**Abstract.** Compound flooding is generated when two or more flood drivers occur simultaneously or in close succession. Multiple drivers can amplify each other and lead to greater impacts than when they occur in isolation. A better understanding of the interdependence between flood drivers will facilitate a more accurate assessment of compound flood risk in the coastal regions. This study employed the Delft3D-Flow Flexible Mesh model to simulate the peak coastal water level, consisting of storm surge, astronomical tide, and the relative sea level rise (RSLR) in Shanghai over 1961-2018. It then applies a copula-based methodology to calculate the joint probability of peak water level and rainfall during historical tropical cyclones (TCs) and to calculate the marginal contribution of each driver. The results indicate that the astronomic tide is the leading driver to peak water level, followed by the contribution of storm surge. In a longer term, the RSLR has significantly amplified the peak water level. This framework could be applied to other coastal cities which face the similar constraint of unavailable water level records.

## 1 Introduction

Compound flooding is generated when two or more flood drivers, e.g., water level, rainfall, and high river discharges, occur simultaneously or in close succession. Such flood drivers can amplify each other and lead to greater impacts than when they occur in isolation (Leonard et al., 2014; Zscheischler et al., 2018; Visser-Quinn et al., 2019; Chao et al., 2021). Coastal cities like Shanghai are particularly prone to compound flooding associated with tropical cyclones (TCs), which often bring heavy rainfall and storm surge. For a more accurate assessment of compound flood in the coastal regions, a thorough understanding of the interdependence between multiple flood-drivers is necessary. In other words, an enriched knowledge about the

dynamic interaction between flood-drivers would significantly improve the quantification of compound flooding risks in  
35 estuarine environments (Feng and Beighley, 2020). As such, the joint probability theory has been incorporated into the  
analysis of compound flood risk to take the advantage of the Sklar's Theorem that any multivariate joint cumulative  
distribution function can be expressed in terms of univariate marginal distribution functions and a copula which describes the  
structure of dependency between the variables (M. Sklar, 1959; Bevacqua et al., 2019).

Shanghai is the largest and most developed coastal megacity in China. Rainstorm and storm surge caused by typhoon from  
40 June to October often cause substantial losses (Li et al., 2018; Yin et al., 2021). For example, extreme storm flooding caused  
nearly 30 thousand casualties in 1905 (Li et al., 2019). In 1962, storm flooding inundated half of the downtown region for  
nearly 10 days due to 46 failures along the floodwalls of the Huangpu River and its branches and led to huge losses of 1/6 of  
the total GDP in Shanghai (Ke, 2014). In 1997, Typhoon Winnie killed seven people and flooded more than 5,000  
households due to the extreme storm surge and rainfall (Ke et al., 2021). Although the construction of flood control measures  
45 in the past 50 years (especially after the typhoon Winnie in 1997) has effectively reduced the risk of storm surge and  
rainstorm floods, Typhoon Matsa in 2005, Typhoon Fitow in 2013, and Typhoon Lekima in 2019 also brought significant  
damage to Shanghai (Du et al., 2020). Therefore, compare the encounters of rainfall and storm surge during typhoon season  
is important to understand the frequency of compound flooding in Shanghai. However, owing to the unavailability of water  
level records during typhoon events, there is no research that has been able to calculate the joint probability of peak water  
50 level and rainfall during historical TCs and to calculate the marginal contribution of each driver as we have done in this  
research.

The copula method is widely use in statistics to model the interdependence between two or more variables (Anandalekshmi  
et al., 2019; Balistrocchi et al., 2019; Xu, P. et al., 2019). Recent research using the copula model emphasizes the importance  
of studying the combined effects of rainfall and water level processes in estuaries and coastal regions. For example, Xu, H. et  
55 al. (2018) showed the existence of some positive dependences between rainfall and water level in a coastal city of Hainan  
Island, while the water level poses an additional risk of flooding. The studies of both Xu, P. et al (2019) and Xu. H. et al.  
(2018) confirmed that the is a promising tool for studying multivariate problems in hydrology and coastal engineering.  
However, when applying the copula-based methods to 3 dimensions, controversies arise and uncertainty can become  
explosive (Bevacqua et al., 2017; Santos et al., 2021). The univariate flood driver cannot provide an accurate evaluation if  
60 the underlying drivers are modelled as independent extreme events (Li et al., 2016; Khanal et al., 2019).

Flood induced by TCs is the most frequent natural disaster in the eastern coastal region of China (Zhang et al., 2020).  
China's climate is mainly shaped by the East Asian Monsoon. The East Asian typhoon season is characterized by heavy  
inland rainfall and high storm tide, which are the major driving factors of coastal flood hazards in China. The slowdown in  
forward speed of landfalling TCs in the Northwest Pacific over 1949-2015 had increased the risk of flooding from water  
65 level and rainfall even without considering the changes in storm strength (Kossin, 2018). The simultaneous and/or  
consecutive occurrence, both in time and space, of heavy rainfall and high tide can lead to compound flooding (Wahl et al.,  
2015; Bilskie et al., 2021). Furthermore, the risk posed by the interactions between hydro-meteorological events under the

condition of sea level rise and changing tidal regimes is bound to increase in the future (Idier et al., 2020). Despite the increasing threat of compound flooding events along the Chinese coast, owing to the unavailability of water level records during typhoon events, the associated joint probabilities and driving mechanisms have not been explored (Fang et al., 2020). This research intends to fill this important niche.

