that the
 531 typhoon-induced damaged vegetation area (i.e., pixels with $NDVI_r$ and Δ FVC of <50%)
 532 detected by $NDVI_r$ (106.5 km²) was greater than that detected by Δ FVC (51.3 km²). The
 533 dissimilarity in the ability of $NDVI_r$ and Δ FVC to detect the destruction of vegetation caused
 534 by the typhoon can be ascribed to the alteration in the color of the vegetation post-typhoon.
 535 This change can be detected more accurately by NDVI compared to FVC because the
 536 vegetation in the affected areas still existed, and there was not a significant reduction in
 537 vegetation coverage after the event (Wang and Xu, 2018). Thus, NDVI is highly sensitive to
 538 the health status of vegetation and a more appropriate approach for assessing the damage to
 539 vegetation induced by the typhoon, while FVC is more representative of vegetation coverage
 540 status (Wang and Xu, 2018; Jing et al., 2011). Consequently, the dramatic vegetation loss (<
 541 80%) that occurred in mostly wetland vegetation is detected mostly mainly in $NDVI_r$. In
 542 addition, moderate greenness loss has been identified in natural forests. Furthermore, the
 543 decrease of $NDVI_r$ values from higher classes to lower classes indicates that the typhoon has
 544 severely damaged the low-lying coastal regions and the wetland vegetation.
 545

546
547
548 Figure 9. Sentinel-2 MSI standard false color composite images before and after Typhoon
549 Soulik exhibit vegetation damage and the corresponding NDVI_t and Δ FVC (Sentinel-
550 2 MSI level 1C satellite images were downloaded from [https://scihub.
551 copernicus.eu/dhus/](https://scihub.copernicus.eu/dhus/)).
552

553 *4.1.2 Influence of topography on vegetation damage caused by Typhoon Soulik*

554 The affected area's topography can influence typhoons' impact on vegetation. The
555 interaction between topography and typhoon-generated wind and rain can result in complex
556 and varied patterns of damage across different landscapes (Abbas et al., 2020; Lu et al., 2020;
557 Zhang et al., 2013). This can affect the severity and spatial patterns of vegetation damage.
558 Therefore, the relationship between topography and damaged vegetation has also been
559 established in the present study. For this purpose, high-resolution (5m×5m) DEM data provided
560 by the NGII are used to calculate the region's topographic slope and explore the relationship
561 between topography and typhoon-induced vegetation damage.

562 The Mopko coastal region showed an elevation range between 0 to 403 meters, as
563 shown in Figure 1(b). It was observed that the number of trees damaged by Typhoon Soulik
564 decreased as the elevation increased, as illustrated in Figure 10a. The highest number of
565 damaged trees was observed in areas with an elevation of 50m or lower. This is likely due to
566 the fact that these areas are predominantly covered by wetlands, which can be more vulnerable

567 to strong winds associated with typhoons Soulik. In general, low-lying areas may not have the
 568 same natural windbreaks and barriers as higher elevations, which can exacerbate the impact of
 569 the wind. In addition, low-elevated vegetation may have shallower root systems due to the less
 570 stable soil conditions, making them more vulnerable to uprooting during heavy rainfall or
 571 strong winds (Zhang et al., 2013; Lugo et al., 1983). A significant difference in the number of
 572 decreased Δ NDVI and Δ FVC pixels was observed among different elevation ranges, and a
 573 correlation analysis between the number of damaged pixels and elevations showed a negative
 574 correlation (i.e., damaged pixels decreased with increasing elevation). The majority of
 575 damaged pixels (76.37%) were observed at elevations between 0 and 50m, with a decrease to
 576 13.5% between 51 and 100m. The vegetation exhibited a sharp decline at higher elevations, as
 577 shown in Figure 10(a), with the proportion of pixels displaying negative Δ NDVI and Δ FVC
 578 decreasing to 6.1% between 100 and 150m and decreasing to 0.02% between 350 and 403m.

