**Abstract.** Extreme precipitation is a weather phenomenon with tremendous damaging potential for property and human life. As the intensity and frequency of such events is projected to increase in a warming climate, there is an urgent need to advance the existing knowledge on extreme precipitation processes, statistics and impacts across scales. To this end, a working group within the Germany-based project ClimXtreme, has been established to carry out multidisciplinary analyses of high-impact events. In this work, we provide a comprehensive assessment of the 29 June 2017 Heavy Precipitation Event (HPE) affecting the Berlin metropolitan region (Germany), from the meteorological, impacts and climate perspectives, including climate change attribution. Our analysis showed that this event occurred under the influence of a mid-tropospheric trough over western Europe and two short-wave surface lows over Britain and Poland (Rasmusund and Rasmusund II), inducing relevant low-level wind convergence along the German-Polish border. Over 11000 convective cells were triggered, starting early morning 29 June, displacing northwards slowly under the influence of a weak tropospheric flow ( $10 \text{ m s}^{-1}$  at 500 hPa). The quasi-stationary situation led to totals up to  $196 \text{ mm d}^{-1}$ , making this event the 29<sup>th</sup> most severe in the 1951-2021 climatology, ranked by means of a precipitation-based index. Regarding impacts, it incurred the largest insured losses in the period 2002 to 2017 (€60 Mill) in the greater Berlin area. We provide further insights on flood attributes (inundation, depth, duration) based on a unique household-

level survey data set. The major moisture source for this event was the Alpine-Slovenian region (63 % of identified sources) due to recycling of precipitation falling over that region 1 day earlier. Implementing three different Generalized Extreme Value (GEV) models, we quantified the return periods for this case to be above 100 years for daily aggregated precipitation, and up to 100 years and 10 years for 8 h and 1 h aggregations, respectively. The conditional attribution demonstrated that warming since the pre-industrial era caused a small, but significant increase of 4 % in total precipitation and 10 % for extreme intensities. The possibility that not just greenhouse-gas-induced warming, but also anthropogenic aerosols affected the intensity of precipitation is investigated through aerosol sensitivity experiments. Our multi-disciplinary approach allowed us to relate interconnected aspects of extreme precipitation. For instance, the link between the unique meteorological conditions of this case and its very large return periods, or the extent to which it is attributable to already-observed anthropogenic climate change.

## 1 Introduction

According to the World Economic Forum Global Risks Perception Survey (Forum, 2020), extreme weather is the number one risk by likelihood and one of the top four risks by impact. One of the most impactful weather types is extreme precipitation, which yearly causes local ecosystems and urban areas to suffer important damages and casualties. The probability of occurrence and magnitude of this extreme weather is projected to increase in northern and central Europe in a warming climate, as assessed by the 6th Assessment Report of the Intergovernmental Panel on Climate Change (Douville et al., 2021).

The interaction of processes across scales hampers our comprehension and prediction of Heavy Precipitation Events (HPEs). Extreme precipitation will occur only under favourable synoptic-scale conditions (Brieber and Hoy, 2018) with sufficient moisture transport (Davolio et al., 2020; Caldas-Alvarez et al., 2021), and atmospheric instability (Khodayar et al., 2021), fostered by propitious phases of climate modes (Ehmele et al., 2020). This complexity is further amplified if the impacts of heavy precipitation are to be addressed. In addition to the intensity of the hazard, the impact of an event depends on the exposure and vulnerability of the affected area (Alfieri et al., 2015). This is why multidisciplinary, forensic analysis is a powerful means to deal with the complex interactions underlying an HPE and its impacts. Forensic analysis consists of addressing different aspects of heavy precipitation jointly, so that the interconnections between different findings can be identified. For instance, Bronstert et al. (2018) investigated the Braunsbach flood in 2016, a flash flood event in a sparsely observed area, analysing the damages in the built-up area as well as its geomorphological impacts. Kunz et al. (2013) analysed Hurricane Sandy in 2012, combining an in-depth assessment of its impacts with the usage of information from social networks for event reconstruction. Gochis et al. (2015) and Milrad et al. (2015) presented detailed post-event analyses using measurements, operational data products and application of models especially suited for widespread events in well-observed areas for the Colorado and Alberta floods (2013), respectively. Finally, other studies (e.g., Eden et al., 2016) have complemented forensic studies with climate change attribution experiments.

The favourable synoptic conditions for HPE development in central Europe have been assessed in previous literature. Werner and Gerstengarbe (2010), using weather pattern classification, concluded that summer HPEs over Central Europe are often caused by three synoptic situations, a Trough over Central Europe (Tr), low pressure over Central Europe (TM) and a Trough

over West Europe (TrW), see also Wulfmeyer et al. (2011). Brieber and Hoy (2018) found the highest probabilities for heavy precipitation events in central Germany when a TrW pattern is present, favouring the development of large-scale systems such as Vb-like cyclones or heat lows and prefrontal convergence zones. Depending on the location of the small-scale disturbances, warm and moist air masses are transported from southern Europe towards Germany. When temperatures are already very high, the resulting increased CAPE leads to localized extreme precipitation (Bronstert et al., 2018).

A full understanding of the meteorological drivers and (small-scale) physical processes of extreme precipitation can benefit from high-resolution observations and model simulations. Numerical models offer a robust tool to simulate extreme precipitation events with fine-scale spatio-temporal detail. Furthermore, numerical models can also be used to create climate time series long enough to capture multi-decadal variability and numerous extreme events (Ehmele et al., 2020; Pichelli et al., 2021). Over the last decade, increased computing power has seen the growing use of kilometre-scale "storm-resolving" or convection-permitting models (CPMs; Berg et al., 2012; Barthlott and Hoose, 2015; Schwitalla et al., 2020; Stevens et al., 2020; Lucas-Picher et al., 2021), in which spatial resolution is sufficiently high ( $\Delta x < 3$  km) to explicitly simulate deep convection. CPMs have thus shown added value for the simulation of sub-daily extreme precipitation intensities, their spatial extent and duration, as well as their diurnal cycles (Kendon et al., 2012; Warrach-Sagi et al., 2013; Fosser et al., 2014; Stevens et al., 2020; Meredith et al., 2021). This added value offers important utility for climate-change attribution studies since CPMs give a better representation of convective extremes and are thus more reliable for detecting their climate-change response (Prein et al., 2013, 2015; Ban et al., 2021).

The impacts of extreme precipitation and the resulting pluvial flooding on society can include the loss of life, physical damage to assets such as buildings or infrastructure, as well as intangible consequences such as health impacts or traffic disruptions (Merz et al., 2010; Rözer et al., 2016). The impacts depend on the hazard intensity, the exposed assets and their vulnerability (Kron, 2005). The hazard level itself is a function of meteorological factors, e.g. precipitation intensity or affected area. The exposure and vulnerability depend on aspects such as the inundation depth, the topography, the degree of sealing of surfaces, or the sewer system capacity (Kron, 2005; Smith et al., 2015).

To analyse the associated impacts, not only meteorological data is crucial, but also targeted information collected during or after an event, e.g. damage to buildings and contents. Such data can be collected, for example, through surveys of affected households or through assessments by loss surveyors during insurance claim validation (Spekkers et al., 2014, 2017; Van Ootegem et al., 2015, 2018; Rözer et al., 2019). However, when analysing damage records, it is important to consider that results depend on how the affected society understands, records, and remembers those impacts (Kuhlicke et al., 2020). The case under study here, the 29 June 2017 HPE in the metropolitan Berlin area (Germany), has been investigated before based on survey data of affected households in Berlin-Brandenburg. Berghäuser et al. (2021) and Dillenardt et al. (2021) addressed the tangible and intangible consequences of extreme precipitation and associated pluvial flooding for households for this event, respectively, but a focused analysis comparing its impacts to those of similar HPEs in the climatology is still lacking.

From the climate perspective, information on how the frequency of HPEs has changed in the recent climate is demanded by interested stakeholders. This can be provided through estimation of probabilities of exceedance or return periods for specific events. Generalized Extreme Value (GEV) models can be fitted to a climate observational precipitation dataset to derive this

information (Wilks, 2006). Previous studies have provided estimations of return periods for similar events, finding extreme values of over 200 years for the Seine river flooding (France) in 2016 (Philip et al., 2018), the Braunsbach flooding (southern Germany) in 2016 (Piper et al., 2016) and the three-week flooding in Germany in 2018 (Mohr et al., 2020). The flooding in 85 July 2021 in the Ahr, Erft and Meuse rivers, was analysed by Kreienkamp et al. (2021), who found that an event of similar meteorological characteristics can be expected in the present climate in Central Europe once every 400 years.

Also at the climate scale, extreme event attribution has proven useful to estimate how the severity and/or likelihood of an event has been affected by anthropogenic influences (Allen, 2003; Stott et al., 2004; Otto, 2017). Anthropogenic influence typically refers to climate change, but could also include, e.g., land-use changes (Sebastian et al., 2019) or changes in atmospheric pollutants (Liu et al., 2020). To this end there are two mainly-used approaches. The first approach is probabilistic event 90 attribution, which consists of simulating how the dynamics of the climate system evolve under climate change. It can therefore be used to detect significant changes in the severity and frequency of extreme events. This technique, however, is applicable to model data with a relatively coarse resolution and is, therefore, best suited for attribution studies of large-scale events. The second approach is conditional event attribution (Trenberth et al., 2015), which evaluates to what extent observed climate 95 change may have impacted the magnitude of an event. The attribution is thus conditional on the presence of a given dynamical situation, and implies that thermodynamic changes due to climate change have been demonstrated. However, a limitation of this approach is that changes in the probability of the event's underlying dynamical situation cannot be determined.