The TCs often produce strong onshore winds and low barometric pressure, which would cause extreme storm surge, at the same time, generate heavy rainfall on the coastal region (Hoque et al., 2018; Sohn et al., 2021). Peak water level during TCs not only results from the combination of storm surge and astronomical tide. Additionally, the combination of absolute sea level rise (SLR) due to the global warming and land subsidence due to urbanization has caused relative sea level rise (RSLR) (IPCC, 2021; Jebbad et al., 2022). According to the Regulations of Shanghai Municipality on the Administration of Land Subsidence Prevention and Control, the land subsidence rate was 6.19 mm/yr from 1965 to 2001. Since 2001, the land subsidence rate has been controlled to varying degrees by adaptation measures such as recharging water to aquifers.

This study establishes the joint distribution of water level and rainfall during typhoon season in the Shanghai estuary region, with the aim to better understand the risk of compound flooding and to improve the assessment of flood-defence design standard for adaptation strategies. Our modeling framework couples a state-of-the-art hydrodynamic model and statistic model. This model coupling enables us to quantify the joint distribution of rainfall and storm surge events during typhoon season, and also to consider the comparative cases with and without RSLR for Shanghai. The procedure of the modeling framework is as follows. First, the peak water levels, consisting of astronomical tides, storm surges associated with TCs, and RSLR, in Shanghai over 1961-2018 are generated using the Delft3D-Flow Flexible Mesh model, then a compound hazard scenario for deriving design values is chosen. Second, we compare and investigate the peak water level with and without RSLR, and select the extreme compound flood events according to the design standard of the joint hazard scenario. Finally, we analyse the contribution of storm surge, astronomical tide and RSLR to peak water level based on the top seven extreme compound flood events over the study period. We provide a framework that could be applied to other coastal cities which face the similar constraint of unavailable water level records. The findings from our research could be useful for decision-making in developing coastal flood defence measures in Shanghai and other East Asian coastal cities. This is the major contribution of this research.

## 2 Materials and Methods

### 2.1 Study Area

Shanghai is surrounded by water on three sides, and the Huangpu River and Suzhou River pass through the city (Figure 1). The total area of Shanghai is 6,340.5 km<sup>2</sup> with a population of 24.87 million in 2020. The annual rainfall is around 1,200 mm. June to September are the rainy months. From late August till early September, Shanghai is frequently affected by typhoons and rainstorms (Yin et al., 2021). Storm flooding caused by typhoons is the main natural disaster in Shanghai. Shanghai's flood risk is about US \$63 million/year under an optimistic scenario of a maximum protection level of 1/1000 per

100 year (Hallegatte, Green, Nicholls, & Corfee-Morlot, 2013). Although the construction of flood control measures in the past  
 50 years has effectively reduced the risk of storm floods, TC Matsa in 2005, the 2013 TC Fitow, and the 2019 TC Lekima  
 caused substantial losses in Shanghai. Particularly, typhon Winnie in 1997 led to an economic damage of over US \$100  
 million. During typhoon Winnie period, the water level at Huangpu Park (city center) rose to 5.72 m, equivalent to the water  
 level with a 500-year return period. During typhon Fitow in 2013, the water level at Mishidu in the inland area of the  
 105 Huangpu River was recorded at WD (Wusong Datum is adopted as the reference) as 4.61 m, which broke the record (Ke et  
 al., 2018). In the context of climate change, relative sea level rise, and urban expansion, Shanghai will face greater  
 compound flood risks and challenges from TCs, storm surge, and extreme rainstorm in the future (Wang et al., 2018).