579 On the other hand, Figure 10(b) illustrates the extent of damaged vegetation across
 580 different slope ranges. It has been noted that there is a negative correlation between the slope
 581 and the percentage of damaged vegetation pixels, indicating that the amount of vegetation
 582 damage decreases with a higher slope. For instance, when the slope was between 0-5°,
 583 approximately 47.63% of vegetation pixels were damaged. As the slope increased, the
 584 percentage of damaged vegetation pixels decreased accordingly, with values of 18.15%,
 585 15.01%, 10.71%, 7.74%, 0.73%, and 0.009% observed for slope ranges of 5-10°, 10-15°, 15-
 586 20°, 20-30°, 30-40°, and greater than 40°, respectively.

587

588

589 Figure 10. The relationship between topography and vegetation damaged due to typhoon
 590 Soulik: (a) numbers of damaged vegetation at different elevation ranges, and (b)
 591 numbers of damaged vegetation at different slope ranges.

606

To understand the coastal morphodynamics over the typhoon period (i.e., short-term), we classified the entire coastal region into four major coastal landform classes: land, wetland vegetation, wetland, and water (Fig. 11a-b). The accuracy and *kappa* coefficient of the classified maps exhibited a reasonable degree of consistency with the reference data, as illustrated in Table 5. The overall accuracy of the pre-and post-typhoon coastal landform maps was 86.5% and 84.3%, and *kappa* coefficients were 0.82 and 0.79, respectively. The results of the coastal landform classification showed a reduction in wetland vegetation over the typhoon period. Table 6 illustrates that before the typhoon, the area of the wetland vegetation class was 4.21% (77.63 km²) of the total area of all categories (1845.60 km²). However, after the hitting of the typhoon storm, the wetland vegetation area reduced to 1.08% (19.90 km²), recording a degradation of 57.73 km² (-74.37%).

Table 5. Accuracy assessment of pre-and post-typhoon classified coastal units.

Coastal Units	Description	Pre-typhoon		Post-typhoon

The most remarkable gain was the wetland class after the typhoon. This is shown by an increase of wetlands from 258.14 km² to 334.97 km², i.e., an increase of 29.76% (76.83 km²) during the analyzed period-short periods. Furthermore, the land class has increased by only 0.20% over the typhoon period, i.e., from 45.34% (before the typhoon) to 45.44% (after the typhoon). In addition, it has been noticed the waterbody decreased by 3.09% (20.78 km²) after the typhoon. Thus, it can be inferred that most wetland vegetation and waterbody have been converted into wetlands, which caused the coastal deterioration.

Table 6. Area changes of the different coastal unitunits during the pre--and post-typhoon periods in the Mokpo coast.

Coastal Units	Area at pre-typhoon	Area at post-typhoon	Changed area
---------------	---------------------	----------------------	--------------

	km ²	%	km ²	%	km ²	%

Thereafter, the coastal land transformation model was developed through mutual spatial replacements between coastal units. The land transformation model has identified the nine coastal-change units, as shown in Figure 11(c). The results show that the ~~low-land~~ lowland coastal area drastically changed after the typhoon, where the majority of coastal classes have been transformed into wetlands or mudflats. Furthermore, approximately 5.61% of the land area has been replaced by wetlands and water, whereas 83.79% of the wetland area has accreted over the wetland vegetation and water due to the impact of typhoon Soulik (Table 7).

636 4.3 Sediment resuspension during the pre-and post-typhoon period

637 The spatial distribution of relative suspended sediment concentration has been derived
638 through NDSSI for both before and after typhoon images (Fig. 12). Pre-typhoon SSC patterns
639 have been observed more SSC inside the creeks of the inner-shelf region of the Mokpo coast
640 as compared to the post-typhoon NDSSI image. However, it has been noted that the SSC has
641 significantly increased along the entire coast in the post-typhoon period (Fig. 12b). Therefore,
642 the spatial changes of relative SSC have been determined during the August (pre) and October
643 (post) periods, as depicted in Figure 12(c). In general, a flood always transports many
644 suspended materials and concentrates those materials on the upper surface of the water. After
645 the strong events, the flood-transported suspended material is deposited across the delta. A
646 similar phenomenon was observed in the post-typhoon period due to extensive rainfall, which
647 turned into a coastal flood.

