9 **Abstract**

10 The lightning location system consisting of multiple ground-based stations is an
11 effective means of lightning observation. The dataset from CNLDN (China National
12 Lightning Detection Network) in 2016-2022 is employed to analyze the temporal and
13 spatial lightning distributions and the differences between +CG (positive cloud-to-
14 ground lightning) and -CG (negative cloud-to-ground lightning) stroke in China. On
15 the annual scale, lightning activity is most prevalent during the summer months (June,
16 July, and August), accounting for 72.6 % of the year. Spring sees more lightning than
17 autumn, and winter has only a small amount in southeastern coastal areas. During the
18 day, the frequency of lightning peaks at 15:00-17:00 CST (China Standard Time) and
19 is lowest at 8:00-10:00 CST. For the period with high CG stroke frequency (summer of
20 a year or afternoon of a day), the proportion of +CG stroke and the discharge peak
21 current is relatively small. Winter in a year and morning or midnight in a day
22 corresponds to a greater +CG stroke proportion and discharge current. Spatially, low
23 latitude, undulating terrain, seaside, and humid surface are favorable factors for
24 lightning occurrence. Thus, the southeast coastland has the largest lightning stroke
25 density, while the northwest deserts and basins and the western and northern Tibetan
26 Plateau, with altitudes over 6000 meters, have almost no lightning. The proportion of
27 +CG stroke and the peak current are low in the southern region with high density but
28 diverse in other regions. The Tibetan Plateau leads to the diversity of lightning activity
29 in China and lays the foundation for studying the impact of surface elevation on
30 lightning. Results indicate that the +CG stroke proportion on the eastern and southern
31 Tibetan Plateau is up to 15 %, larger than the plain regions. The peak current of -CG
32 stroke is positively correlated with altitude, but +CG stroke shows a negative
33 correlation, resulting in a large difference in peak current between +CG and -CG on the
34 plain and approach on the plateau.

36 1. Introduction

37 Most lightning is generated mainly through mesoscale or small scale severe
38 convective weather, with occasionally occurring in tropical cyclones, volcanic
39 eruptions, and dust storms (Rakov and Uman, 2003). Lightning, a violent long-distance
40 transient discharge phenomenon, could cause severe disasters such as human and
41 animal casualties, forest fires, and electronic and communication equipment
42 interruptions. Lightning is also associated with extreme weather events such as heavy
43 rainfall, hail, and strong winds. These events can cause damage to infrastructure, crops
44 and property, and pose a threat to public safety. Therefore, the timely and accurate
45 monitoring of lightning serves as an effective approach for the development of lightning
46 science and scientifically mitigating the hazards of lightning strikes.

47 Lightning discharge emits electromagnetic spectrums with a broad range,
48 providing an essential avenue for lightning detection. The very low frequency / low
49 frequency (VLF/LF, 20-300 kHz) band radiation is mainly produced by the cloud-to-
50 ground lightning (CG) return strokes, intracloud (IC) K-changes, and other discharge
51 processes with a large spatial scale (Preston and Tolver, 1989; Schulz et al., 2016;
52 Cummins et al., 1998). VLF/LF electromagnetic waves can propagate along the ground
53 surface or be reflected between the surface and ionosphere propagation, with the
54 superiority of long propagation distance (hundreds to thousands of kilometers) and slow
55 attenuation. This frequency range thus is suitable for large-scale lightning detection and
56 is currently the most commonly used target detection band for ground-based lightning
57 location systems (Wang et al., 2020).

58 Representative examples of modern lightning location systems working in
59 VLF/LF band are mainly the U.S. National Lightning Detection Network (NLDN)
60 (Rudlosky and Fuelberg, 2010), Los Alamos Sferic Array (LASA) (Shao et al., 2006),
61 European Cooperation for Lightning Detection (EUCLID) (Schulz et al., 2016),
62 Vaisala's Global Lightning Dataset (GLD360) (Said et al., 2013), World Wide
63 Lightning Location Network (WWLLN) (Rudlosky and Shea, 2013), etc. The three
64 nationwide detection networks in China are China National Lightning Detection
65 Network (CNLDN), operated by the Meteorological Observation Centre of China
66 Meteorological Administration (CMA), the Lightning Location System (LLS) of the
67 State Grid Corporation of China, and the Three-Dimensional Lightning Location
68 System (3D-LLS) deployed by the Institute of Electrical Engineering of Chinese
69 Academy of Sciences (CAS). There are also small-scale and refined detection systems
70 in local China areas, such as the Beijing Lightning Network (BLNET) established by
71 the Institute of Atmospheric Physics of CAS, the Guangdong-Hongkong-Macao
72 Lightning Location System (GHMLLS) deployed by the meteorological departments
73 of Guangdong Province, Hongkong, and Macao.

74 China spans a wide range of latitudes from north to south, and significant terrain

75 changes from east to west. The western and northern parts of the Tibetan Plateau have
76 large uninhabited areas with altitudes above 6000 m. The above factors pose challenges
77 for the installation of lightning detectors and the improvement of the accuracy of
78 locating algorithms. Currently, most of the analyses of lightning characteristics in China
79 are based on lightning imagers on satellites and the World-Wide Lightning Location
80 Network (WWLLN) (Ma et al., 2005; You et al., 2019; Ma et al., 2021). However, the
81 Optical Transient Detector (OTD) on Microlab-1 and Lightning Imaging Sensor (LIS)
82 on TRMM (Tropical Rainfall Measuring Mission) satellite discontinued updates, and
83 the Chinese Lightning Mapping Imager (LMI) on FY-4A is not oriented to the China
84 area all year round. Meanwhile, the detection efficiency of the satellite sensor and
85 WWLLN is relatively low and not valuable for analyzing the difference between
86 positive cloud-to-ground lightning (+CG) and negative cloud-to-ground lightning (-
87 CG). CNLDN is nowadays the most widely used system by the meteorological
88 departments in China and has accumulated observational data for many years. Currently,
89 there has been no study evaluating the detection performance of CNLDN on a national
90 scale. Based on some localized assessments, the detection efficiency for lightning flash
91 and stroke in Beijing was reported to be 49.4 % and 36.5 % (Srivastava et al., 2017). In
92 Jiangsu, the detection efficiency for lightning flash was documented as 61.4 % (Min-
93 Xue et al., 2015). In our previous study, we calculated the lightning density in the
94 vicinity of the Canton Tower in Guangdong using optical observation by the Tall-Object
95 Lightning Observatory in Guangzhou (TOLOG), which is currently regarded as a
96 nearly no-miss observation (Wu et al., 2019; Jiang, 2021). The result was that the CG
97 flash density was $20 \text{ km}^{-2}\cdot\text{yr}^{-1}$ within a 3 km radius of the Canton Tower. The detection
98 efficiency of lightning flash for CNLDN was correspondingly only 33.7 % in the same
99 region. Despite the relatively lower detection efficiency of CNLDN compared to other
100 advanced international systems, it still holds significant importance in analyzing the
101 lightning characteristics in nationwide China.