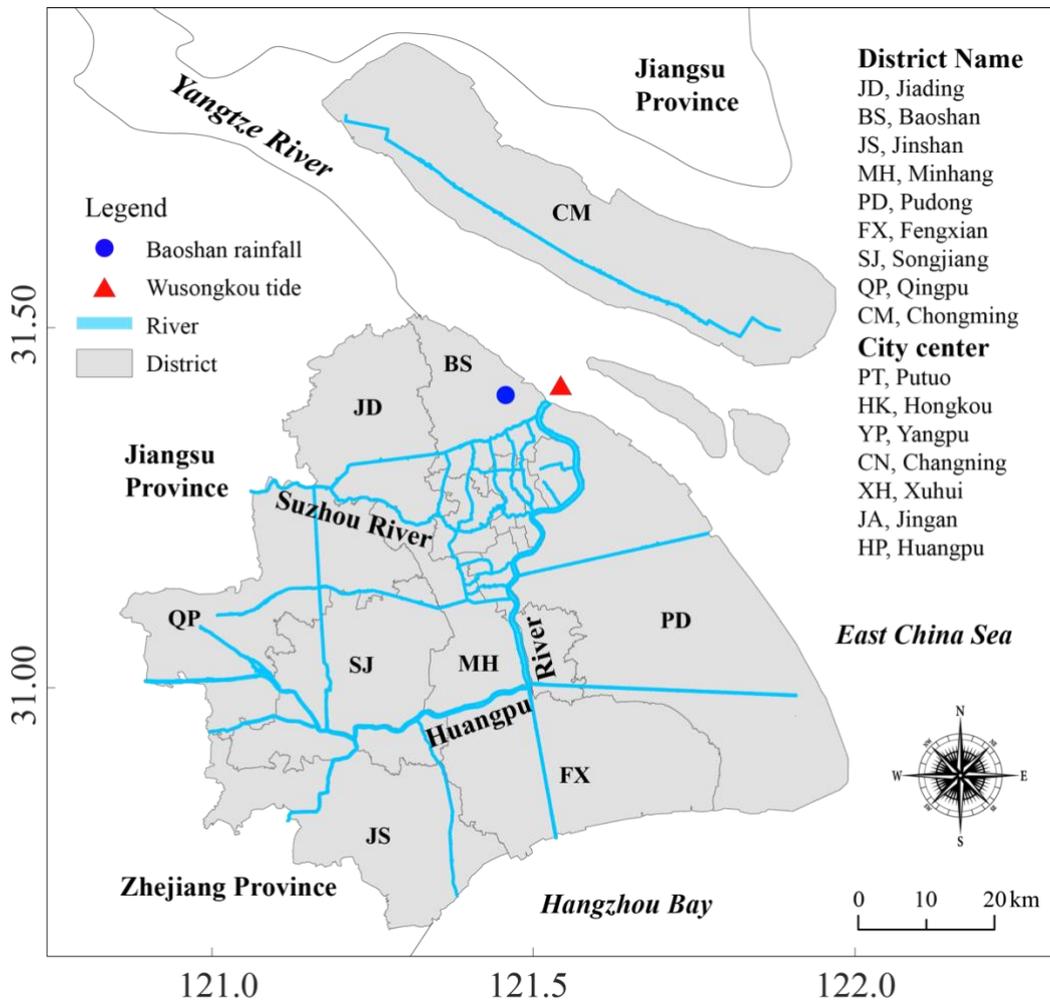

Figure 1: Location map of Shanghai.

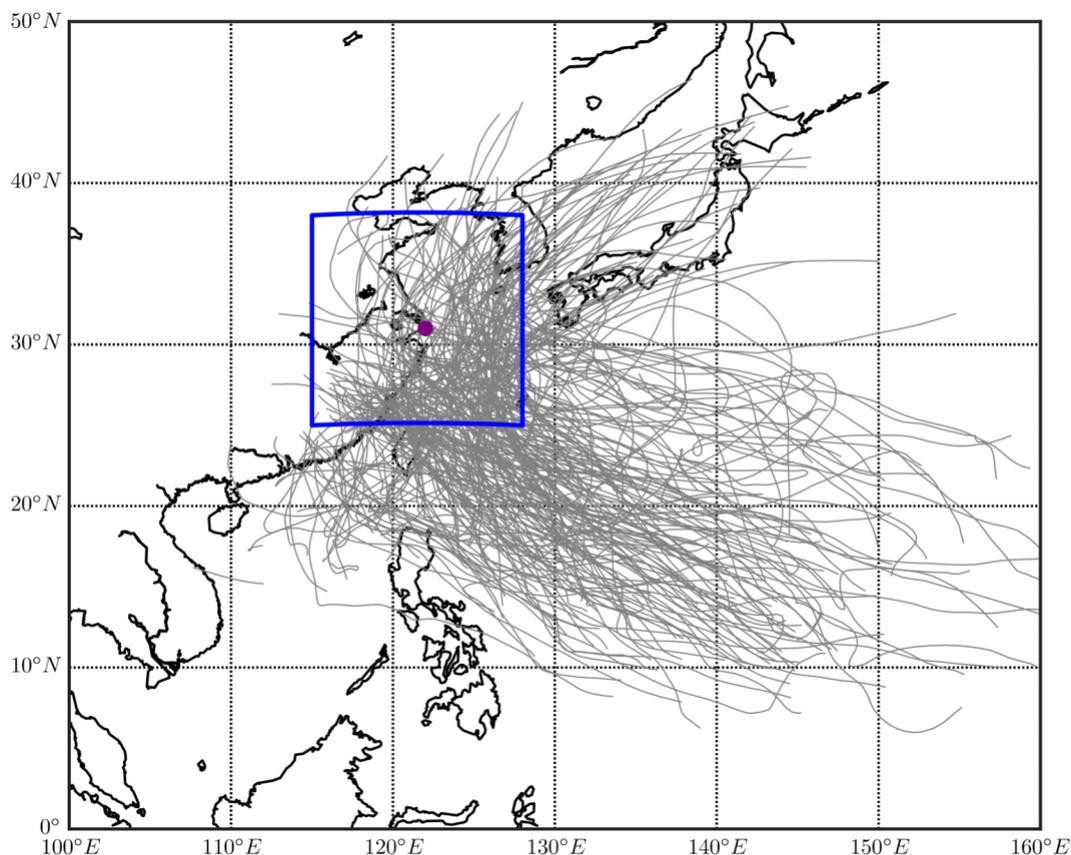

## 110 2.2 Data

This study systematically collected the geographic and meteorological data of the study area, including TC tracks (1961-2018), and daily accumulated rainfall (1961-2018). Due to the unavailability of measured water level data from historical TCs, in this study we evaluate the dependence coefficient between rainfall and water level based on observed rainfall and simulated peak water level during TCs. Observations come from a set of rain gauge measurements. Modelled data consist of  
115 data sets created using the International Best Track Archive for Climate Stewardship (IBTrACS) from NOAA's National Climatic Data Center.

We use the Delft3D-Flow model (Knapp et al., 2010) to simulate water level during TC periods. IBTrACS contains 6-hourly TC centre's longitude and latitude, minimum central pressure ( $P_c$ ) and sustained maximum surface wind velocity ( $V_{max}$ ). Multiple agencies provide TC best tracks in the West Pacific, and we opt to use the best track from Hong Kong Observatory  
120 (www.hko.gov.hk). This choice was made because it includes the most complete set of observations from TCs making landfall in China (Chen et al., 2011).