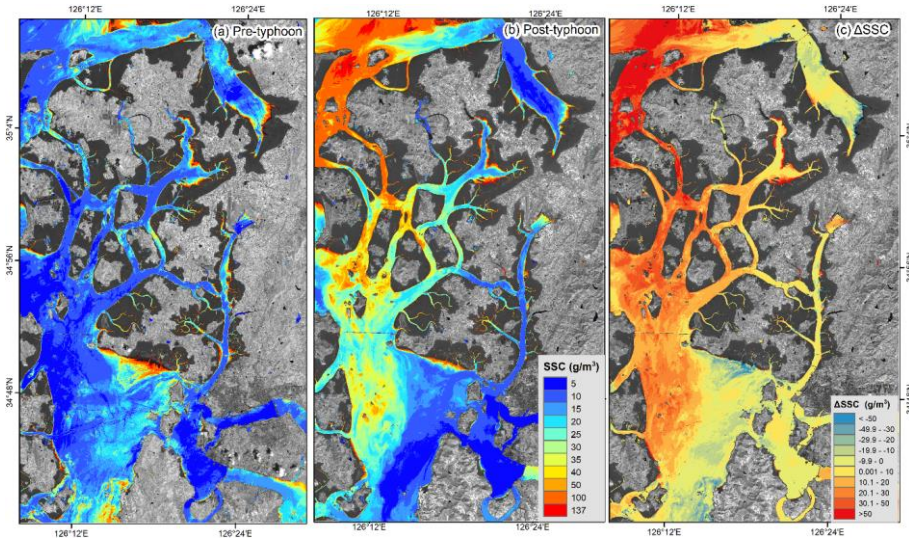

648 On the other hand, it has been observed that the SSC gradually increased as the wind
649 speed increased from the pre to post-typhoon period. The increasing SSC amplitudes indicate
650 the rapid sediment erosion/resuspension over the storm passage. Furthermore, the amplitudes
651 of SSC variations were more visible in shallower water than in deeper water. The effect of
652 typhoons on the SSC variation along the Mokpo coast has been observed through Δ NDSSI
653 distribution (Fig. 12c). The negative Δ NDSSI values represent the increase of SSC due to
654 typhoon-induced strong wind and coastal flooding.

655
 656 Figure 12. Relative SSC for (a) pre-typhoon and (b) post-typhoon period, while (c) represents
 657 the changes in the NDSSI.
 658

659 Furthermore, a quantitative analysis of SSC has been performed based on the algorithm
 660 developed by Choi et al. (2014). During the pre-typhoon period, the SSC in the near shore
 661 waters was significantly higher than that of the offshore region (Fig. 13a). The post-typhoon
 662 image shows a sharp increase in the SSC distribution, indicating that Typhoon Soulik
 663 significantly impacted the SSC variation, with a maximum of $>50 \text{ g/m}^3$ (Fig. 13c). In Figures
 664 13(a) and (b), the spring-neap tidal influence broadly regulated the distribution and change of
 665 SSC throughout the shallow coastal water. The resuspension of SSC has been observed in the
 666 entire study region during the passage of Soulik. The pattern of relative SSC distribution (Fig.
 667 12c) and the empirically derived SSC distribution (Fig. 13c) of pre-and post-typhoon are
 668 similar.