102 This study makes use of CNLDN data from 2016-2022 to analyze the lightning
103 climate over China by dividing the continental region into four blocks. We also focus
104 on comparing the differences between +CG and -CG stroke regarding temporal and
105 spatial distribution. Furthermore, China's extensive geographical expanse, spanning a
106 wide range of latitudes and longitudes, coupled with its intricate topography, provides
107 a unique opportunity for investigating the correlation between lightning occurrences
108 and geographic factors.

109 2. Data source

110 CNLDN was initially developed in 2007 by the National Space Science Center
111 (NSSC) of CAS and is now operated by the Meteorological Observation Centre of
112 CMA. It carries out the monitoring and early warning of strong convective weather in
113 thunderstorms. The CNLDN system comprised 435 sub-stations (as of 2020), each
114 equipped with a lightning detector, and a central data processing station located at the

115 National Meteorological Information Center. The baseline distance typically ranges
116 from tens to hundreds of kilometers. Although with some blind areas in the desert
117 regions of Xinjiang and the uninhabited high-altitude areas of Tibet, CNLND can
118 generally achieve nationwide lightning detection. The distribution of sub-stations is
119 illustrated in Fig. 1.

120 The network uses a time-of-arrival (TOA) technique, with a GPS timing error of
121 fewer than 20 ns (in clear sky conditions), to detect VLF/LF pulses of CG return strokes.
122 A lightning flash may consist of several CG strokes, and the stroke locations within
123 each flash always do not overlap, causing striking disasters in different areas. In this
124 study, we analyze lightning stroke characteristics in inland China using the CNLND
125 dataset from 2016-2022, downloaded from the CMA big data cloud platform. For each
126 stroke, we can obtain information on the time of occurrence, latitude, longitude, peak
127 current value, and the number of reporting sensors.

128
129 **Fig. 1. CNLND sites distribution and altitude distribution map of China with labeled names of each**
130 **province and municipality. The alphabetical labels (a, b, c, d, etc.) in the figure indicate the positions of the**
131 **mentioned locations referred to in the text.**

132 3. CG characteristics in China

133 China's climate features are greatly influenced by its wide latitudinal span,
134 significant terrain disparity, complex topography, and ocean currents (Ren et al., 2012).

135 Lightning is a fundamental meteorological element, and its long-term accumulation
 136 characteristics are closely linked to China's climate. The spatial distribution of lightning
 137 in China is determined by a combination of factors, including atmospheric circulation,
 138 topography, distance from the sea, latitude, etc.

139 3.1 CG stroke distribution in China

140 Previous studies have often divided China into four major geographical regions,
 141 each with relatively uniform climatic characteristics. These regions are Southern China
 142 (Region-I), Northern China (Region-II), Northwestern China (Region-III), and the
 143 Qinghai-Tibet region of China (Region-IV), as illustrated in Fig. 2. The Qinling
 144 Mountains (a) - Huaihe River (b) line, which roughly coincides with the 0 °C isotherm
 145 and 800 mm annual precipitation line in January, serves as the boundary between
 146 Region-I and Region-II. The Daxing'an Mountains (c) - Yinshan Mountains (d) - Helan
 147 Mountains (e), which divide the monsoon and non-monsoon regions and the 400 mm
 148 annual precipitation line, serve as the boundaries between Region-II and Region-III.
 149 The boundary between Region-IV and Regions I-II-III is approximately the line
 150 between China's first and second steps in terrain.

151 **Tab. 1 Statistics on the annual average numbers of return strokes, the stroke densities, and the peak current**
 152 **values of the four regions**

	Region-I	Region-II	Region-III	Region-IV
-CG stroke number ($10^3 \cdot \text{yr}^{-1}$)	3653	499	127	129
+CG stroke number ($10^3 \cdot \text{yr}^{-1}$)	388	151	37	18
stroke number ($10^3 \cdot \text{yr}^{-1}$)	4041	650	166	147
Mean stroke density ($\text{km}^{-2} \cdot \text{yr}^{-1}$)	1.68	0.34	0.05	0.07
Mean peak current of -CG (-kA)	-41	-39	-37	-45
Mean peak current of +CG (kA)	47	54	65	66

153 The statistical results of the annual average number of -CG return stroke, +CG
 154 return stroke, all types of stroke, as well as the mean stroke density of four regions are
 155 shown in Tab. 1. The data indicates a sequential decrease in lightning activity across
 156 the four regions. Fig. 2 displays the distribution of annual average CG stroke density
 157 from 2016-2022. When calculating lightning density, it is necessary to determine the
 158 size of grid cells. According to the research of Diendorfer (2008), lightning is a highly
 159 stochastic phenomenon, and if we require an uncertainty of less than $\pm 20\%$ per grid
 160 cell, there should be more than 80 events in it. Therefore, we establish the grid size as
 161 $0.25^\circ \times 0.25^\circ$, ensuring that the results are within the confidence interval for almost all
 162 regions, except part of areas in Xinjiang and Tibet. Lightning primarily occurs in
 163 convective precipitation and, to a lesser extent, in stratus cloud precipitation. Generally,
 164 the spatial distribution of lightning stroke in Fig. 2 is consistent with the distribution of
 165 annual average precipitation in China, as illustrated in Fig. 3 in Jin et al. (2021).

166 Region-I has the highest concentration of CG stroke, with an average density of
 167 $1.68 \text{ km}^{-2} \cdot \text{yr}^{-1}$. The leap line of lightning density corresponds well with the 0 °C

168 isotherms in January, the 800 mm annual equivalent precipitation line, and the eastern
 169 dividing line of the first and second terrain steps. The climate in Region-I is mainly
 170 influenced by the tropical/subtropical monsoon. The southeast monsoon from the
 171 Pacific Ocean and the southwest monsoon from the Indian Ocean make the summer hot
 172 and humid and prone to thunderstorms. In particular, the monsoon influence is more
 173 pronounced in coastal areas with abundant water vapor and thermal conditions. In the
 174 mountainous regions of Hainan, Guangdong, Fujian, and Zhejiang, where the rolling
 175 topography lifts the warm and humid air masses, thunderstorm activity is most frequent,
 176 resulting in high lightning density. Although the Sichuan Basin and Yunnan are far from
 177 the coastline, they are located at the eastern and southern windward slopes of the
 178 Tibetan Plateau, which benefits the generation of thunderstorm activities due to the
 179 topographic uplift. The distribution in Region-I is similar with the observation results
 180 by Xia et al. (2015).