The research presented here has been carried out in the framework of the Germany-based project Climate change and eX-treme events (ClimXtreme), which brings together governmental and research institutions in the fields of atmospheric physics, 100 statistics, impact studies and computing. This framework facilitates the multi-disciplinary approach of this study, where in addition to the usual communication and collaboration tools, the ClimXtreme Central Evaluation System (XCES) (Kadow et al., 2021) has allowed centralized consultation and analysis of all the data within the project.

The aim of this study is to provide a comprehensive assessment of the 29 June 2017 HPE in the area of Berlin (Germany) from the meteorological, impacts and climate perspectives, including climate change attribution. The paper is structured as follows: 105 in Sect. 2 we present the observational and modelling datasets used, in Sect. 3, the particular techniques and methodologies used are introduced. Section 4 shows the main analyses and outcome of our work and in Sect. 5 we present our conclusions and outlook.

## 2 Data sets

### 2.1 Observations

#### 110 **REGionalisierte NIEederschlaege (REGNIE)**

REGNIE is a gridded data set of 24-hour totals (from 06 UTC to 06 UTC) based on approximately 2,000 rain gauges distributed across Germany. A post-processing is applied to station data for regridding to a  $1 \times 1 \text{ km}^2$  mesh taking into account elevation, exposure and climatology, avoiding smoothing observed precipitation extremes (Rauthe et al., 2013; Hu and Franzke, 2020). The data are provided by the German Meteorological Service (Deutscher Wetterdienst, DWD) from 1951 for all of Germany

115 (for the former West Germany, the daily values are available since 1931). The long-term availability of REGNIE is its main  
advantage for climate studies.

### **RADar KLIMatologie (RADKLIM)**

RADKLIM is a precipitation climate data set derived from the C-band radar network (17 radar sites) operated by DWD.  
120 The data set comprises two products; the gauge-adjusted one-hour precipitation sum (RW) and the quasi gauge-adjusted five-  
minute precipitation rate (YW), with  $1 \times 1 \text{ km}^2$  resolution. The data are post-processed using the Radar-Online-Aneichung  
(RADOLAN) method, correcting existing artifacts by adjusting precipitation sums from the radar with precipitation measure-  
ments from rain gauge stations (Bartels et al., 2004). Due to the dense spatial and temporal resolution, RADKLIM detects  
short-term, convective extreme intensities frequently missed by station data (Lengfeld et al., 2020; Winterrath et al., 2017).

125

### **Deutscher Wetterdienst (DWD) stations**

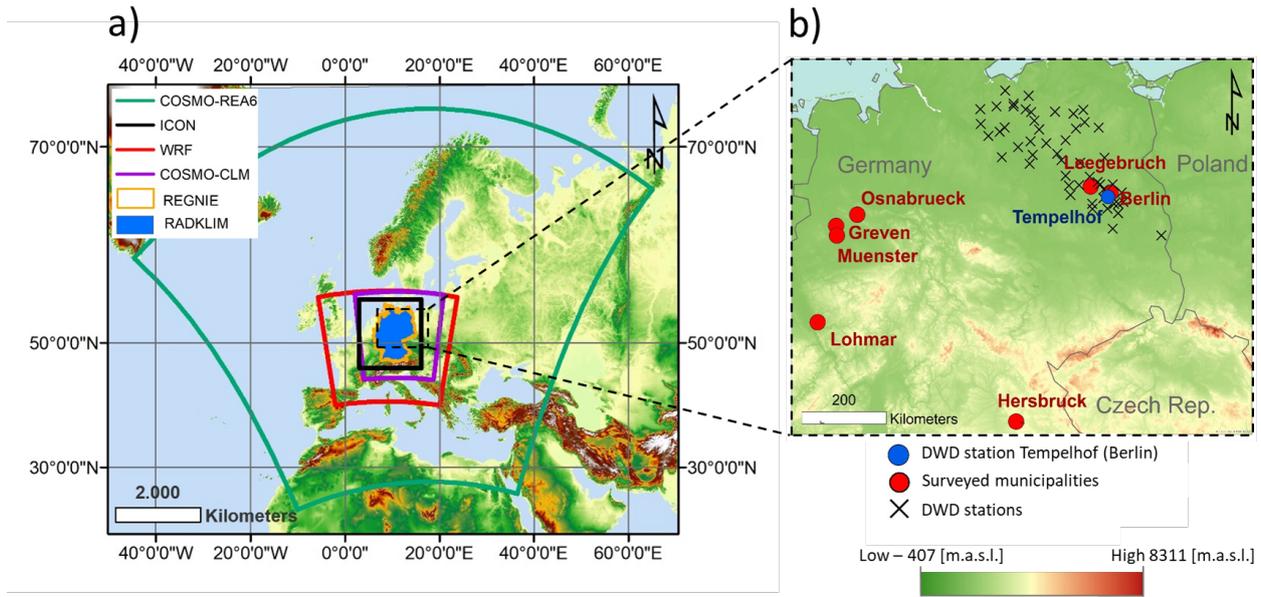

Daily precipitation measurements from the DWD high-density network were used as reference. The data are quality controlled,  
but a continuous homogenization is not applied. Hence, the data could be subject to partial inhomogeneities, such as station  
relocations or changes in the instrumentation (Kaspar et al., 2013). The DWD high-density network has a high accuracy and  
130 resolution (Kaspar et al., 2013) and therefore we select it for validation. Nonetheless, this dataset is used for deriving the  
REGNIE gridded product and for adjusting RADKLIM which makes these data sets dependent. We concede this dependency  
to profit from the best rain gauges product available in the region.

### **European Cooperation for Lightning Detection (EUCLID)**

135 The lightning activity in and around Berlin is investigated with data from the ground-based low-frequency lightning detection  
system EUropean Cooperation for LIghtning Detection (EUCLID) network, which covers the whole European continent (Drüe  
et al., 2007; Schulz et al., 2016; Poelman et al., 2016). Cloud-to-ground strokes are used to illustrate the temporal development  
of convective activity during the extreme event, similar to Piper and Kunz (2017) and Wilhelm et al. (2021). The spatial  
resolution of EUCLID has been improved to less than 90 m in the year 2016 due to algorithm optimizations (Schulz et al.,  
140 2016).

### **Catalogue of Radar-based heavy Rainfall-Events (CatRaRE)**

The RADKLIM data set at 1 h and  $1 \times 1 \text{ km}^2$  km resolution (RW) was used as the basis to derive an HPE catalogue for Germany  
(CatRaRE) for the period 2001 to 2020. Here we use Version 2017.002 (Lengfeld et al., 2021a, b), including precipitation sums  
145 with 11 different accumulation periods (1, 2, 3, 4, 6, 9, 12, 18, 24, 48 and 72 hours). For each duration and time step, extreme  
events are detected based on the DWD Warning Level (WL) 3 for severe weather, or if they have a return period of 5 years.  
The duration in hours, the affected area in  $\text{km}^2$ , the location (county and community), the maximum and mean precipitation  
amount in mm as well as affected residents in the event area and further meta information is included.

**Figure 1.** a) Spatial extent of the used data sets REGNIE, RADKLIM, COSMO-REA6, WRF-1.5km, ICON-625m and COSMO-CLM-2.8. b) Close-up view of Berlin and surroundings, as well as the DWD stations used for validation (crosses), the location of surveyed events from Table 1 (red dots) and the Berlin-Tempelhof station analysed in Figure 11 (blue dot), Basemap: Global Land One-kilometer Base Elevation (GLOBE) (Hastings et al., 1999).

## 2.2 Reanalyses

### 150 ERA5

ERA5 data are used to identify and track the low pressure systems, find moisture sources and force numerical simulations. This is the fifth generation of the European Center for Medium-Range Weather Forecasts' (ECMWF) atmospheric reanalysis of the global climate (Hersbach et al., 2020). It has a spatial resolution of  $31 \times 31 \text{ km}^2$  and is available from 1950 to present at hourly resolution. ERA5 is based on the Integrated Forecasting System (IFS) and uses a 4D-Var assimilation scheme, assimilating 155 different observation types. ERA5 has demonstrated a good performance in representing heavy precipitation (Keller and Wahl, 2021).

### COSMO-REA6

COSMO-REA6 is a regional reanalysis product for the European CORDEX domain, developed by University of Bonn and 160 the Hans-Ertel-Centre for Weather Research. It has a  $6 \times 6 \text{ km}$  horizontal resolution and is available from Jan 1995 to Aug 2019. It is based on the NWP-system COSMO and uses a nudging scheme for data assimilation. Subgrid-scale convection is parameterized with the Tiedtke scheme (Tiedtke, 1989) and precipitation from meteorological stations or radar is not assim-

ilated (Bollmeyer et al., 2015). COSMO-REA6 has shown low biases for extreme precipitation compared to other reanalysis products (Keller and Wahl, 2021).

## 165 2.3 Convection Permitting Models

### Weather Research and Forecasting (WRF)

WRF model version 4.2.1 (Skamarock et al., 2021) at a convection permitting resolution of 1.5 km with 100 vertical levels is used. The model domain covers central Europe (Fig. 1a) and the simulation was initialized with the operational ECMWF analysis at 00 UTC on 29 June 2017 (12 hours before the event). Lateral boundary conditions were provided every 6 hours. The  
170 setup of the physical parametrizations is similar to Schwitalla et al. (2021) except that 1) the Mellor–Yamada–Nakanishi–Niino (MYNN) planetary boundary layer parametrization (Nakanishi and Niino, 2006, 2009; Olson et al., 2019) is applied, and 2) the microphysics scheme of Thompson and Eidhammer (2014) is used. Land cover maps have been updated using the high-resolution European Space Agency Climate Change Initiative (ESA CCI) data set (ESA, 2017). In addition, the green vegetation fraction and leaf area index (LAI) have been adjusted for 2017 by means of the Copernicus Global Land Service portfolio 1  
175 km resolution data sets (<https://land.copernicus.eu/global/>). Finally, high-resolution soil texture data from Poggio et al. (2021) (<https://soilgrids.org>) were used.