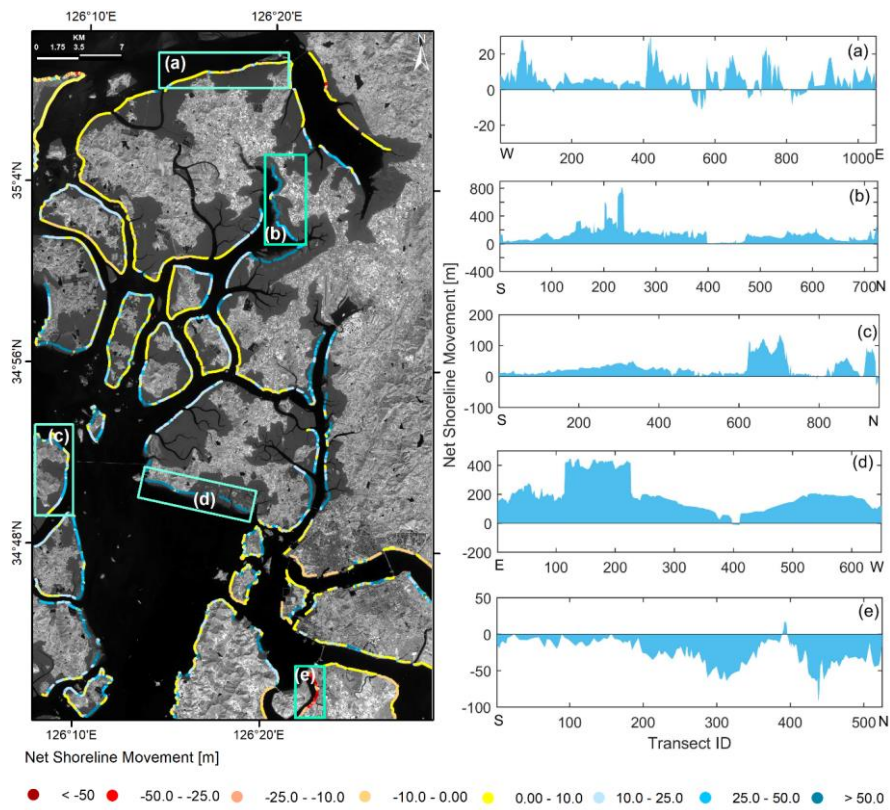

669 The outcomes showed that the storm surge and strong waves have considerably aided
 670 the sediment resuspension. Thus, the storm waves played an essential role in increasing bottom
 671 stress and stirring the seabed sediment (Gong and Shen, 2009). The transport of sediment
 672 during the storm adds another mechanism to the long-term morphological evolution of the
 673 Mokpo coast. This research revealed the profound significance of typhoons on inner shelf
 674 sedimentation along the coast.

675
 676 Figure 13. The simulated SSC distribution for the surface water of (a) pre-typhoon, (b) post-
 677 typhoon period, and (c) represents the spatial changes of SSC from pre- to post-
 678 typhoon.
 679

680 4.4 Impact on coastal erosion and deposition

681 The impacts of the severe typhoon storm Soulik at a speed of 62 m/s on the coastline
 682 of Mokpo have been determined using the NSM method, considering 38313 transects (10m
 683 transect intervals) along the shoreline. Figure 14 shows the shoreline alteration in the entire
 684 Mokpo coastal region from the pre- to post-typhoon period; (i.e., short-term), with an accretion
 685 of 87.5% transects and erosion of 12.5%. The mean deposition of 28.89m and a mean erosion
 686 of -8.29m were recorded (Table 8). The shoreline movement between 0-10m was recorded in
 687 the northern part of the coastal region. It has been observed that most transects experienced
 688 significant accretion; however, erosion has been observed in a few transects along the southern
 689 coastline (Fig. 14). The southern coast experienced sporadic landward movement of the
 690 shoreline. In contrast, the rest of the study region experienced significant seaward shoreline
 691 movement (Fig. 14 a-e).

692
 693 Figure 14. Land Short-term land water boundary change from the changes (pre-typhoon period
 694 to the post-typhoon period) based on the NSM method (left panel). Subplots (a-e)
 695 show the net movement of the shoreline at different sites.

The wind generated surface water currents that transported and dispersed erogenous material to deep seas areas from pre- to post-typhoon. On the other hand, the coastal flooding induced by the typhoon storm increased the sediment from the land to the near-shore region (Figs. 12c & 13c). This allowed sediment to deposit on the wetland or beach areas. The coastal land transformation map also revealed changes in shoreline shift-area as the wetland accreted class.

The net surface area changes along the coastal region have been estimated and are depicted in Figure 15. The total beach area increases and losses throughout the typhoon period were 16.23 km² and 1.1 km², respectively (Fig. 15f). It was observed that typhoon Soulik ~~has~~ drastically increased the wetland (mudflat). These observations were also supported by other proxies, as discussed above.