181
 182 **Fig. 2. 2016-2022 annual average CG stroke density distribution in China. Region-I: Southern China;**
 183 **Region-II: Northern China; Region-III: Northwestern China; Region-IV: Qinghai-Tibet region of China.**
 184 **The grid size is 0.25° × 0.25°.**

185 Region-II has a temperate monsoon climate, with summer influenced by the
 186 southeast monsoon carrying temperate marine air mass or degenerative tropical marine
 187 air mass, making summer warm and rainy. Most areas have CG stroke density between
 188 0.1-1 km⁻²·yr⁻¹, slightly lower than Region-I. The lightning activity in Region-II is also

189 greater in the seaside area than inland areas. Shanxi is located in a mountainous region,
190 and the undulating terrain makes it a high incidence area for thunderstorm activity.
191 Region-II has the most extensive plain, Northeastern China Plain (f), surrounded by the
192 Daxing'an Mountains (c) - Xiaoxing'an Mountains (g) - Changbai Mountains (h). The
193 landform is conducive to the southeast monsoon reaching the inland areas of Region-II
194 and forming summer thunderstorms. Jilin is only a dozen kilometers from the Sea of
195 Japan, facilitating the entry of Japanese warm air currents. Therefore, despite its high
196 latitude, thunderstorm activity is relatively intense in Region-II.

197 Region-III, which includes Xinjiang, northern Gansu, and most land of Inner
198 Mongolia, has a temperate continental climate. There are significant differences in
199 lightning distribution characteristics within this region. The southern and central parts
200 of Region-III consist primarily of vast deserts and gobies. The Tibetan Plateau blocks
201 the humid South Asian monsoon, and its arid surface cannot produce abundant water
202 vapor, resulting in few thunderstorms. However, the Tianshan Mountains (i), Kunlun
203 Mountains (j), and Altay Mountains (k), located in the hinterland of the Eurasian
204 continent, are provided with water vapor for thunderstorm generation through the
205 westerly circulation that transports evaporated water vapor from the Atlantic Ocean and
206 the Eurasian continent. As a result, the northern mountainous areas occupy almost all
207 the lightning activity in Xinjiang. The southeastern monsoon flowing through Region-
208 II can also bring some thunderstorm processes to the eastern and central mountainous
209 regions in Inner Mongolia during summer.

210 Region-IV's primary landmass is the Tibetan Plateau, which includes Tibet,
211 Qinghai, southern Xinjiang, and western Sichuan. It has a highland mountain climate,
212 and the overall geomorphic distribution trend increases from east to west (Ma et al.,
213 2021). The uninhabited areas above 4500 meters in elevation in the west and north of
214 Region-IV are icy all year round, covered by snow and glaciers. The Qaidam Basin (l)
215 in Qinghai is a closed, huge, interrupted basin, where dry sinking airflow from the
216 northern edge of the plateau in summer leads to water shortage. Consequently, there are
217 few thunderstorm activities in these areas, and the distribution of sub-stations is sparse,
218 making them the regions with the lowest lightning density detected in China, with CG
219 stroke density less than $10^{-3} \text{ km}^{-2} \cdot \text{yr}^{-1}$. In contrast, the southern Himalayas Mountains
220 (m), near the Yarlung Tsangpo River Grand Canyon (n), have a relatively low altitude,
221 opening a "gap" for the influx of abundant water vapor from the Bay of Bengal.
222 However, this narrow plain area, located in Mêdog County (o), has very high
223 precipitation but low lightning density, which can also be concluded from the
224 observations of TRMM. The remaining moisture continues northward across this plain,
225 causing most thunderstorms between the east-west Himalayas Mountains and Tanggula
226 Mountains (p). The thunderstorms on the east side of the plateau are mainly influenced
227 by the low vortex and the shear line, which is usually stable at around 32.5°N (You et
228 al., 2019; Qie et al., 2003). The high lightning density area is precisely located on the
229 south side of the shear line.