### Consortium for Small Scale Modelling in CLimate Mode (COSMO-CLM)

COSMO-CLM version 5.0\_clm16 is run at a convection-permitting resolution of  $0.025^\circ$ . The model has  $461 \times 421 \times 50$   
180 gridpoints (lat/lon/height), a model top at 22.7 km and a relaxation zone of 50 km. Hourly lateral boundary conditions include cloud ice, cloud water and cloud graupel, and are provided by ERA5-forced  $0.11^\circ$  simulations (Section 3.6). Deep convection is treated explicitly and shallow convection is parametrized with a modified Tiedtke scheme (Tiedtke, 1989). A full description of all model physics is found in Baldauf et al. (2011).

### 185 Icosahedral Non-hydrostatic Model (ICON)

The ICON simulations follow Costa-Surós et al. (2020) and were initialized with the operational ECMWF analysis (IFS data) at 00 UTC on 29 June 2017 and lateral boundary conditions are provided every 6 h. For analysis, the daytime period between 06:00 and 20:00 UTC is chosen.

## 3 Methods

190 This section introduces the methods used in the different aspects of the analysis.

### 3.1 The Precipitation Severity Index (PSI)

We use the Precipitation Severity Index (PSI; Caldas-Alvarez et al., 2022) to detect extreme precipitation events according to three different but complementary characteristics of heavy precipitation: intensity, spatial extent and persistence. The PSI

in its current form is an adaptation of the Storm Severity Index (SSI; Leckebusch et al., 2008; Pinto et al., 2012) and is a  
195 unitless index that indicates the degree of daily precipitation severity with respect to a predetermined climatological threshold  
(in our case the 80<sup>th</sup> percentile). Large PSI values represent high intensity, geographically extensive and temporally persistent  
precipitation events.

### 3.2 Lagrangian convective cell tracking

We perform Lagrangian convective cell tracking for the years 2001 to 2020 for a region of 200 x 200 km centered over Berlin.  
200 Pixels of YW RADKLIM radar data exceeding a threshold of 8.12 mm/h were identified as convective cells (Purr et al., 2021).  
The displacement of the cell is projected applying the 700 hPa wind of ERA5. If in the consecutive timestep a convective cell  
has been found in the area defined by a search radius around the projected position, both cells are assigned to the same cell  
track. If multiple cells are found within the search radius, the cell with the minimum distance is assigned to the cell track.

### 3.3 Lagrangian moisture backward trajectories

205 We calculate Lagrangian backward trajectories following Sodemann et al. (2008), based on ERA5 reanalysis data (Hersbach  
et al., 2020), in a mid-European region around the center of maximum precipitation (red box in Fig. 9). We start the trajectories  
from 1000 hPa to 200 hPa in steps of 50 hPa for every hour of 29 June 2017, with a horizontal grid spacing 80 km and going  
back 240 h in time. From all trajectories, we selected those that have a relative humidity of at least 80 % in the target box  
and for which the specific humidity decreases during the last time step (precipitation) (Sodemann et al., 2008; Grams et al.,  
210 2014). Along each selected trajectory, moisture uptake has been computed based on hourly specific humidity increases in  
the planetary boundary layer associated with evapotranspiration from the surface. The boundary layer height is available as a  
diagnostic model variable in the ERA5 data set and, again following Sodemann et al. (2008), is multiplied by a factor of 1.5 to  
account for potential uncertainties in this diagnostic estimate. These uptakes have been weighted according to their contribution  
to the precipitation (moisture loss) at the target location, taking into account that earlier moisture uptake may contribute less  
215 due to precipitation loss on their way to the target region.

### 3.4 Household surveys for impact evaluation

To assess the overall losses caused by the 29 June 2017 HPE, we review reports from the German Insurance Association  
(GDV), which published loss estimates for severe extreme precipitation events in Germany in the period 2002-2019 (GDV,  
2018, 2020, 2021), and other technical reports (Hydrotec et al., 2008). At the household level, we use losses, flood-duration  
220 and flood-depth data derived from household surveys in Berlin and Brandenburg (Dillenardt et al., 2021). We furthermore use  
survey data from private households in Hersbruck (affected in 2005), Lohmar (affected in 2005), Osnabrueck (affected in 2010)  
(Rözer et al., 2016) and Muenster (affected in 2014) (Spekkers et al., 2017). In the surveys, affected households were asked,  
inter alia, when they were last affected by heavy rain and what impact they suffered. The results of the surveys are based on  
the responses of those households and are thus subjective.

The standard GEV distribution applied to heavy precipitation in this work is given by Coles (2001):

$$G(R) = \exp \left( - \left\{ 1 + \xi \left( \frac{R - \mu}{\sigma} \right) \right\}^{-1/\xi} \right), \quad (1)$$

where  $\mu$  denotes the location parameter,  $\sigma$  the scale ( $\sigma > 0$ ) and  $\xi$  the shape parameter. A special case of the standard distribution (Eq. 1) is the Type I or Gumbel distribution (Gumbel, 1958) obtained in the limit  $\xi \rightarrow 0$  used as well in previous works  
230 (e.g. Grieser et al., 2007; Svensson and Jones, 2010; Van den Besselaar et al., 2013; Maity, 2018; Piper et al., 2016):

$$F(R) = \exp \left( - \exp \left( \frac{\mu - R}{\sigma} \right) \right). \quad (2)$$

This simplification allows estimation of the two free GEV parameters  $\mu$  and  $\sigma$  by means of the Method of Moments, which is less computationally intensive and has been proven useful in the past (e.g. Svensson and Jones, 2010; DWA, 2012; Piper et al., 2016). Characteristic of the Gumbel distribution is an exponential decay of the probability density function, meaning  
235 that only two free parameters of the GEV-fit have to be estimated. However, the Gumbel is not a heavy-tailed distribution and is characterised by constant skewness and kurtosis.

We fit block maxima series to Eqs. 1 and 2 obtained by splitting the sample into non-overlapping intervals of the same size and then taking the maximum value of each interval. Previous studies have demonstrated that the annual block maxima approach is suitable for mid-latitude precipitation series (Kharin and Zwiers, 2000; Rust, 2009). We specify the uncertainty of  
240 the models by using 95 % confidence intervals obtained from 1000-fold bootstrapping (re-sampling with replacement) from the maxima series of the original data set (Efron and Tibshirani, 1993), following the ordinary non-parametric bootstrap percentile method of Mélèse et al. (2018). From these 1000 samples the 2.5 % and 97.5 % quantiles of the wanted property (either return periods or return values) indicate their confidence boundaries.

We further implement a duration-dependent (*d*-GEV) model with 7 parameters, which covers different durations to achieve  
245 a more efficient usage of observations. This way, information about short time scales (minutes to hours), can be derived, to a certain extent, from information of longer time scales (hours to days). Duration-dependency is incorporated into the GEV in order to reduce assumptions about the underlying distribution and have a free shape parameter  $\xi$  in the GEV (Coles, 2001). Another reason for using the GEV instead of one of their special cases, is that Gumbel, as well as the other two GEV special cases Fréchet and Weibull, require large data sets to fulfil the limiting theorem for large block sizes (Papalexiou and  
250 Koutsoyiannis, 2013). The *d*-GEV includes all three types and is a good choice if block size does not reach the asymptotic regime required for Gumbel. A duration-dependent GEV (*d*-GEV) as suggested by Koutsoyiannis et al. (1998) and refined by

Fauer et al. (2021) is introduced by varying the characteristic parameters of the GEV:

$$G_d(R; d) = \exp \left( - \left\{ 1 + \xi \left( \frac{R - \mu(d)}{\sigma(d)} \right) \right\}^{-1/\xi} \right), \quad (3)$$

$$\sigma(d) = \sigma_0(d + \theta)^{-(\eta_1 + \eta_2)} + \tau,$$

$$\mu(d) = \tilde{\mu}(\sigma_0(d + \theta)^{-\eta_1} + \tau),$$

$$\xi = \text{const.},$$

where  $\tilde{\mu}$  is the re-scaled location parameter,  $\sigma_0$  is the scale offset,  $\theta$  is the duration offset,  $\eta_1$  and  $\eta_2$  are duration exponents and  $\tau$  is the intensity offset. Parameters were estimated with Maximum Likelihood Estimation (MLE), a flexible and efficient parameter estimation method which is known to provide asymptotically unbiased and smallest-possible variant estimates (Coles, 2001; Davison and Huser, 2015). However, MLE is more computationally expensive than the method of moments. Jurado et al. (2020) justified the use of the MLE for duration-dependent extreme precipitation studies as the explicit consideration of the dependence between durations in a model leads to only marginal differences in estimation. The  $d$ -GEV has been recently applied successfully by Ulrich et al. (2020).