We analysed the historical TCs influencing Shanghai between 1961 and 2018. We first defined a 6-degree-latitude square box around Shanghai (Figure 2). The area covered by the blue box can be regarded as an alert area in terms of a TC causing potential damage in Shanghai. The size of the blue box was designed to be just large enough to include the partial tracks of  
125 the top 10 most costly TCs for Shanghai since 1949 (personal communication with Shanghai Climate Centre). We then selected historical TCs lasting for at least 24 hours in the blue box. After this best-track pre-processing, 210 TCs for the period of 1961-2018 are selected in this study (Figure 2). Additionally, we obtained tidal level data (1997) at the Wusongkou tide gauge from the Shanghai Municipal Water Authority, which are used for hydrodynamic model validation.

130 **Figure 2: Location map for the area of interest. (Grey colored lines indicate major historical typhoon tracks within the region. Blue box indicates the selection criteria.)**

Daily rainfall records from 1961 to 2018 are collected from the China Meteorological Administration (CMA, <http://data.cma.cn>) for the Baoshan gauge station, being the closest to the Wusongkou surge station (Figure 1). The annual precipitation in Shanghai is 1,200 mm with the rainiest months being from June through September. Rainfall data are used in  
135 this study to approximate the TC-induced runoff. To implicitly account for the rainfall travel time to the catchment outlet, 1-, 2-, and 3-days accumulated rainfall were also estimated and the correlation between such accumulated rainfall and peak water level was then estimated.

According to the Chinese Sea Level Bulletin of 2020, which was compiled by the State Oceanic Administration of China, the absolute sea-level rose at a rate of 3.4 mm/yr. According to the Regulations of Shanghai Municipality on the  
140 Administration of Land Subsidence Prevention and Control, the land subsidence rate was 27.93 mm/yr from 1921 to 1964. From 1965 to 2001, the land subsidence rate was 6.19 mm/yr. After 2001, the land subsidence rate has been under varying extents of control by adaptation measures such as recharging water to aquifers, and in most regions being 5-15 mm/yr. We use 10 mm/yr as the land subsidence rate from 2001 to 2018. The downside of such an assumption is that it fails to consider

possible accelerating factors such as population growth, vertical and horizontal urban expansion, and deep strata motions,  
145 but these complex factors are beyond the scope of this research.

### 2.3 The framework

The objectives of this study are to overcome the limitation of unavailable water level records during TCs and set up a  
framework to improve the methods for selecting the most suitable TCs for the research and for investigating TCs' influence  
on storm tide. Due to the limited storm tide data availability, we employ an empirical track model for pressure and wind  
150 fields, followed by a physics-based ocean model to simulate storm tide and astronomical tide during typhoon season in  
Shanghai. A numerical simulation is carried out to better understand the distribution and timing of the peak storm tide and  
the areas of the country affected. The surge model was calibrated using the recorded atmospheric pressure and focused on  
ones with the most severe damages, comparing well with the results of the field survey data (Ke et al., 2021). Following this,  
the copula function was used to connect peak water level with rainfall and construct a joint distribution. After that, we  
155 compare and investigate difference between peak water level and rainfall under the effect of RSLR, and select the extreme  
compound flood events according to the design value of the joint hazard scenario. Finally, we analyse the contribution of  
storm surge, astronomical tide and RSLR to peak water level (Figure 3).

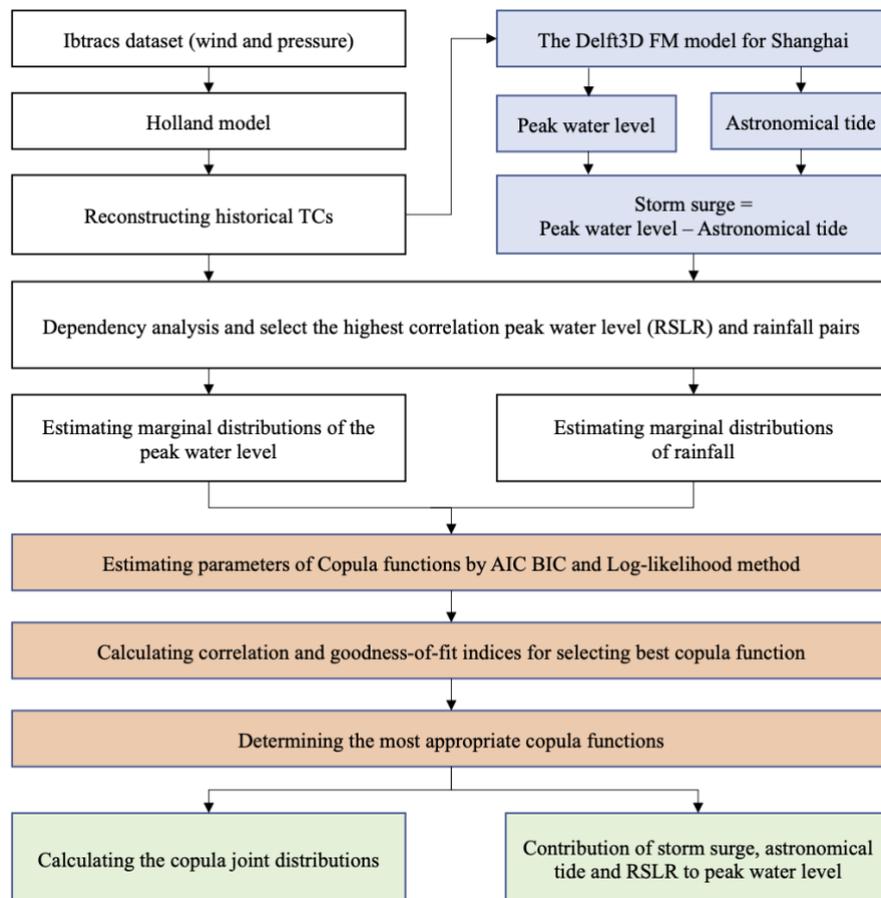

Figure 3: Flowchart of this study.