230 3.2 Differences between +CG and -CG stroke

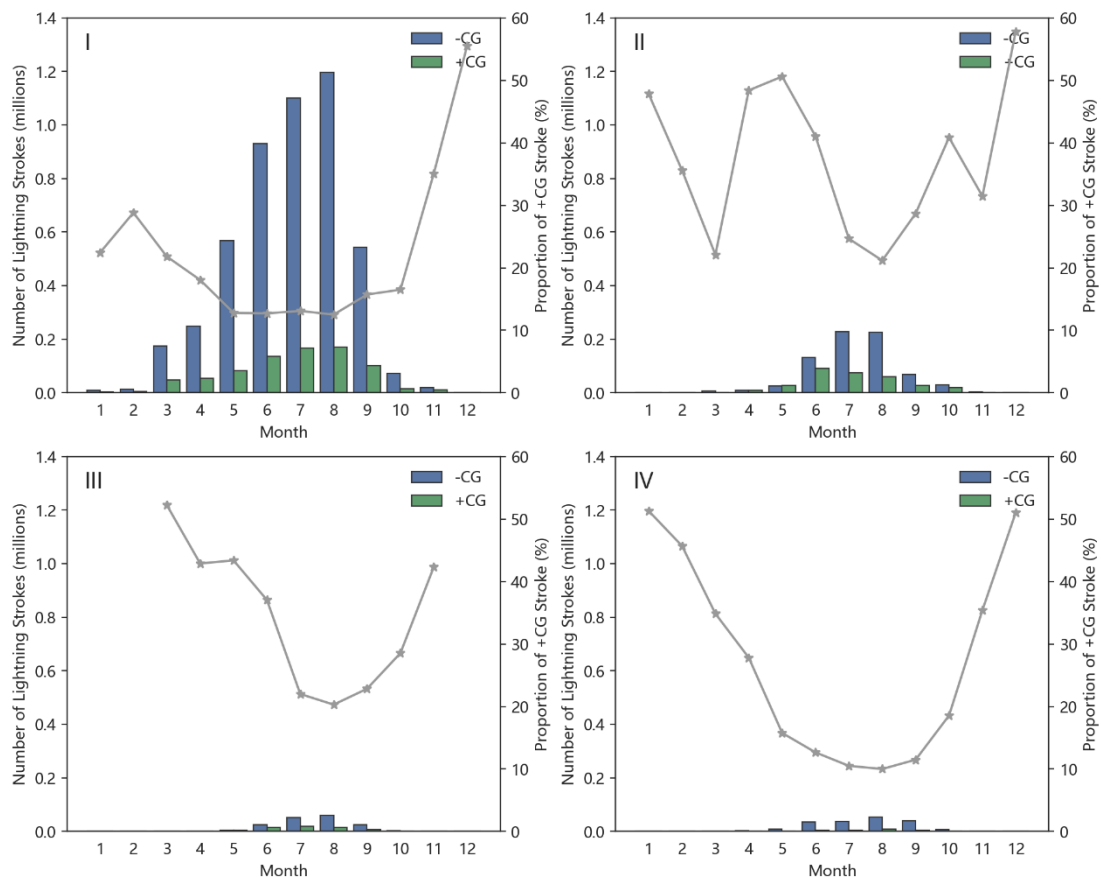

231 Based on the different polarities of neutralized charges in thunderclouds, CG can
232 be classified into two types: +CG and -CG. Generally, +CG has a lower occurrence
233 probability, accounting for only about 10 % of all CG, but it is characterized by a larger
234 charge transfer, which results in a more significant hazard (Preston and Tolver, 1989;
235 Carey and Buffalo, 2007). Studies have suggested that thunderstorms dominated by
236 +CG are more likely to result in tornadoes and hail, particularly if the dominant phase
237 lasts for tens of minutes. This may be related to changes in the charge distribution
238 structure within thunderstorm clouds during extreme weather events (Williams, 1985).
239 Previous research has been conducted on the comparative analysis of +CG and -CG in
240 specific regions (Nag et al., 2014; Rakov and Uman, 2003). Based on these findings,
241 this study aims to investigate further the spatial and temporal variability of +CG and -
242 CG stroke in China, taking into account the complex climatic and geographical factors
243 that influence lightning activity.

244 3.2.1 Comparison of temporal distribution of +CG and -CG stroke

245 The geographical and climatic features differ considerably across the four regions.
246 Therefore, we analyze the temporal distribution of lightning stroke separately for each
247 region.

248 Fig. 3 illustrates the monthly average CG stroke frequency distribution in China
249 over a seven-year period from 2016 to 2022. The stroke frequency varies significantly
250 across the four regions, with Region-I having the highest frequency, followed by
251 Region-II and Region-III, and Region-IV having the lowest. But the stroke frequency
252 shows similar fluctuations throughout the year among the regions, with August having
253 the highest frequency and December having the lowest. Lightning activity is also scarce
254 in November, January, and February, with a sudden surge in March and a gradual
255 increase in the following months. Based on the seasonal classification, lightning
256 activity is most active in summer (June, July, and August), accounting for 72.6 % of the
257 year. In other seasons, lightning is more frequent in spring (18.4 %) than in autumn
258 (8.6 %), but much less frequent than in summer. This is mainly because the summer
259 monsoon affecting China starts to form during April and May, while the cold and dry
260 winter monsoon starts to build up and push southward from September, making
261 thunderstorm activity in spring and autumn mainly concentrated in southern areas,
262 particularly coastal areas. In winter, most regions in China are controlled primarily by
263 cold high pressure, resulting in very little lightning, with only a small amount occurring
264 in southeastern coastal areas, accounting for just 0.4 % of the year. Overall, lightning
265 stroke distribution follows a seasonal trend that advances from south to north and then
266 retreats southward, which is consistent with the trend of the summer monsoon. The
267 above proportions of four seasons closely resemble the statistical results conducted in
268 the US by Holle and Cummins (2010).

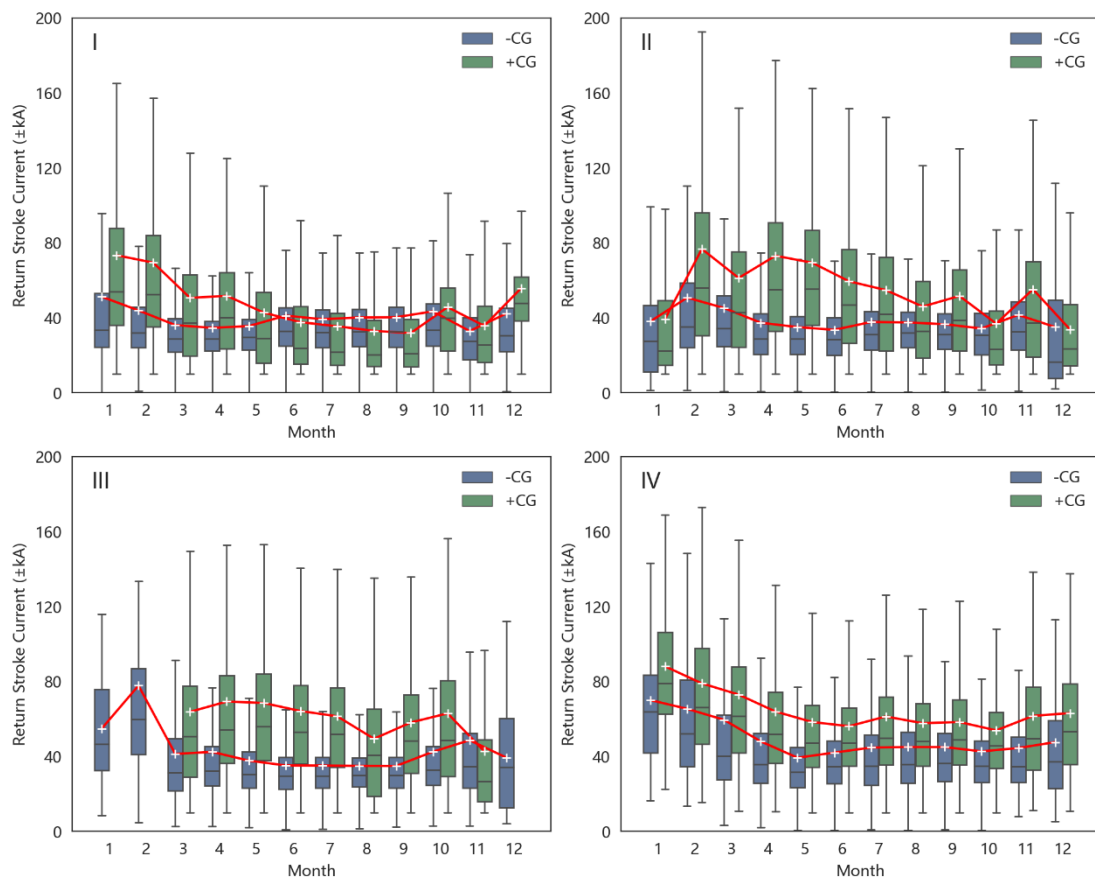

269 Furthermore, the proportion of +CG stroke in different months is calculated and
 270 represented by the gray line in Fig. 3. To ensure the reliability of the analysis, months
 271 with less than 50 +CG strokes are excluded to avoid the impact of outliers. Results
 272 indicate an evident inverse relationship between the proportion of +CG stroke and the
 273 frequency of stroke. Notably, the months with the highest incidence of CG stroke,
 274 namely July and August, exhibit the lowest proportion of +CG stroke across the four
 275 regions. During this period, Region-I and Region-IV, located at lower latitudes, exhibit
 276 a proportion of +CG stroke of approximately 10 %, while Region-II and Region-III
 277 display proportions between 10 % and 30 %. Winter in four regions have rare
 278 thunderstorms but demonstrates the highest proportion of +CG stroke, even reaching
 279 over 50 % in December in Region-I, Region-II and Region-IV. In other months, some
 280 irregular fluctuations are observed, Region-I and Region-II show significantly high
 281 proportions of +CG stroke in February and April-May, respectively.