### 3.6 Conditional event attribution with CPM

For the conditional climate-change attribution experiment (Section 4.5), high-resolution ensembles (17 members) of the event under present and pre-industrial conditions are simulated with the COSMO-CLM (Rockel et al., 2008). For the present climate, ERA5 reanalysis (Hersbach et al., 2020) is dynamically downscaled to  $0.11^\circ$  for 17 members (Fig. S3) using the domain-shift ensemble technique (e.g. Rezacova et al., 2009; Noyelle et al., 2019). All members are then further dynamically downscaled to a convection-permitting  $0.025^\circ$  resolution over a geographically-fixed sub-domain (see Section 2.3). To create the pre-industrial ensemble, the warming signal since the pre-industrial period, here taken as 1850-1859 versus 2007-2016 (over the  $0.11^\circ$  domain), is first computed from a subset of 17 Coupled Model Intercomparison Project Phase 6 (CMIP6) models (O'Neill et al., 2016). The warming signal (Fig. 12a) is then subtracted from the ERA5 initial and boundary conditions of the  $0.11^\circ$  simulations (surface temperatures are modified based on the warming signal at the lowest model level). A similar procedure is repeated for soil temperature. The atmospheric moisture content is adjusted based on the assumption that relative humidity remains constant. Pressure at the COSMO-CLM height-levels is adjusted by numerically integrating the hydrostatic balance equation downwards from the model top (Kröner, 2016). The  $0.11^\circ$  and  $0.025^\circ$  simulations are initialized on 28 June at 12:00 and 23:00 UTC, respectively, giving sufficient spin-up and adjustment time prior to the analysis period of 07:00 to 22:00 UTC the following day (chosen based on the analysis in Fig. S4). The attribution analysis consists of comparing the precipitation between the  $0.025^\circ$  ensembles with the pre-industrial ensemble as the reference state. COSMO-CLM model settings are as described in Meredith et al. (2021). Further details of the simulations and the CMIP6 models can be found in the supplementary material.

### 3.7 Aerosol sensitivity experiments

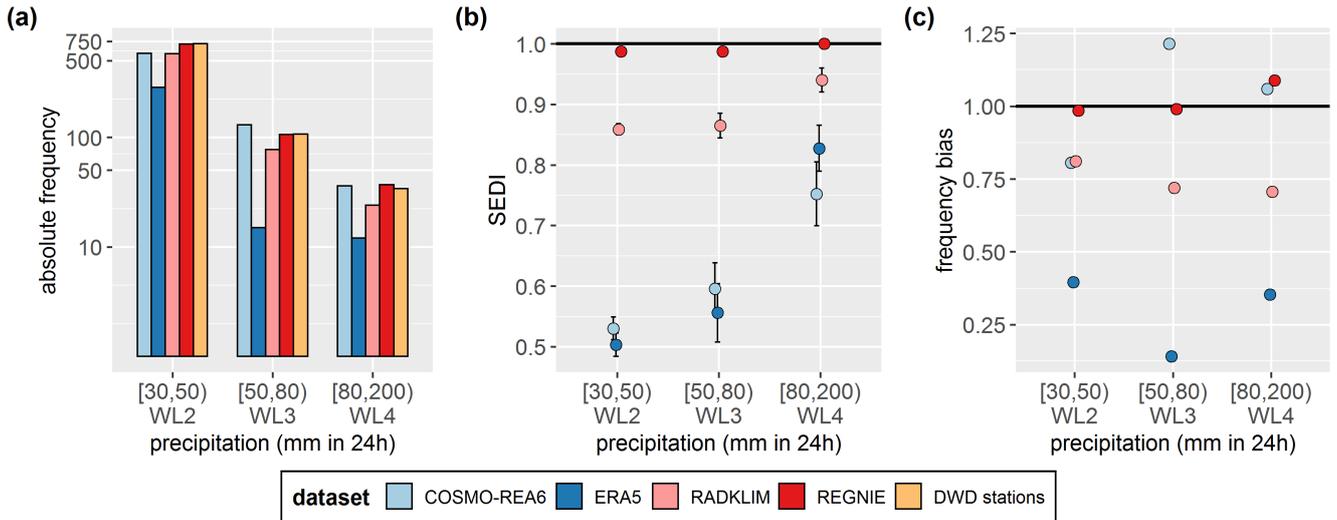

Simulations with the ICOSahedral Non-hydrostatic (ICON) atmospheric model were conducted to examine the possible role of anthropogenic aerosols in the analysed event. The model domain covered central Europe (Fig. 1), for which one-way nested simulations at resolutions of 625 m and 1.25 km, respectively, are produced with 90 vertical levels. Two hectometer ICON simulations are carried out with two different imposed concentrations of cloud condensation nuclei, i.e. one with low concentrations, corresponding to current conditions (CLN), and one with elevated aerosol concentrations (POL), corresponding approximately to the peak aerosol concentrations over Central Europe observed in the mid-1980s.

## 4 Results

Provided our multi-disciplinary approach, we need to verify that there are no inconsistencies among the different datasets used. To reduce this uncertainty we need to ensure that all of them represent a similar climatology of heavy precipitation in the region. To this end, we provide a quantitative validation of the products REGNIE, RADKLIM, ERA5, and COSMO-REA6 for the period 2001-2018. We compare these datasets pointwise (by selecting the nearest neighbour grid cell) to observations made at 53 DWD stations (Sect. 2.1; Fig. 1). COSMO-REA6 is included in this comparison to provide a reference for ERA5 with another reanalysis product. We compute absolute frequencies, as the number of days with a specific amount of precipitation for each data set; the Symmetric External Dependency Index (SEDI), estimating the dependency between an event in the given data set and the reference observations (Ferro and Stephenson, 2011); and the frequency bias as the ratio between the number of events in the data sets and the reference observations (Hogan et al., 2009). The evaluations are made for three precipitation intervals based on the warning levels used operationally by the DWD, namely WL2 ( $> 30$  mm), WL3 ( $> 50$  mm) and WL4 ( $> 80$  mm). The 29 June 2017 HPE falls into the WL4 category.

REGNIE, RADKLIM and COSMO-REA6 perform well, in representing the climatology of extreme precipitation (WL4 category). In particular, REGNIE fits best the DWD station observations for absolute frequency (37 events in REGNIE, 34 in the DWD stations at WL4), followed by RADKLIM (24 events in WL4). ERA5 (Fig. 2.a) only has 12 events (WL4). Regarding SEDI (Fig. 2.b), REGNIE again compares best with station observations, also followed by RADKLIM (Fig. 2b) in contrast to the coarser resolution reanalysis products which show lower SEDI values. However their performance is better for extreme precipitation (WL4). Finally, for frequency bias, REGNIE shows no deviations, RADKLIM has a negative but acceptable bias, i.e. less events detected, and ERA5 performs poorly for all WLS.

To summarize, we find a good agreement of REGNIE and RADKLIM with the DWD station observations which gives us confidence that their representation of HPEs will be consistent. ERA5, however showed a bad performance for absolute and frequency bias and the moderate precipitation categories (WL2 and WL3) for SEDI. The performance of ERA5 was worse than the other reanalysis product, COSMO-REA6, possibly due to their difference in model resolution. For this reason ERA5 will not be used hereafter to study heavy precipitation fields. Its use will be restricted to other relevant large-scale atmospheric fields such as water vapour (Fig. 9) that are well constrained by the data assimilation.

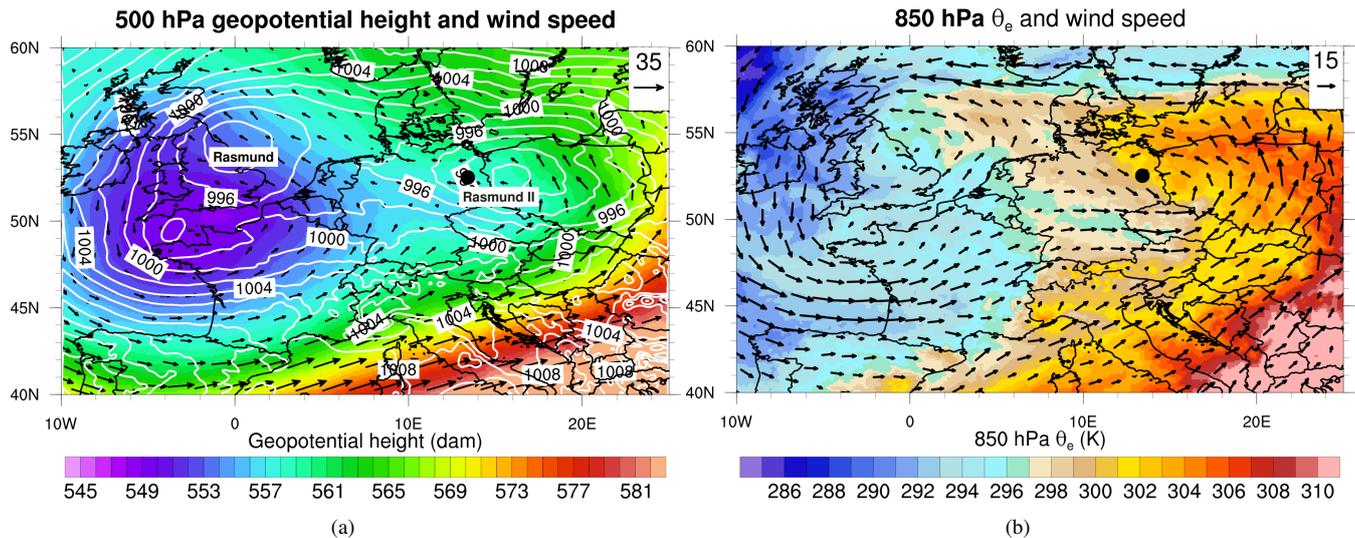

**Figure 2.** Evaluation of daily precipitation estimates from REGNIE, RADKLIM, ERA5 and COSMO-REA6 compared with DWD station observations (see Fig. 1.b). The selected period is 2001 to 2018 (concurrent period of data availability), using the nearest neighbour grid cells to the DWD stations. (a) Histogram showing the absolute occurrences of precipitation within WLs 2, 3 and 4, (b) Symmetric Extremal Dependency Index (SEDI) and (c) frequency bias. Positive (negative) frequency bias indicates an overestimation (underestimation) of events, the black horizontal line represents the optimum value.