#### 160 2.4 Delft3D-Flow Flexible Mesh model

Delft3D WES (Wind Enhance Scheme), a built-in module in Delft3D, is used in this study to generate wind fields of TC scenarios. WES calculates the wind and pressure according to the Holland formula (Holland et al., 2010). It is able to generate tropical cyclone wind and pressure fields around storm center positions on a high-resolution grid. Through asymmetry, WES has been slightly improved. This asymmetry is caused by the use of the translational speed of the cyclone's center displacement as the steering flow, and the rotation of the wind velocity due to friction (Takagi and Wu, 2016). The output of WES is suitable as input for the Delft3D-Flow model to simulate water level including the effect of storm surge.

The hydrodynamic model Delft3D-Flow Flexible Mesh is employed in this study to solve multi-disciplinary problems in coastal, river, and estuarine environments (Deltares, 2013). The domain of the model covers the East China Sea, Hangzhou Bay, the Yangtze Estuary, and the downstream reach of the Yangtze River, ranging from 24 to 34°N and 118 to 128°E, and consists of 69,000 mesh cells. The model has been validated with observed storm tide and astronomical tide at 10 stations

around Shanghai during TC Winnie in 1997 (Ke et al., 2021). The storm tide and astronomical tide of 210 TCs are calculated in this Delft3D-Flow Flexible Mesh model. Then, the peak storm tide is selected from each TC. In addition, the storm surge is calculated by using storm tide minus astronomical tide at the same time of peak storm tide. In this study, we assume the  
175 Yangtze River discharge equals its annual mean at 31000 m<sup>3</sup>/s.

## 2.5 Dependence modelling and design value via copulas

We define the joint distribution of rainfall and water level,  $F_{R,WL}$  as  $F_{R,WL} = C(F_R, F_{WL})$  where  $F_R$  and  $F_{WL}$  are marginal distributions of rainfall and water level, and  $C$  is the associated dependence function, i.e., copula, modelling the dependence between rainfall and water level independently from their marginal distributions (Sklar, 1973; Salvadori and De Michele,  
180 2004). Hence, we select marginal distributions among the most commonly used distribution functions for extremes, namely: Generalized Extreme Value (GEV), Pearson type III (P-III), Gumbel, Exponential and Weibull.

The copula function raised by Sklar can model the dependence structure and joint probability distributions. The Gaussian, Clayton, Frank and Gumbel copula functions are selected to establish joint distribution between water level and rainfall. To evaluate the fitting error and select the appropriate copula function by the non-parametric estimation method, the Akaike  
185 information criterion (AIC), Bayesian information criterion (BIC) and root mean square error (RMSE) are employed.

$$AIC = -2\iota(\hat{\theta} | y) + 2K, \quad (1)$$

$$BIC = -2\iota(\hat{\theta} | y) + K \ln(n), \quad (2)$$

$K$  is the number of estimated parameters in the model including the intercept and  $\iota(\hat{\theta} | y)$  is the log-likelihood at its maximum point of the estimated model;  $n$  is the sample size. The rule of selection was that the smaller the value of AIC was,  
190 the better the model was, and similarly with the BIC.

$$RMSE = \sqrt{\frac{1}{n} \sum_{i=1}^n (X_C(i) - X_O(I))^2}, \quad (3)$$

where  $n$  is the number of observations;  $X_C$  is the theoretical probability from the copula and  $X_O$  is the empirical observed probability. It is also worth noting that the dependence between rainfall and water level is given by their linear correlation, i.e., Spearman's  $\rho$ , or concordant/discordant pairs, i.e. Kendall  $\tau$ .

195 Following Salvadori and De Michele (2004), copulas allow a straightforward definition of two hazard scenarios, i.e. pairs with an occurrence probability greater than a safety threshold, namely “AND” and “OR” scenarios. The “AND” scenario assumes that a hazardous condition is realized when both the dependent variables, in this case rainfall and water level, exceed their predefined thresholds, while the “OR” scenario assumes that a hazardous condition can occur when either one of the two dependent variables exceed their predefined thresholds. The “AND” scenario is commonly used for compound  
200 flooding mostly because the flooding can be generated by excessive runoff, high sea level, or a combination of both

(Moftakhari et al., 2017; Moftakhari et al., 2019; Zellou and Rahali, 2019). The joint exceedance probability based on the “AND” scenario is given by Eq. (4).

$$P((U > u_d) \cap (V > v_d)) = 1 + u_d + v_d - C(u_d, v_d), \quad (4)$$

where  $U = F_R$  and  $V = F_{WL}$  are the marginal distributions and  $u_d$  and  $v_d$  are the safety threshold of rainfall and water level respectively. The dependent design values ( $R_d = (F_r - 1)(u_d)$ ,  $WL_d = (F_{WL} - 1)(v_d)$ ) can be inferred from Eq. (4) based on the level of safety desired.