282
 283 **Fig. 3. Annual scale variation of the frequency distribution of +CG and -CG stroke. The gray line**
 284 **represents the proportion of +CG stroke.**

285 Tab. 1 also displays the mean peak current values of two types of CG stroke in the
 286 four regions. The results reveal that the +CG stroke current in Region-III and Region-
 287 IV exhibits a notably higher magnitude compared to other two regions, and the disparity
 288 between +CG and -CG is more pronounced. While the average peak current values of
 289 both types are found to be in close proximity in Region-I. The value fluctuation in
 290 different months is illustrated in Fig. 4. To avoid outliers, no box is drawn when the

291 stroke count is less than 50. Overall, the distribution range is wider in winter than in
 292 other seasons, and Region-II has a wider current distribution interval than other regions.
 293 The average peak current value of each month is indicated by a white cross, and the
 294 variation trend is shown by a red line. The results indicate that +CG strokes generally
 295 have a higher peak current than -CG strokes. The peak current and the proportion of
 296 +CG stroke exhibit similar trends, with a higher proportion and stronger peak current
 297 in winter and a lower proportion and weaker peak current in summer. In Region-I and
 298 Region-II, the seasonal fluctuations of +CG peak current are more pronounced than -
 299 CG peak current, with the peak current of +CG stroke falling even below -CG stroke
 300 in summer and early autumn in Region-I. The trends of +CG and -CG stroke peak current
 301 are more consistent in Region-III and Region-IV.

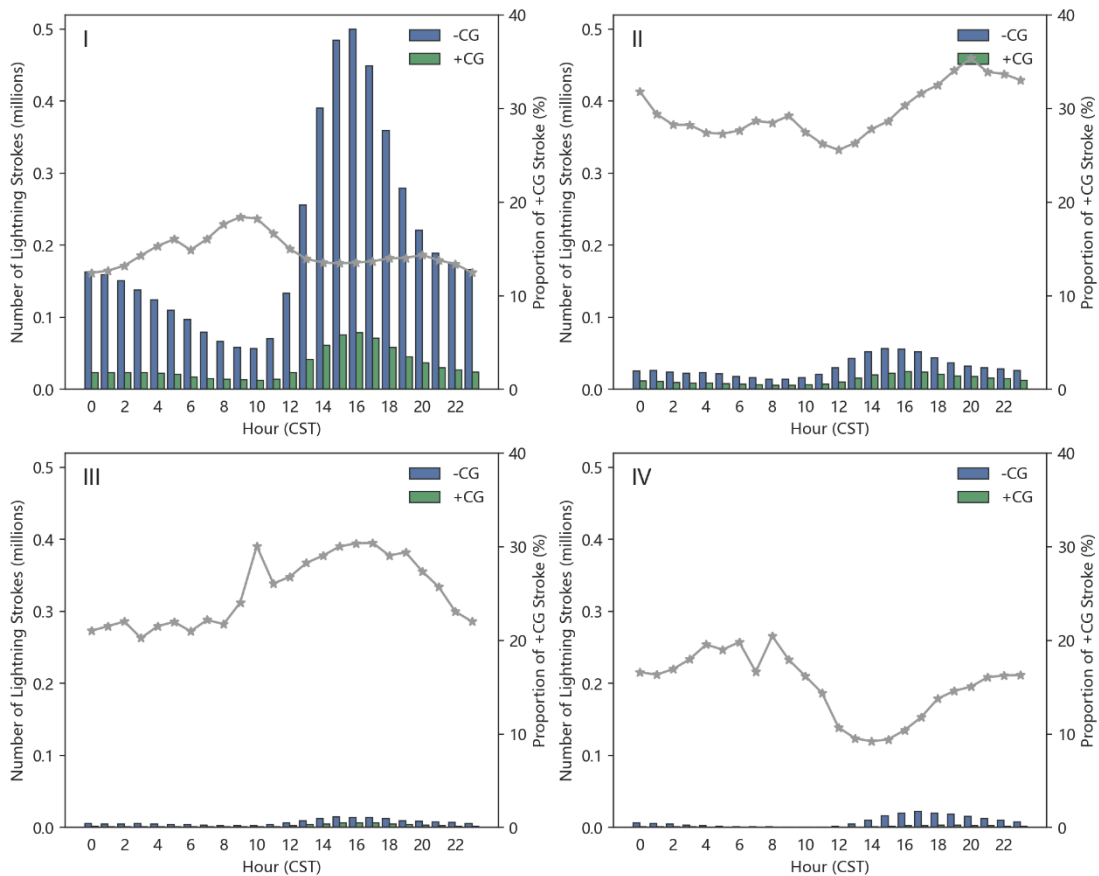

302
 303 **Fig. 4. Annual scale variation of the peak current distribution of +CG and -CG stroke. The red line**
 304 **represents the average peak current value of each month.**

305 Fig. 5 illustrates the hour-by-hour frequency and proportion variation of +CG
 306 stroke throughout the day. The frequency of both +CG and -CG strokes show noticeable
 307 and consistent fluctuations. The active period for lightning activity is concentrated in
 308 the late afternoon to wee hours, which coincides with the maximum accumulation of
 309 radiative heating and vapor conducive to the development of convection, particularly
 310 during summer thunderstorms in China. Stroke frequency peaks at 15:00 to 16:00 CST
 311 (China Standard Time, UTC+8 h) in Region-I and Region-II in the east of China and 1-
 312 2 hours later in Region-III and Region-IV in the west of China. After nightfall, lightning

313 activity gradually weakens due to the decline in unstable energy, dropping to a trough
 314 at 8:00-10:00 CST the following day. The monthly and hourly variations in lightning
 315 frequency are similar to the observations in Europe by EUCLID (Poelman et al., 2015)
 316 and in US by NLDN (Koehler, 2020; Holle and Cummins, 2010).