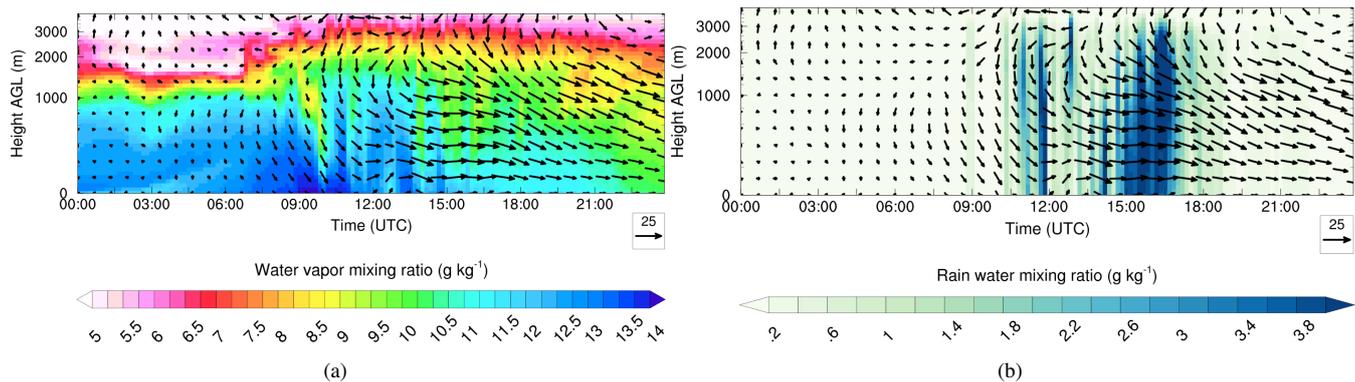

#### 4.1 Event analysis and climate context

315 The 29 June 2017 HPE occurred under the influence of an upper-level trough extending between the Iberian Peninsula and Poland (TrW pattern) between 28 June and 01 July. During this period, several short-wave surface lows developed on the northern side of the trough (Fig. 3.a) inducing favourable conditions for convective development. Two small-wave surface lows caused most of the precipitation collected over Berlin during 29 June. The first system, named Rasmund, remained quasi-stationary east of the British Isles between 28 June and 01 July, reaching values of the Pressure at the Mean Sea Level (PMSL) of 994 hPa (Fig. 3.a). The second surface low, Rasmund II, originated in the night from 28 to 29 June over central Europe (Czech Republic), displaced towards northern Poland over the course of 6 h, and showed PMSL of 990 hPa along the German-Polish border at 12 UTC.

The mesoscale circulation associated with the mid-tropospheric low Rasmund II over northern Poland (550 dam; Fig. 3a) brought a warm and moist cyclonic inflow, crucial for the development of heavy precipitation over Berlin. The Equivalent Potential Temperature ( $\theta_e$ ) at 850 hPa (Fig. 3b) showed values up to 305 K from the Mediterranean up to Poland and Berlin, indicative of a high moisture availability and optimal conditions for associated stationary deep-moist convection. Mixed-Layer Convective Available Potential Energy (ML-CAPE) at the site was moderate, of approx.  $250 \text{ J kg}^{-1}$ , while Convective Inhibition (CIN) was to zero, as shown for the Lindenberg station (black dot in 3) at 06 UTC 29 June 2017.

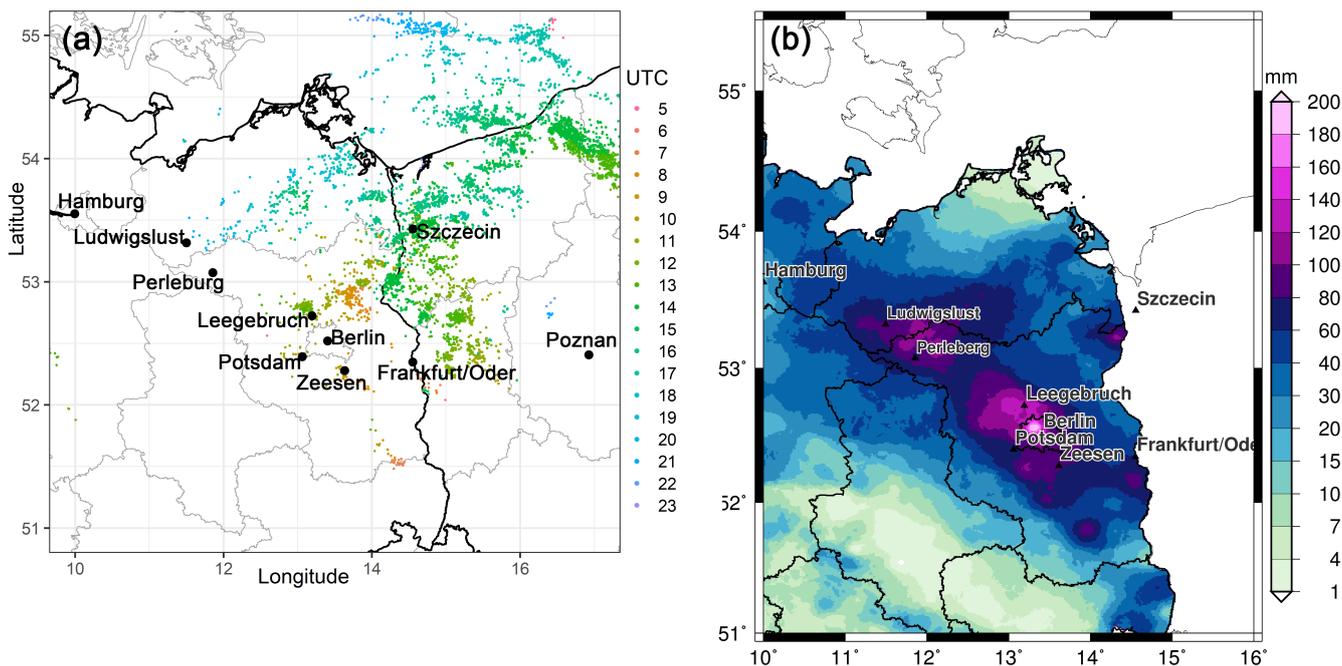

**Figure 3.** a) 500 hPa geopotential height (dam; colour) and wind speed ( $\text{m s}^{-1}$ ) together with sea level pressure (hPa; contours) and b) 850 hPa equivalent potential temperature ( $\theta_e$ ) and wind speed on 29 June, 2017 12 UTC from the ECMWF analysis. The black dot denotes the city of Berlin.

**Figure 4.** Time-height cross section of (a) water vapour mixing ratio ( $\text{g kg}^{-1}$ ) and (b) rain water mixing ratio ( $\text{g kg}^{-1}$ ) at grid point 13.2 °E and 52.85 °N (close to the maximum heavy precipitation location, near black dot in Fig. 3) simulated by the WRF model. The displayed period is 00 UTC until 23:45 UTC on 29 June 2017. Arrows denote the horizontal wind speed ( $\text{m s}^{-1}$ , see lower right of the plots for a length indicating 25  $\text{m s}^{-1}$ ) and direction at the different altitudes. Altitude is above ground level (AGL).

The triggering mechanism was a low-level convergence line fostered by the counter circulations of Rasmund and Rasmund II over eastern Germany (Fig. 3), (Gebauer et al., 2017). The encountering circulations also imposed a weak southerly flow atop with 10  $\text{m s}^{-1}$  at 500 hPa (not shown) and less than 5  $\text{m s}^{-1}$  at 850 hPa (black arrows in Fig. 3b). The weak mid-tropospheric flow was responsible for the slow displacement of the convective systems.

Values of Precipitable Water Vapour (PWV) up to 40 mm were measured at the Lindenberg station, near Berlin (Fig. S1) at 11:30 UTC, and it is probable that water vapour mixing ratios of more than  $6.5 \text{ g kg}^{-1}$  were present at 2500 m above ground level over Berlin 3 h prior to precipitation initiation. This was shown by WRF 1.5 km simulations (Sect. 2.3) covering the greater Berlin area (Fig. 1). For a selected grid point located northwest of Berlin (black dot in Fig. 3.a) WRF simulates water vapour mixing ratios of more than  $13 \text{ g kg}^{-1}$  in the lowest 100 m above ground between 10 UTC and 19 UTC together with a strong low- to mid-level jet evolving after 13 UTC (Fig. 4a). This low-level jet is probably induced by the temperature gradient between the colder and drier air masses in southwest Germany and the warm and moist air masses over northeastern Germany (Fig. 3b). The simulated rain water mixing ratios exceeded  $3.5 \text{ g kg}^{-1}$  (Fig. 4b), potentially indicating a warm-rain type precipitation event (e.g. Song and Sohn, 2018) which is associated with a strong downdraft of  $\sim 5 \text{ m s}^{-1}$  (Fig. S2).