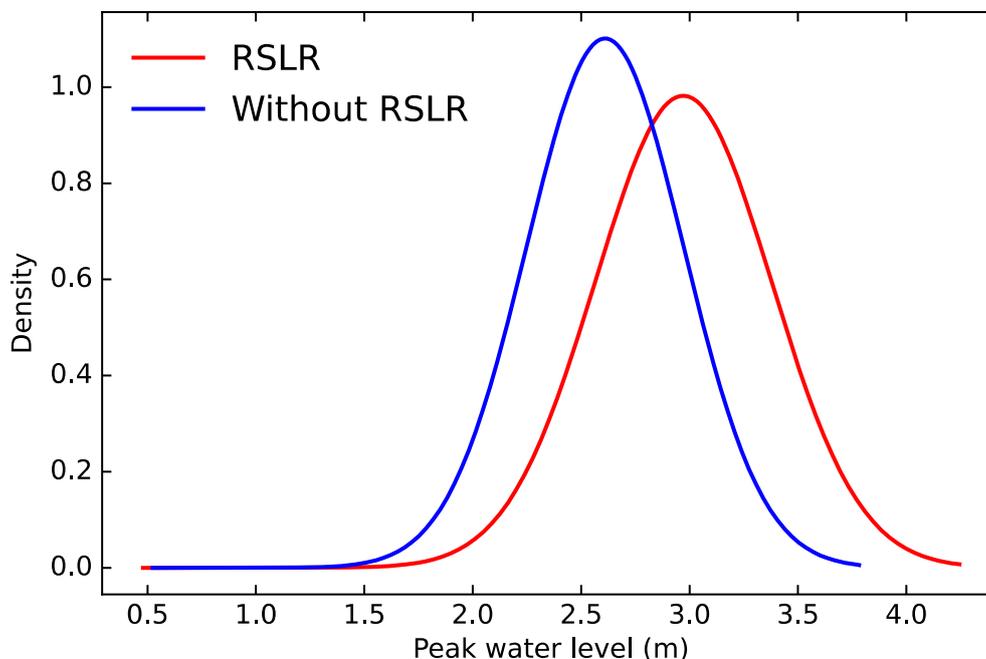

The joint probability cannot be directly used as the reference value of the actual engineering fortification standard. We calculate the joint design value combinations with the joint return period, which can serve as a reference for the engineering design. For given peak water level and rainfall events, under the conditions of a given joint return period, we design a series of  $(u_d, v_d)$  combinations to maximize  $P((U > u_d) \cap (V > v_d))$ , thereby obtaining the optimal combination design value. In the practical calculation, the intersection of the diagonal of critical probabilistic surface and probability isoline is regarded as the design values of  $(u_d, v_d)$ .

### 3 Results

#### 3.1 Effect of RSRL to peak water level

The correlation between extreme water level and rainfall is positive (Table S1). The extreme water level and 2-days accumulated rainfall have the highest correlation compared with 1-days and 3-days accumulated rainfall. The correlation between water level and rainfall is significant ( $P_{value} < 0.05$ ) in all cases. Consequently, the remaining analysis will be performed considering 2-days cumulative rainfall, here after  $R_{2d}$ .

Probability density function is a useful tool for comparing peak water levels between the cases with and without RSLR. Results in Figure 4 shows a clear shift in the distribution of peak water level during the TC periods. It demonstrates that RSLR increases both the mean and variance of peak water levels, thus resulting in higher risk of flooding in Shanghai.

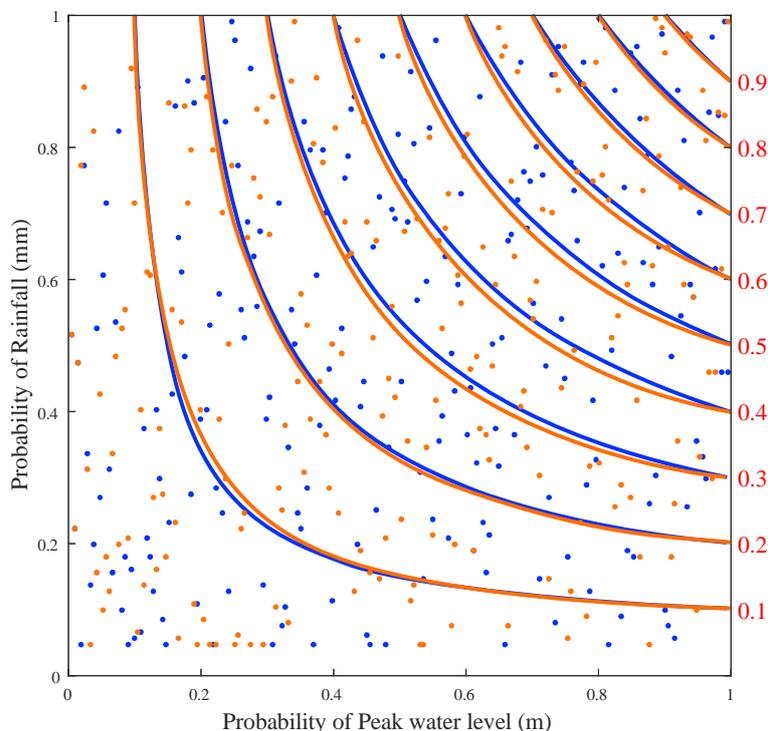

**Figure 4: The shift of the probabilistic distribution of peak water level, “with RSLR” versus “without RSLR”, in Shanghai during 1961-2018.**

225 The marginal distributions are used to transform water level and  $R_{2d}$  into uniform marginals,  $u_{WL}$  and  $u_{R_{2d}}$ , respectively. Then, the preferred copula is selected among the Clayton, Frank, Gumbel and Gaussian copula. In the case without considering RSLR, the preferred copula is Clayton because it has the smallest AIC, BIC, and RMSE (the upper panel in Table 1). In the case with the presence of RSLR, the lower panel in Table 1 shows that Gaussian copula has the smallest AIC, BIC, and RMSE. Therefore, Gaussian copula is selected as the best fit for the peak water level and rainfall under the

230 effect of RSLR. Figure 5 shows the dependence structure between water level and rainfall with RSLR and without RSLR.