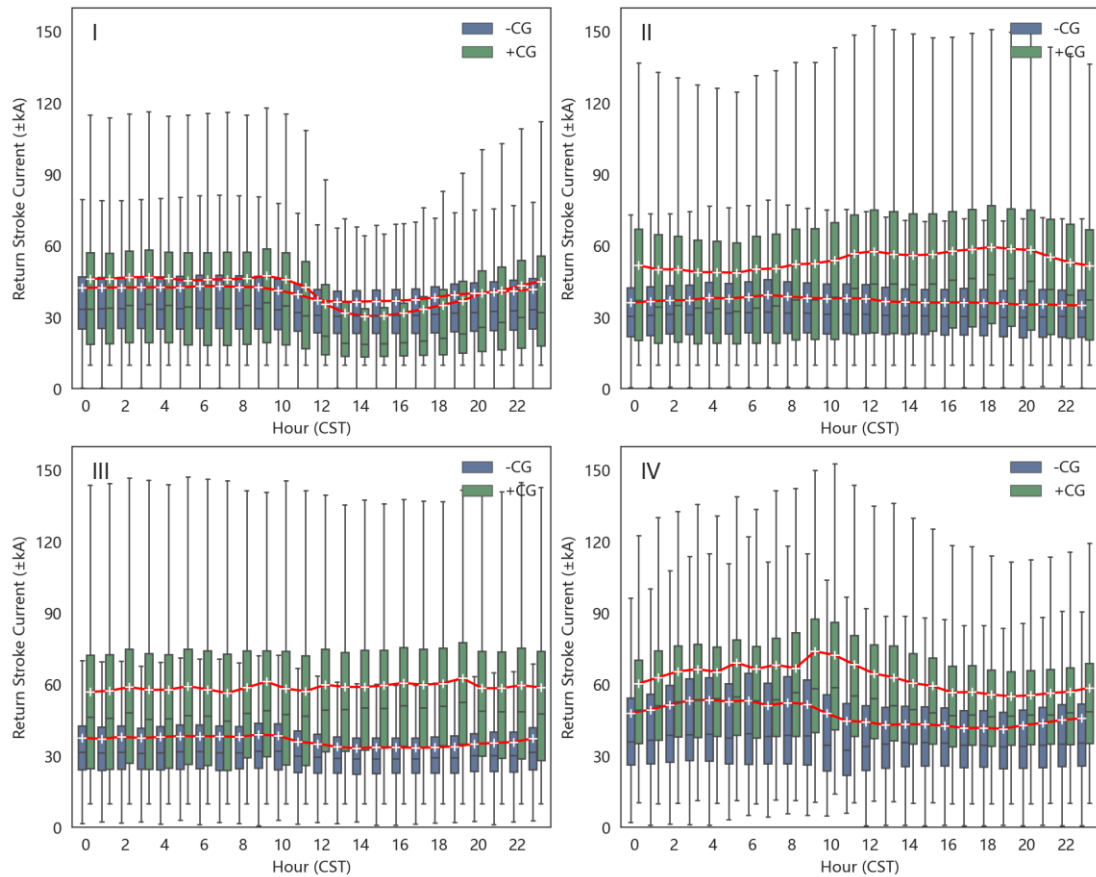

317 The proportion of +CG stroke is inversely correlated with the total number of CG
 318 stroke in a day in Region-I, Region-II, and Region-IV, as shown in Fig. 5. The maxima
 319 of the +CG stroke proportion coincides with the lowest frequency at 8:00-10:00 CST
 320 in all four regions, but the minima appear 2-3 hours earlier than the frequency peak.
 321 Region-I and Region-IV at low latitudes have maximum proportions in the morning,
 322 while Region-II and Region-III at high latitudes have maximum proportions in the
 323 evening. Additionally, the proportion of +CG stroke is lower in Region-I and Region-
 324 IV, with values of less than 20 %, than in Region-II and Region-III, with values of over
 325 20 %. These findings demonstrate a close relationship between thunderstorm
 326 characteristics and geographical features such as latitude, topography, and sea distance.

327
 328 **Fig. 5. Daily scale variation of the frequency distribution of +CG and -CG stroke. The gray line represents**
 329 **the proportion of +CG stroke. The time zone is CST (UTC+8 h).**

330 The hourly distribution of the peak current value and its average is illustrated in
 331 Fig. 6. Region-II and Region-III, situated at higher latitudes, exhibit a broader range of
 332 peak current distribution. Despite this, their variation remains relatively stable, with a
 333 slightly larger current for +CG stroke in Region-III than Region-II. In Region-1, there
 334 is a significant decrease in current during the midday and afternoon periods, with a

335 more pronounced change observed in +CG strokes than in -CG strokes. This
 336 phenomenon leads to a situation where the absolute peak current of the two types of
 337 stroke can even be reversed. Conversely, Region-IV, characterized by the intricate
 338 terrain resulting from the Tibetan Plateau, showcases complex current variations.
 339 Specifically, there is an increase in peak current for +CG strokes and a decrease for -
 340 CG strokes since 8:00 CST in this region. Consequently, a substantial disparity in peak
 341 current between the two types emerges around the daytime hours.