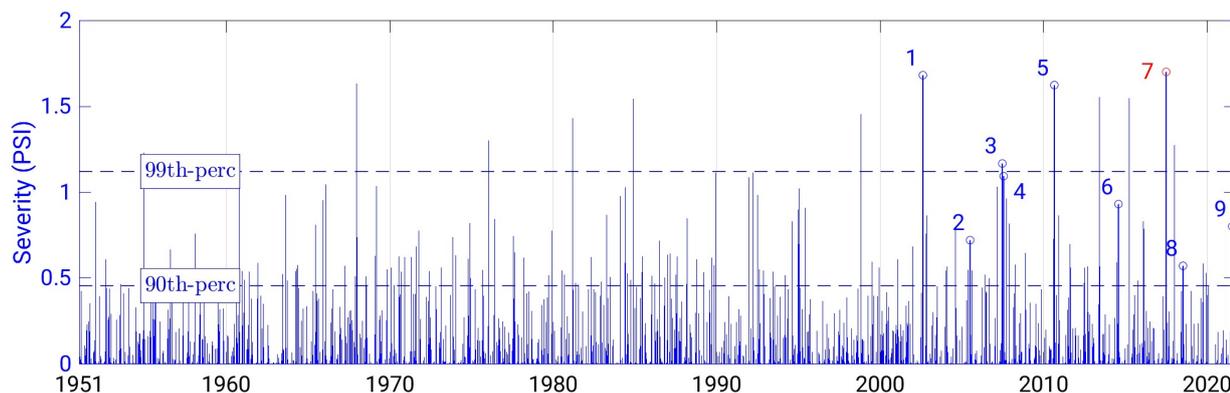

**Figure 5.** (a) Cloud-to-ground strokes from the EUCLID data set, colour-coded according to the time of occurrence from 5 UTC on 29 June 2017 to 0 UTC on the following day and (b) 24-hour precipitation totals (mm) during the study period (29 June 2017 06 UTC to 30 June 2017 06 UTC) from REGNIE .

Thunderstorm activity in the border region between northeastern Germany and Poland was already active in the morning starting at 5 UTC, shaping up a convective line moving westward from Poland towards the city of Berlin, producing the first cloud-to-ground lightning (Fig. 5a). The system strengthened and hit Berlin mainly between 9 and 10 UTC. Afterwards, the system weakened and moved only slightly further west due to weak upper-level flow. The convective line remained relatively stationary over the greater Berlin area and west of it until noon (Fig. 5a). Upstream of the system, a second thunderstorm line

followed, crossing the border between Poland and Germany between 14 and 15 UTC. In the late afternoon, the direction of the convective cells changed and they were transported northward affecting Mecklenburg-Western and the Baltic Sea after 18 UTC.

Due to the weak upper-level flow (Fig. 3a), the thunderstorms were associated with low propagation speeds leading to high local rain rates. Figure 5b shows daily precipitation totals with values up to 200 mm. The convectively enhanced precipitation fell mainly in the course of 12 hours in the German states of Brandenburg (BB), Berlin (BE), and southern Mecklenburg-Western Pomerania (MV). Very high values above 100 mm were recorded in and northwest of the city of Berlin as well as in an area between Ludwigslust (MV) and Perleberg (BB). For example, Berlin-Tegel (BE) recorded 24-hour precipitation of 196.9 mm, while Zeesen (BB) registered 149.9 mm (Fig. 5b and Table S1) in the supplementary material). In many places, more precipitation was measured within 24 hours than the climatological mean for the whole month of June (Wandel, 2017).

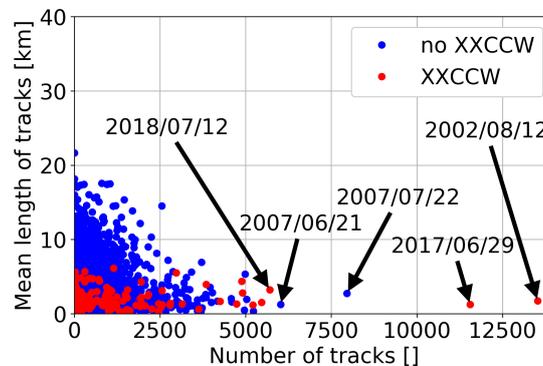

**Figure 6.** Temporal evolution of the PSI (blue bars) for the time period 1951 to 2021. The results are based on REGNIE daily precipitation observations between January 1951 and September 2021. The 99-percentile and 90-percentile of daily PSI values are represented by the dashed blue horizontal lines. Numbered circles highlight nine events analysed in Table 1 or in Fig. 7 as well as other historical events. These are (1) the Saxony floodings on the 12 August 2002; (2) the 29 June 2005 event, affecting Hersbruch and Lohmar; (3) the 21 June 2007 and the (4) 22 July 2007 events affecting Germany in its totality; (5) the 26 August 2010 event in Osnabrueck; (6) the 29 July 2014 event in Muenster and Greven; (7) the 29 June 2017 HPE (red); (8) the 12 July 2018 causing flooding in Berlin; and (9) the Ahr flooding on 14 July 2021.

The unusual precipitation totals made the 29 June 2017 HPE one of the most extreme event in the climatology of the greater Berlin area. Based on the PSI method (Sect. 3.1; Caldas-Alvarez et al., 2021; Piper et al., 2016), the 29 June 2017 event around Berlin was the 29th most severe event in the 1951-2021 period (Fig. 6). This event showed a PSI value (1.71), well above the 99th-percentile of the climatology indicating an extreme event. The PSI quantifies the severity of an event considering grid-point precipitation intensity, surface of affected area and persistence. The 29 June 2017 HPE showed a PSI value 2.3 and 1.8 times larger than the 29 June 2005 event in Hersbruch and Lohmar (Tab. 1; number 2 in Fig. 6) and the 29 July 2014 event in Muenster and Greven (Tab. 1; number 6 in Fig. 6), respectively. The 26 August 2010 event in Osnabrueck (Tab. 1; number 5 in Fig. 6) is the only event of those assessed in the household surveys with a similar meteorological severity and a similar

extent of the damages (€90 Mill.) caused. Compared to other events, the 2002 event in Saxony (number 1 in Fig. 6) showed the most similar meteorological severity. The Ahr flooding in July-2021 (number 9 in Fig. 6) had a PSI value 2.1 lower than the 29 June 2017 HPE due to the weaker grid point intensity (131 mm compared to 196.9 mm) and, especially, to the lack of observations over affected areas in Belgium and the Netherlands in REGNIE.

The convective activity and number of cells triggered were also top-ranked compared to other historical cases. Implementing a lagrangian cell tracking algorithm (Sect. 3.2) using 5 min, 1 km radar data (YW RADKLIM), for the period 2001 to 2020, we found that the only event with more cells triggered than the 29 June 2017 HPE was the Saxony 12 August 2002 event (Kreibich et al., 2007). Also outstanding with regard to the number of convective cells triggered were the events on 21 June 2007, 22 July 2007 and 12 July 2018, where flooding was reported for northern Bavaria, west and south-west Germany and Berlin, respectively (e.g., Kaiser et al., 2021). The former two events showed a strong meteorological severity, with a PSI in the 99th-percentile of the climatology and the latter showed a moderate severity with a PSI close to 0.6. Figure 7 also shows the inverse relationship between the length of the tracks and their number, i.e., the larger the number of cells triggered, the shorter their mean length.

**Figure 7.** Cell track characteristics (mean length and number of tracks) for the research area Berlin and surroundings for days from 2001 to 2020. Colour coding identifies if days have been classified as weather type ‘no prevailing wind direction, cyclonic circulation in 950 and 500 hPa and above-average humidity content of the troposphere - XXCCW’ or another type - not XXCCW (Bissolli and Dittmann, 2001). Arrows indicate days with flooding events in Germany.

## 4.2 Impacts and monetary losses

Insured losses in the Berlin-Brandenburg area amounted to €60 Mio. (GDV, 2018) making the 29 June 2017 HPE the most damaging extreme event in Berlin and Brandenburg since 2002. Insurance data of the GDV showed that 1.8 % of the buildings in Berlin incurred damages during the event, with an average loss of €6,830. The Oberhavel district was more heavily affected, with 5.3 % of the buildings damaged and an average loss of €10,550 (GDV, 2021). In Berlin, the long-lasting rainfall overloaded the sewer system, resulting in widespread inundation that caused disruption of traffic (i.e., blocked roads), flooded

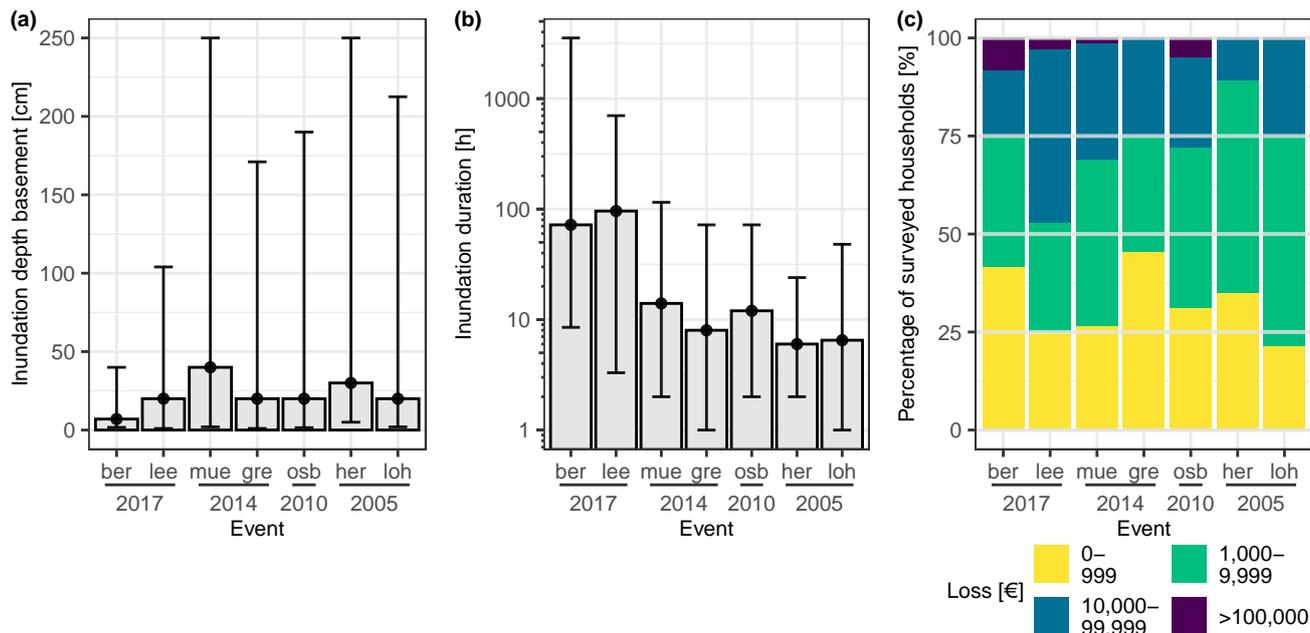

basements and underground stations, as well as intangible consequences including restrictions in daily routine and mental  
 385 discomfort (GDV, 2018; Berghäuser et al., 2021). The high number of rainfall-related missions on these two days forced the  
 Berlin fire brigade to declare an ‘exceptional weather situation status’ (Kox and Lüder, 2021). The small municipality of Leege-  
 bruch (~6,800 inhabitants, located 40 km north of Berlin in the Oberhavel district) was even more severely affected due to its  
 location in a topographical depression and a typically high groundwater table. The resulting inundation cut off the settlement  
 from its surroundings, affected 40 % of the municipality, and persisted for several weeks (GDV, 2018).