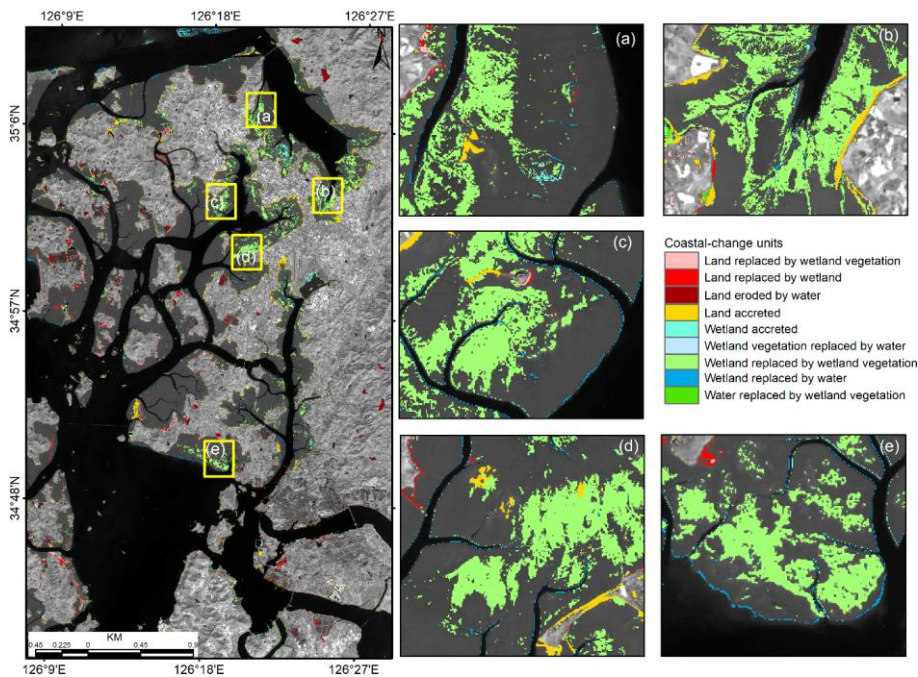

712
 713 Figure 15. NetShort-term net surface area changes (i.e., erosion and accretion) due to typhoon
 714 Soulik along the Mokpo coast. Subplots (a-d) show extensive accretion, while
 715 erosion is shown in plot (e). The bar graph (f) represents the area changes from the
 716 pre to post-typhoon period.
 717

718 4.5 Coastal recovery status after typhoon Soulik

719 The recovery status, i.e., medium-term coastal changes of the Mopko coastal region
 720 after typhoon Soulik has been analyzed using the NSM and coastal landform change model.
 721 For this purpose, another Sentinel-2 MSI level 1C satellite image was downloaded for October
 722 2019 (one year after the typhoon), as listed in Table 1. After that, the coastal landform change
 723 model and NSM were performed based on the Sentinel-2 MSI images of October 2018 and
 724 2019 (both images taken during the post-typhoon period) to understand the recovery status of
 725 the coastal morphometry. The coastal landform change model exhibits that the wetland
 726 vegetation increased drastically after one year of typhoon Soulik, as depicted in Figure 16.

727 Table 9 indicates that approximately 16.52% of the land area has accreted over the wetland and
 728 water, whereas 39.71% of the wetland vegetation area has accreted over the wetland and water
 729 after the typhoon. Further, the outcome of the coastal recovery status was visually compared
 730 with the high-resolution aerial imagery obtained from the National Land Information Platform
 731 website (<https://map.ngii.go.kr/>) and showed strong agreement. Thus, the coastal landform
 732 change model successfully determined the longer-term recovery status in the topography and
 733 landforms of the Mokpo coastal area after the typhoon.

734
 735
 736 Figure 16. Recovery status of different coastal landforms after typhoon Soulik of Mokpo
 737 coastal region, whereas zoom boxes (a-e) show the increase of wetland vegetation at
 738 various sites.
 739

740 Table 9. The details of medium-term coastal land transformation classes identify during the
 741 post-typhoon period.