**Table 1. Performance measures of the estimated copula functions**

	Copula type	Max-likelihood	AIC	BIC	RMSE
Without <i>RSLR</i>	Gaussian	1024.1	-2046.1	-2042.8	0.1105
	Clayton	1034.7	-2067.5	-2064.1	0.1050
	Frank	1009.4	-2016.8	-2013.4	0.1185
	Gumbel	972.0	-1941.1	-1938.7	0.1415
Presence of <i>RSLR</i>	Gaussian	1038.8	-2075.5	-2072.2	0.1030
	Clayton	1029.4	-2056.7	-2053.4	0.1077
	Frank	1016.4	-2030.9	-2027.5	0.1146
	Gumbel	992.7	-1983.5	-1980.2	0.1282

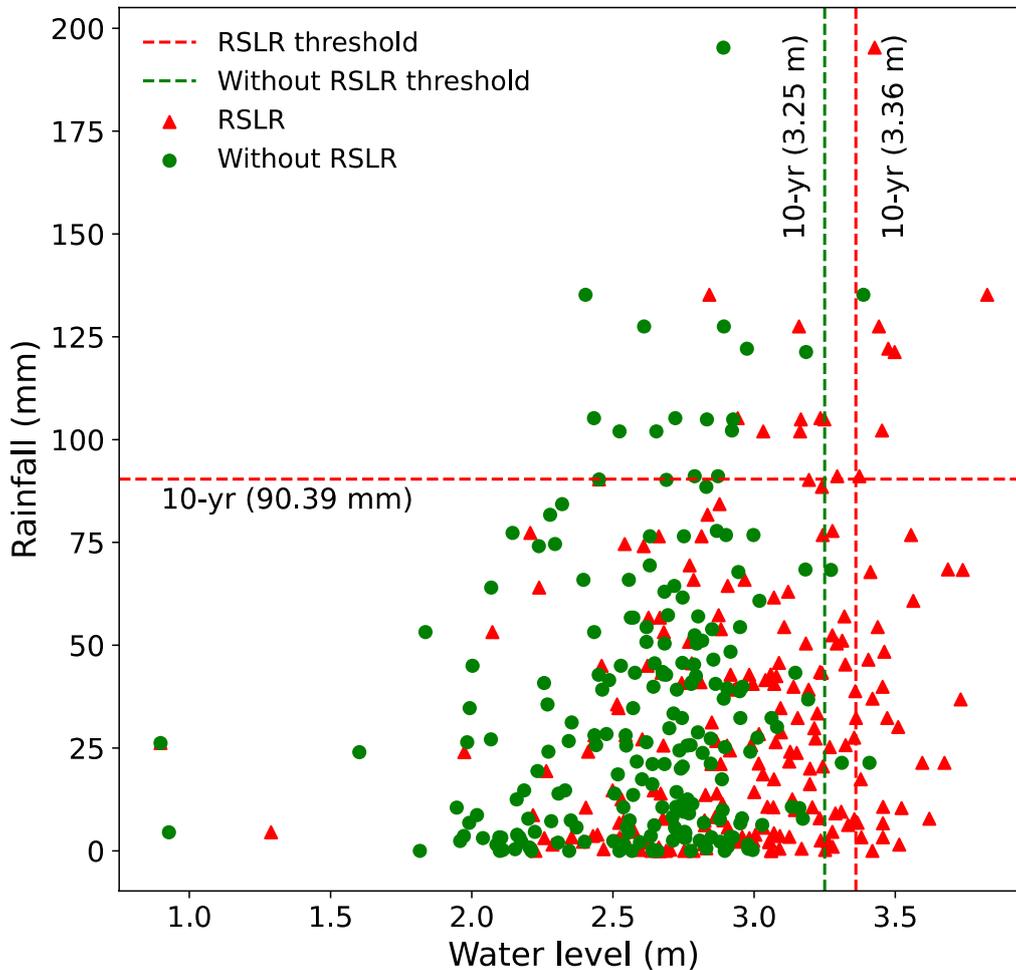

235

**Figure 5: Copulas difference between RSLR (yellow) and without RSLR (blue). The isolines are the fitted Gaussian copula. Numbers on the right side is the joint probability value of isolines.**

### 3.2. Contribution of storm surge, astronomical tide and RSLR to peak water level

Figure 6 presents the scatter plot of peak water level and rainfall with and without RSLR. It shows that the influence of RSLR pushes up the design value of peak water level from 3.25 m to 3.36 m under the 10-yr joint return period, with the corresponding design value of rainfall at 90.39 mm. The traditional approach is to assume independence between rainfall and sea level, then the independence assumption would generally lead to lower design values compared to scenarios from the copula-based method. It usually depends on how one selects the pairs and the statistical model used (independent/dependent). This is a direct consequence of the difference in the sampling of extreme observations between both approaches.