**Table 1.** Pluvial flooding events where surveys were conducted at affected households. Five events were surveyed at seven locations. The start and end dates, the affected area, the maximum daily precipitation, and the affected population are obtained from the CatRaRe database (Sec. 2), based on RADKLIM precipitation data. The overall losses within the municipality (\*) are from GDV (2020) and refer to insured losses, while loss values with a (\*\*) are from Hydrotec et al. (2008) and refer to total losses (non-insured and insured losses). Losses are referred to constant 2019 prices. Note that Hersbruck was hit by two events in close succession, which are listed separately.

City	Date Start yyyy-mm-dd	Date End yyyy-mm-dd	Aff. Area km <sup>2</sup>	Max. Prec. mm	Population 10 <sup>3</sup> people	Losses Mio. €	Surveys

Lohmar	2005-06-29 00:50	2005-06-30 00:50	2,669.7	100.9	2,571	3.5 (**)	62

390 Table 1 compares the meteorological severity, the impacts and the number of surveyed households between the 29 June  
 2017 HPE in Berlin and Leegebruch event and the events in Muenster and Greven (2014), Osnabrueck (2010) and Hersbruck  
 and Lohmar (2005). The meteorological indicators show that the Berlin-Leegebruch-2017 event was characterised by its large  
 spatial extent and long rainfall duration. As shown in Sect. 4.1, the long rainfall duration was caused by the slow propagation  
 of the convective system given the weak mid-tropospheric winds. The maximum accumulated precipitation in Berlin (Table 1)  
 395 somewhat differs from the REGNIE observations (Fig. 5b) since the values of CatRaRe are based on the RADKLIM RW  
 1-hour product that uses a different gridding method and data source.

Figure 8 allows for a more detailed view of the impacts and related mechanisms by looking at the distributions of surveyed  
 flood indicators and monetary losses at a household level. The results reveal that basements were inundated less severely in  
 Leegebruch-2017 and Berlin-2017 than in the other events. Further, the inundation durations in Berlin-2017 and Leegebruch-  
 400 2017 exceed the inundation durations of the other events. Monetary losses to buildings were particularly large in Leegebruch-  
 2017, Muenster-2014 and Osnabrueck-2010, where approximately 75 % of the surveyed households reported a loss of €1,000

**Figure 8.** Comparison of (a) inundation depth, (b) inundation duration and (c) building loss between pluvial flood events in seven municipalities as reported in the surveys Berlin-2017 (ber), Leegebruch-2017 (lee), Muenster-2014 (mue), Greven-2014 (gre), Osnabrueck-2010 (osb), Hersbruck-2005 (her), Lohmar-2005 (loh). Points indicate median values, while whiskers show 5 % and 95 % percentiles.

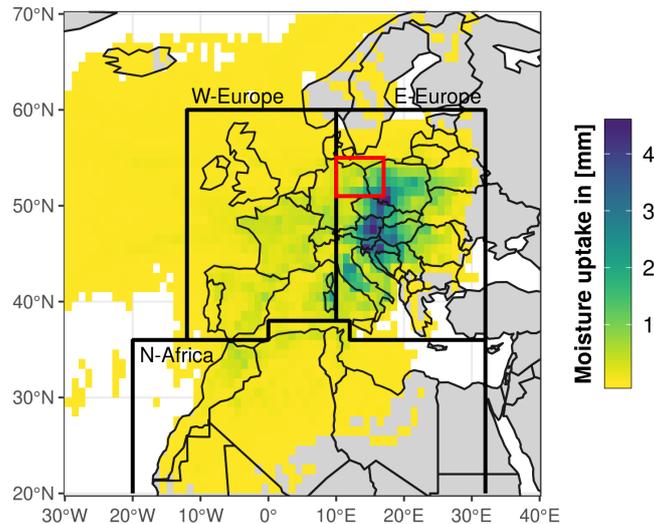

and more. In Leegebruch-2017, almost half of the surveyed households suffered building loss in the largest two categories ( $\geq \text{€}10,000$ ).

Altogether, a clear relationship between precipitation indices (intensity, duration, extent) and resulting losses across the group of study cases could not be found. Instead, flood characteristics at the affected buildings (inundation depth and duration) can explain much (although not all) of the incurred losses. Ultimately, flooding in urban areas is a complex process that depends not only on the meteorological nature of an event but also on the local characteristics of the terrain defined by topography, land use, sewer system capacity and operability, and hydro-geology, as well as on socioeconomic conditions such as settlement structure, building codes and private risk-mitigation.

### 410 4.3 Lagrangian moisture trajectories

A sufficiently moist environment is needed for deep moist convection to develop (Markowski and Richardson, 2010). Section 4.1 showed how a very moist atmosphere with up to 40 mm of Precipitable Water Vapour preconditioned the initiation of convection in the greater Berlin area. Now the question is where did the precipitating moisture originate. To this end we use Lagrangian backward trajectories based on hourly ERA-5 data (Sect. 4.3).

415 We found that land masses were the main sources of moisture uptake. Out of the selected 15,074 trajectories fulfilling the selection criteria, 82.9 % originated over land areas, whereas only 17.1 % of the precipitating moisture evaporated over the

**Figure 9.** Moisture uptake within the planetary boundary layer, calculated based on Lagrangian backward trajectories using ERA5 reanalysis data. Hourly initialised trajectories on 29 June 2017 (0 UTC to 23 UTC) at the region of heavy precipitation (red box) from 1000 hPa to 200 hPa in steps of 50 hPa and 80 km horizontal distances, going back 240 h in time, are used to compute moisture uptake based on humidity changes, if they are associated with precipitation in the target region.

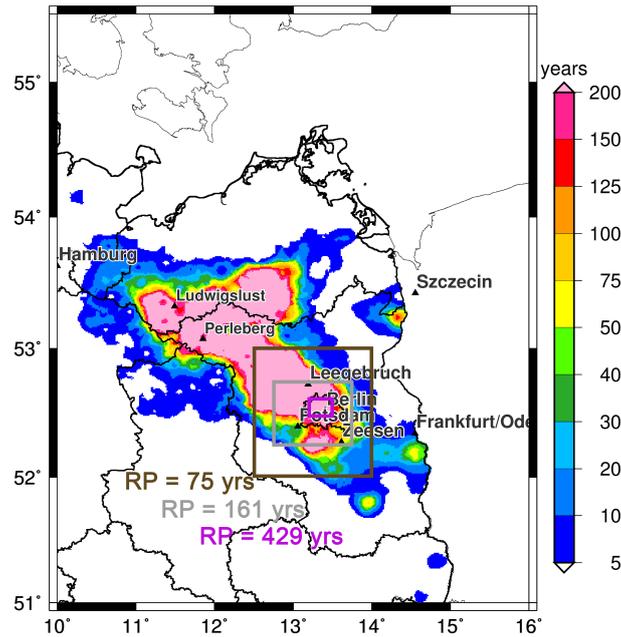

ocean. With this method, about 49.8 % of the precipitating moisture for the day of 29 June could be traced back to its moisture source. The eastern European region (around 10°E to 32°E and 37°N to 60°N) was by far the main source of moisture uptake (63.0 %). Additionally, the moisture uptake in this region was relatively evenly distributed, ranging from Poland (east of the precipitation event) towards Croatia and Italy, with a maximum moisture uptake of about 4.6 mm per single grid point (Fig. 9). Other, but less important, land moisture sources were the western European region (around 12°W to 10°E and 37°N to 60°N), with a contribution of 13.9 %, and the northern African region (around 20°W to 32°E and 20°N to 37°N), with a contribution of 5.9 %. The oceanic moisture sources were primarily the Mediterranean Sea (11.9 %) and Atlantic Ocean (4.6 %), but these played a minor role compared to the moisture uptake over land. A similarly important role of moisture recycling from land sources has been found previously for an extreme precipitation event in eastern Europe in May 2010 (Winschall et al., 2014) and for the central European floods in June 2013 (Grams et al., 2014; Kelemen et al., 2016). In the case of the 29 June 2017 HPE studied here, moisture recycling likely happened on relatively short time scales of 1-2 days, as June 2017 was generally dry, but northeastern Italy, Slovenia, Austria and southeastern Poland were affected by convective precipitation on 28 June. The moistening of the soil due to prior precipitation is thus hypothesised to be an important precondition for the Berlin event.