Coastal land transformation	Area (km ²)	%
Land replaced by wetland vegetation	4.06	6.67
Land replaced by wetland	4.59	7.54
Land eroded by water	7.23	11.88
Land accreted	10.05	16.52
Wetland accreted	2.82	4.64

Wetland vegetation replaced by water	2.12	3.48
Wetland replaced by wetland vegetation	24.17	39.71
Wetland replaced by water	4.41	7.25
Water replaced by wetland vegetation	1.41	2.32

742
743 On the other hand, the ~~short~~medium-term effects of a typhoon on the shoreline have
744 also been determined based on the NSM model. The results exhibit the extensive shoreline
745 alteration in the entire Mokpo coastal region after one year of typhoon Soulik, with an accretion
746 of 48.03% transects and erosion of 51.97%. The NSM statistics showed an average shoreline
747 movement of -1.08m, with a recorded mean erosion of -9.25 and deposition of 7.75m (Table
748 10). The overall erosion was recorded in response to typhoon Soulik even after one year along
749 the Mokpo coastal region. This is due to the extensive damage to wetland vegetation during
750 the typhoon period (Table 7). In addition, it was observed that the wetland experience accretion
751 during the typhoon period, but it made the coastline vulnerable to erosion in the near future.
752 The natural native vegetation and wetland vegetation play a critical role in the shoreline
753 stability of the coastal region due to its anti-erosive nature. This phenomenon was evident in
754 the NSM statistics obtained during the post-typhoon period. Therefore, the use of these models
755 can help predict how the shoreline and adjacent coastal landforms will respond to typhoons,
756 identify vulnerable areas, and inform recovery efforts. This can enhance the area's resilience to
757 natural disasters and reduce the risk of future erosion and other environmental problems.

760
761
762 **5. Conclusion**

763 The objectives of this study were to assess the impact of typhoon Soulik on the coastal ecology,
764 landform, erosion/accretion, suspended sediment movement and associated coastal changes

765 along the Mokpo coast. This research developed an integrated approach for identifying coastal
766 dynamics impacted by typhoons and determining damage severity. The coastline movement,
767 coastal morphodynamics and quantified severity of vegetation damage from the pre- to post-
768 typhoon period have been determined based on the Sentinel-2 MSI images. NDVI and FVC
769 have been used to assess the severity of damage caused by typhoon Soulik on the vegetation.
770 The results showed that about 493.9 km² (26.7%) of vegetation had been affected in the Mokpo
771 coastal region. Further, it was observed that 6.1% (112.4 km²) of vegetated areas in low coastal
772 land were severely damaged. The land transformation model exhibited that the 'wetland'
773 replaced most of the 'wetland-vegetated land' in the post-typhoon period. Also, it has been
774 found that more aggregated vegetation regions were less susceptible to damage.

775 The SSC of the Mokpo coastal region is higher in the post-typhoon period compared to
776 pre-typhoon time. The SSC variation influenced the coastal accretion and changed the deltaic
777 islands. The NDSSI and empirical-based SSC distribution of pre- and post-typhoon images
778 exhibit sedimentation drastically increased after the typhoon. The land accretion process also
779 dominated during the pre- to post-typhoon period. The wetlands and water have replaced
780 approximately 9.77% of the land area. On the other hand, 65.52% of the wetland area has
781 accreted over the wetland vegetation and water. Shoreline change analysis is also performed to
782 understand erosion and accretion in coastal regions. Typhoon Soulik accelerated shoreline
783 movement, affecting the local environmental condition, biodiversity imbalance, and aerial
784 change. In addition, 87.35% of shoreline transects experienced seaward migration over the
785 typhoon period. The wetland experience accretion in a shorter period, but it makes the coastline
786 vulnerable to erosion in the near future because the natural native vegetation and wetland
787 vegetation are crucial factors in shoreline stability of the coastal region due to its anti-erosive
788 nature. This phenomenon was evident in the NSM and coastal landforms change model
789 obtained ~~during the post-typhoon period in the medium-term analysis. However, more high-~~
790 ~~resolution, cloud-free multi-temporal images and in-situ observations are required to better~~
791 ~~understand the medium to long-term typhoon-induced morphodynamics of the coastal region.~~

792 It can be concluded that the Mokpo coastal ecosystem has been devastated by this extreme
793 event. Although the observed changes are not alarming, shoreline protection measures still
794 need to be addressed, especially the reforestation in wetland or mudflat regions. The outputs
795 of the present study are needed to better understand the sediment transport process and estuary
796 changes during the pre-and post-typhoon period. It can also be used to develop appropriate
797 strategies to protect natural ecosystems and post-disaster rehabilitation.