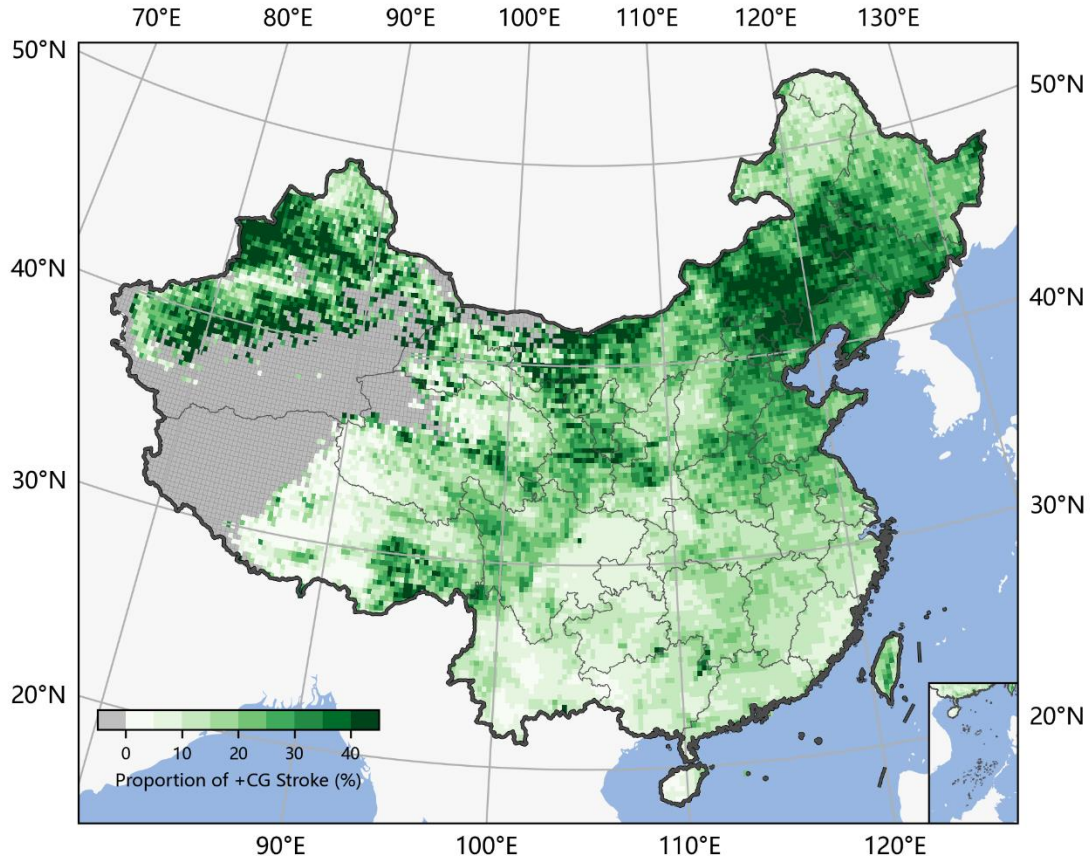

342
 343 **Fig. 6. Daily scale variation of the peak current distribution of +CG and -CG stroke. The red line represents**
 344 **the average peak current value of each hour. The time zone is CST (UTC+8 h).**

345 3.2.2 Comparison of spatial distribution of +CG and -CG stroke

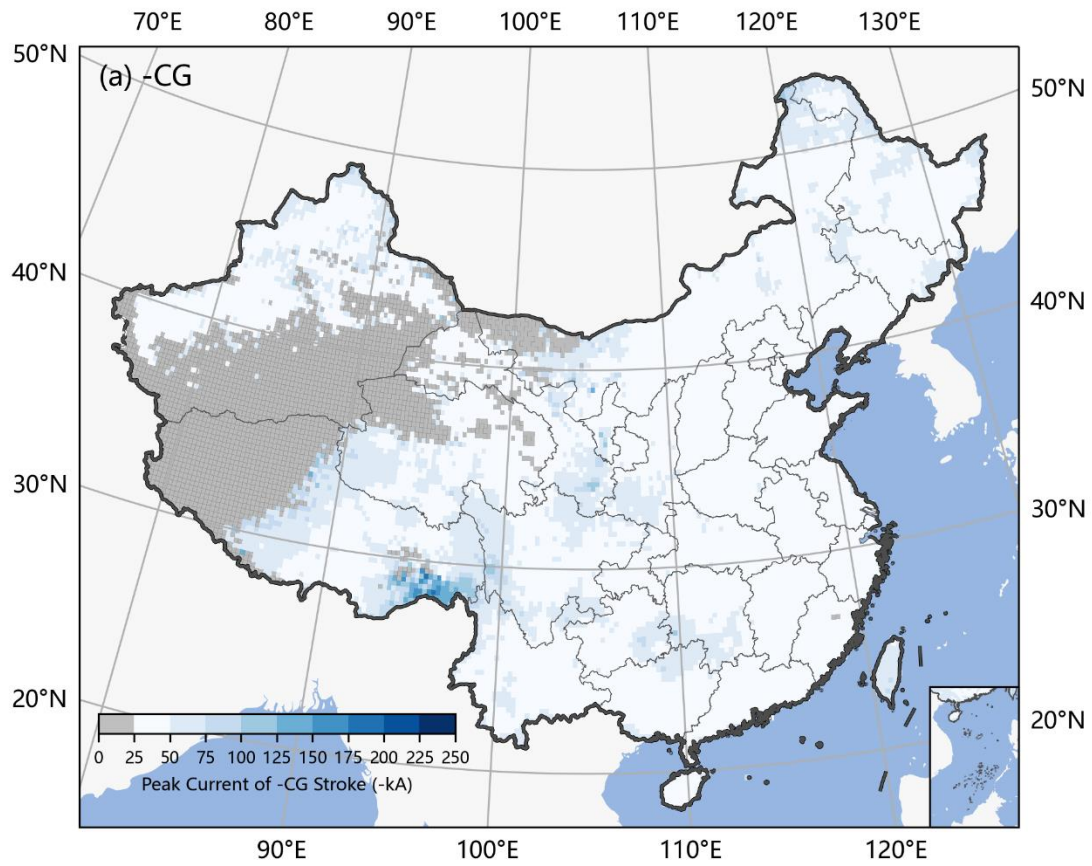

346 The geographical features of China contribute to the complex distribution of +CG
 347 and -CG strokes across various regions, which is reflected in the variability of the ratio
 348 of +CG and -CG strokes. Fig. 7 illustrates the spatial distribution of the proportion of
 349 +CG stroke, with gray areas indicating grids with less than 50 CG strokes accumulated
 350 over a seven-year period. These grids are mainly located in the central, western, and
 351 northern parts of Tibet and the western and southern parts of Xinjiang. Region-I, which
 352 has the highest density of CG stroke, has a low proportion of +CG stroke, at less than
 353 10 %. Conversely, the other three regions have a higher proportion of +CG stroke,
 354 particularly the North China Plain and adjacent Inner Mongolia, as well as some parts
 355 of Xinjiang, where the +CG proportion can reach 30-40 %. The proportion of +CG

356 stroke in Shanxi and Shaanxi, both located in Region-II, is lower than in other regions
357 of the same area. Overall, regions with lower CG stroke density tend to have a higher
358 proportion of +CG stroke, and high latitudes correspond to a higher +CG stroke
359 proportion.

360
361 **Fig. 7. Distribution of the proportion of +CG stroke in China. The gray grids have a CG stroke number of**
362 **less than 50 in seven years and thus are not calculated. The grid size is $0.25^\circ \times 0.25^\circ$.**

363 Based on Fig. 8, it can be inferred that the spatial distribution of the peak current
364 values for both +CG and -CG stroke is generally similar, with lower peak current values
365 observed in southeast China where lightning activity is more frequent, and higher peak
366 current values found in other inland areas. Notably, the peak current in Mêdog County
367 (o) is especially high, with most areas with an average of over 100 kA. Besides,
368 southern Gansu, southern Shaanxi, and the intersection of Guizhou, Hunan, and
369 Guangxi are also recognized as high-value regions, where the proportion of +CG stroke
370 is also relatively high. Therefore, it can be concluded that a high proportion of +CG
371 stroke typically corresponds to larger peak current values in terms of temporal and
372 spatial scales.