240

245 **Figure 6: Scatter plot of water level and rainfall analysed. Red lines show the design value of 10-yr joint return period with effect of RSLR. Green lines show the design value of 10-yr joint return period without effect of RSLR.**

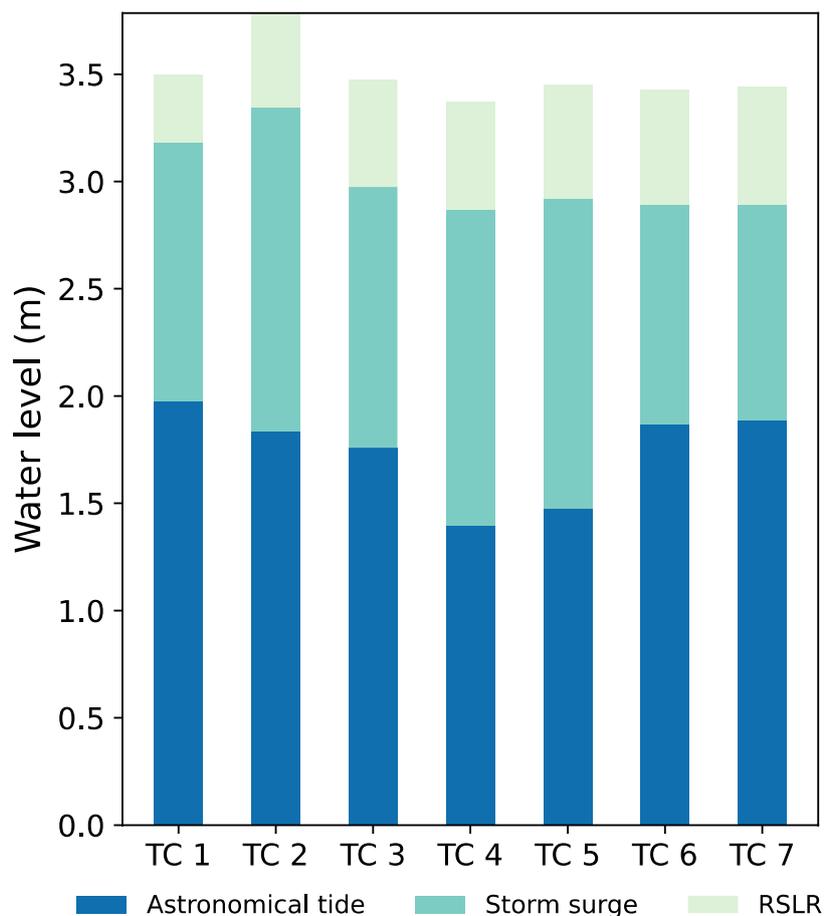

Based on the results in Figure 6, we defined the compound flood events as the peak water level and rainfall both being greater than their design values of 10-yr joint return period (i.e., peak water level > 3.36 m and rainfall > 90.39 mm). Based on this criterion, we identified seven compound flood events under the influence of RSLR (Figure 7).

250 Peak water level results from the combination of storm surge, astronomical tide and RSLR. Figure 7 shows the contribution of storm surge, astronomical tide and RSLR to peak water level from the seven extreme compound flood events in Shanghai. We consider the cases including the effect of RSLR and split the peak water level according to the contributions of its components, i.e., storm surge, astronomical tide, and RSLR, to investigate their shares of contribution.

Overall, storm surge explains 32% of the peak water level, while astronomical tide account for 55% and RSLR account for  
255 13% of the peak water level. The astronomical tide is in general the leading contributor to the peak water level, but storm surge can be the leading contributor in some cases, e.g., TC 4, in which the contribution of storm surge accounted for 45% of

peak water level. Under the scenario of future global warming and further urbanization, the impact of RSLR would increase and should not be treated as less important.

260 **Figure 7: The contribution of storm surge, astronomical tide and RSLR to peak water level. (Cases are samples greater than 10-yr joint return period.)**

## 4 Conclusions

It is important to consider the compounding effects of multiple interdependent extremes or drivers to accurately characterize the underlying hazard. In this study, we focused on the joint impact of peak water level and rainfall in Shanghai, a coastal  
265 mega-city located in the Yangtze River Delta region. We showed that Shanghai is prone to compound flooding and this justifies the adoption of a probabilistic modelling framework to incorporate the interdependence of multiple flood-drivers. Between 1961 and 2018, the RSLR had increased by 0.55 m in Shanghai. With the on-going global warming and further urbanization vertically and horizontally in the city, the process of RSLR would continue and amplify the peak water levels in extreme flooding events. The sample data we consolidated show an increase in the probability of peak water level under the

270 effect of RSLR. We also identify the extent of shift in the joint distribution of peak water level and rainfall during TC  
periods between the theoretical setting without RSLR and the real setting with RSLR by employing the best fitted copula  
functions. The shift indicates that the RSLR lead to an increase in both the mean and variance of peak water levels, thus a  
significantly higher level of flooding risk in Shanghai.

The design value of peak water level and rainfall are 3.36 m and 90.39 mm during TCs period under the 10-yr joint return  
275 period and with the influence of RSLR. We selected the potential compound flood events according to this pair of design  
value and identified seven potential compound flood events. The analysis of these seven events shows that astronomic tide is  
in general the most important driver of the peak water level, however, there is one case in which storm surge is the leading  
driver of the peak water level. If the astronomic tide relative to mean high water instead of mean sea level, the length of the  
tide part bars may be smaller. However, we argue that the peak water level is the most dangerous hazard to coastal cities.  
280 The combination of astronomical tide, storm surge and RSLR drives the peak water level. We cannot neglect the  
contribution of tide during the typhoon season.

The framework developed in this study could be applied to other coastal regions in East and Southeast Asia. The impact of  
the RSLR in amplifying the peak water levels would significantly increase in the future. Therefore, the monitoring and  
prediction of the RSLR should be an important component in the development of the future design standards for flood  
285 preparedness. Furthermore, RSLR caused by climate change and intensive use of urban land would also increase social  
vulnerability, which can be an interesting topic for future research.

### **Data availability**

IBTrACS data were obtained from the NOAA National Centers for Environmental Information from their website at  
<https://www.ncdc.noaa.gov/ibtracs>. Daily rainfall records from 1961 to 2018 are collected from the China Meteorological  
290 Administration (CMA, <http://data.cma.cn>).