The proportion of +CG stroke in different altitude layers is calculated, as shown by the gray line in Fig. 9. Below 4500 meters altitude, the proportion increases with altitude, ranging from 7 % to over 15 %. A sub-peak is observed at 1500 meters, which is caused by the high proportion region of +CG strokes in Xinjiang and Inner Mongolia. However, above 4500 meters altitude, which mainly comprises the uninhabited areas of the western and northern Tibetan Plateau, the proportion of +CG stroke decreases rapidly. It is worth noting that only 91 CG strokes were observed above 6000 meters of altitude during the seven-year period and are not included in the statistics.

The box plot in Fig. 9 shows the peak current distribution of +CG and -CG strokes at different altitudes. The distribution of +CG peak current narrows with increasing altitude. Interestingly, the average peak current of -CG strokes shows a slight positive correlation with altitude, whereas +CG strokes exhibit a negative correlation with altitude. The opposite trend of the two types of lightning strokes leads to a large difference in their peak current at low altitudes and coincidence at high altitudes. The Tibetan Plateau is primarily responsible for the intricate lightning activity versus altitude over China. As the "third pole" of the Earth, the charge structure of thunderstorm clouds on the Tibetan Plateau always has some special characteristics due to the high-altitude ground surface (Li et al., 2013; Qie et al., 2005). Furthermore, its influence on the uplift and obstruction of water vapor can also affect the climatic characteristics of other regions.

4. Conclusion

401

China is primarily located in temperate and subtropical zones, with climate subject

402 to a variety of factors, including cold and warm monsoons, the interplay of land and
403 sea, and varied topography. As a result, there are frequent convective weathers and a
404 high prevalence of lightning activities. This paper utilizes the dataset from a ground-
405 based lightning location system, CNLDN, which serves as the most extensively
406 deployed national lightning detection system in China, to analyze the CG characteristics
407 in China over the past seven years. The spatial and temporal distribution of +CG and -
408 CG strokes exhibit regular patterns in terms of their frequency, proportion, and peak
409 current.

410 The results indicate that there is more CG in southern regions than in northern
411 regions, more in mountainous areas than in plains at the same latitude, more in humid
412 areas than in arid areas, and more in coastal areas than in inland areas within the same
413 climate zone. The southeast coastland of China has the highest CG stroke density, while
414 the northwest deserts and basins as well as the east and north Tibetan Plateau have the
415 lowest density. The monsoon system plays a critical role in lightning activities in
416 southern and Northern China, while the Tibetan Plateau contributes to the variability of
417 lightning activities in Northwestern China and the Qinghai-Tibet region. Overall, the
418 distribution of lightning activity across China is consistent with the precipitation
419 distribution observed at a climatic scale.

420 In general, +CG strokes have a lower occurrence rate than -CG strokes, but they
421 carry higher currents and are more destructive. The spatial and temporal distribution of
422 +CG and -CG stroke also varies significantly due to different storm structures. In terms
423 of annual scale, the lightning activity follows a seasonal pattern, with the highest
424 frequency occurring during summer (72.6 %), followed by spring (18.4 %) and autumn
425 (8.6 %), and the least frequent in winter (0.4 %). In spring, autumn, and winter,
426 lightning is mainly concentrated in the southeastern coastal areas. The percentage of
427 +CG stroke is always inversely correlated with lightning frequency. High stroke
428 frequency in summer generally corresponds to a low proportion of +CG stroke, while
429 low frequency in winter corresponds to a high proportion of +CG stroke. The proportion
430 of +CG stroke in December in most regions reaches up to 50 %. The average peak
431 current of return stroke is strongly correlated with the proportion of +CG stroke and
432 also follows a seasonal pattern of being high in winter and low in summer. The seasonal
433 fluctuations of +CG stroke are stronger than -CG stroke in Southern China and Northern
434 China, where the average intensity of +CG stroke in summer is even below -CG stroke.
435 On the hourly scale, lightning is active in the late afternoon, with a peak between 15:00-
436 17:00 CST, and drops to a trough the following day between 8:00-10:00 CST. The
437 proportion of +CG stroke throughout the day follows an inverse trend with the
438 frequency of stroke in most regions, but the minimum proportion occurs 2-3 hours
439 earlier than the maximum frequency. The highest proportion of +CG stroke at low
440 latitudes always occurs in the morning, while at high latitudes, it tends to occur at
441 midnight. The changes in peak current during the day at high latitudes are not
442 significant. In Southern China, the peak current of +CG and -CG stroke drops
443 significantly at noon and afternoon, with +CG dropping even lower than -CG.

444 The distribution of the +CG stroke proportion exhibits significant spatial
445 variability. In Southern China, where the density of CG is the highest, the +CG stroke
446 proportion is the lowest, at less than 10 %. In contrast, the high-latitude regions such as
447 the North China Plain, Inner Mongolia, and northern and central Xinjiang have a much
448 higher proportion of 30-40 %. The proportion of +CG stroke below 4500 meters is
449 positively correlated with altitude and drops sharply after exceeding 4500 meters in the
450 western and northern regions of the Tibetan Plateau. The spatial distribution of peak
451 current values of +CG and -CG stroke is consistent, and a higher proportion of +CG
452 stroke is generally associated with greater peak current for both types. As latitude
453 increases, the current distribution widens. The peak current of +CG shows a slight
454 decrease with increasing altitude, while the peak current of -CG increases with altitude.
455 Consequently, there is a significant difference in discharge intensities between the two
456 types at low altitudes, but they tend to be similar at higher altitudes.

457 The lightning location system sites cannot be evenly distributed due to geographic
458 factors, thus bringing about errors in lightning distribution analysis. The observation
459 from the Lightning Mapping Imager (LMI) on the FY-4A satellite will be used to correct
460 the distribution deviations by ground-based data in our following research. Given the
461 vast size of China, a simple division into four regions may be too crude to study the
462 influence of geographic and climatic factors on CG characteristics in depth. Therefore,
463 a more detailed division will be necessary for future studies.

464 Acknowledgments:

465 This study is supported by the Key Technologies Research and Development
466 Program of China (2020YFB1600103). We appreciate the Meteorological Observation
467 Centre of CMA and the Institute of Electrical Engineering of CAS for their data support.
468 We also thank the reviewers and editors for their valuable suggestions for this study.