#### 4.4 GEV models and return periods

We provide an estimation on how rare the 29 June 2017 HPE was calculating probabilities of exceedance  $p$  and return periods  $t_{RP}$  fitting observations of extreme precipitation to GEV models (Sect. 3.5). Return values  $RV_{RP}$  (quantiles) and the associated

return periods  $t_{RP}$ , or directly the probability of exceedances  $p$ , are related to the GEV distribution as  $t_{RP} = 1/(1-G(RV_{RP}))$  (Coles, 2001). For example, a probability of exceedance  $p = 0.01$  for annual data can be interpreted as on average 1 event in 100 years rare an event has been. This information is also used by reinsurance companies and hydrological studies.

We start by estimating return periods using the Gumbel distribution (Eq. 2) per grid-point ( $1 \times 1 \text{ km}^2$ ) for 24-hour precipitation totals in Germany based on a 70 year time series (REGNIE; Fig. 10). The results show return periods of more than 200 years between Ludwigslust (MV), Perleberg (BB) and Berlin; covering a total area of  $8.729 \text{ km}^2$ . Past work has shown how estimated return periods that are much longer than the observational record exhibit large uncertainty (Makkonen, 2006; Grieser et al., 2007). This is why we truncate all return periods above 200 years (Fig. 10), acknowledging that the 70 year observational record might be too short to provide accurate values for such long return periods.

**Figure 10.** Return periods of the 24-hour precipitation totals based on REGNIE using a Gumbel distribution (Extreme Value Type I; reference period: 1951 – 2020). Note: All return periods above 200 years are shown uniformly in one colour due to statistical uncertainty (see text for more information). Coloured polygons (in pink, grey, brown) including the associated averaged return periods (RP) indicate three different-sized averaging areas explained in Table S2 and in the text.

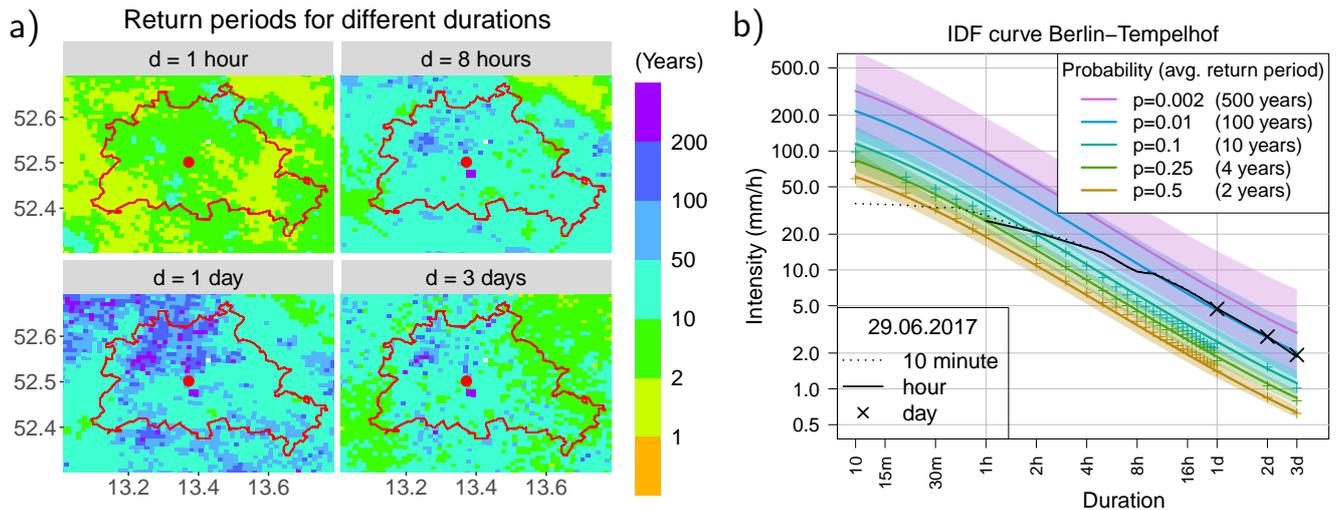

The second approach, consisting of fitting a GEV distribution to spatial averages of different size also showed very large return periods, however decreasing with increasing size of the considered areas. The rationale behind this analysis is that return periods at individual grid points may not best-characterise the event and its associated impacts since an event with a very long return period at a given site can have a small spatial extent. Such spatial averaging of observations is also required for validation of simulated return periods in climate models and assessment of the model biases (see e.g. Philip et al., 2020).

For this approach we fit a standard GEV distribution (Eq. 1) and estimate return periods of the yearly block maxima of REGNIE precipitation data from 1951 to 2020, spatially averaged over three boxes of different size (brown, grey, and pink boxes in Fig. 10 and Table S2 in the supplementary material). The results show that the return period of the event decreases with increasing box size. At the finest analysed scale ( $340 \text{ km}^2$ ; pink polygon in Fig. 10), the extreme event has a return period of over 420 years, which decreases to 75 years for the largest area ( $11,100 \text{ km}^2$ ; brown polygon in Fig. 10). Compared to other historical events, the 29 June 2017 HPE was the most extreme in the time series when considering the smallest analysed region, however, an event with a larger spatially-averaged precipitation sum and thus a larger return period was detected on 8 August 1978 in the two larger areas (grey and brown boxes). In the supplementary material, the return period of the 29 June 2017 HPE is compared to the July 2021 heavy rainfall event impacting Western Europe.

One useful approach to reduce uncertainty in the estimation of return periods from temporally short observational records is using different accumulation durations between 1 hour and 3 days (Eq. 3), however at the expense of more demanding computing power. The  $d$ -GEV model (Eq. 3) is applied to grid point intensity from RADKLIM RW (2001–2020; Fig. 11a). For this dataset, the estimated  $d$ -GEV shape parameter  $\xi$  has a median value of 0.24. Accumulations (duration  $d$ ) of one day showed very high return periods ( $> 800$  years) for seven grid points in north-western Berlin. Over this area, most grid points showed return periods between 50 and 200 years. The small grid box size of  $1 \text{ km} \times 1 \text{ km}$  could explain the very high return periods in cases of statistical outliers. On shorter time scales of 8 hours and 1 hour, north-western Berlin shows lower return periods, between 10 and 100 years for the two former temporal aggregations and between 2 and 10 for the latter (Fig. 11.a). The short time range of historical RADKLIM data (20 years), however, limits the reliability of these spatially resolved return period estimates.

To overcome the short time span of the RADKLIM dataset, we implement a duration-dependent GEV model (Eq. 3) on DWD ground station data at Berlin-Tempelhof (Fig. 1). The return levels (quantiles) for any exceedance probability and time scale (duration  $d$ ) are presented in Intensity-Duration-Frequency (IDF) curves (Fig. 11). This station was chosen because data records are longer than the RADKLIM data. 10-minute aggregations span 1995 to 2020 and daily aggregations cover the period 1948 to 2020. The longer time series lead to shorter and—due to the reduced uncertainty—potentially more plausible return periods. The analysis shows return periods of 100 years for durations above than 10 hours, 114 years for daily aggregations. However, confidence intervals in the IDF curves also remain large (Fig. 11b).

All used approaches highlight that the analysed event was rare, with return periods longer than 100 years in the Berlin area. The efficient use of information from the observation data (accumulation periods from 10 minutes to 3 days) lead to more plausible return period estimation from the  $d$ -GEV model, compared to Gumbel using daily accumulations. However, long data records with high measurement frequency and enough computing resources are not always available, in which case a non-duration-dependent model using daily data could be a better choice. Finally, including a climate change signal into the  $d$ -GEV estimation (Ganguli and Coulibaly, 2017) could improve the results, since the assumption of a non-changing climate leads to over-estimated return periods for events that become more likely with climate change.

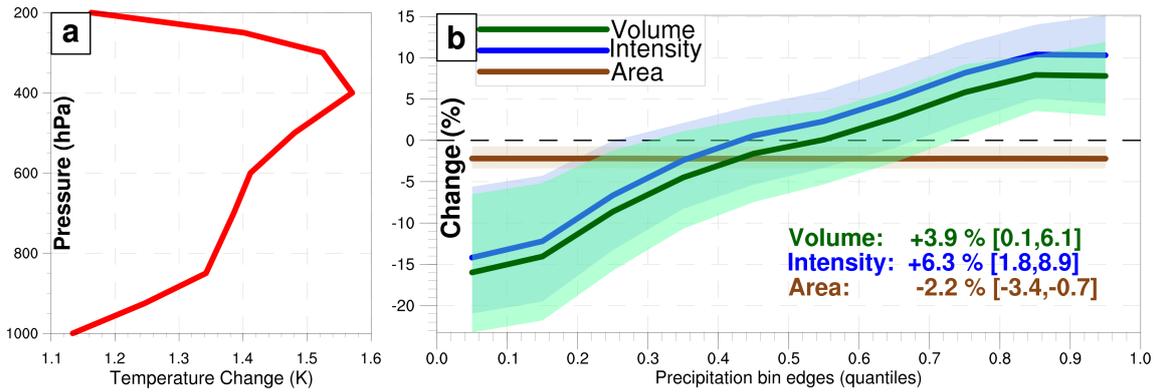

**Figure 11. a):** Return periods of this event’s intensity from gridded RADKLIM ( $1\text{ km} \times 1\text{ km}$ ) data using a duration-dependent GEV distribution. Red dot: position of DWD weather station Tempelhof, used to construct the IDF curve in (b). **b):** IDF curves from station-based data. The coloured lines show return periods from the  $d$ -GEV model, the black line indicates intensity of the event on the 29 June for different temporal measurement resolutions. Empirical quantiles are denoted as coloured "+". 95 % confidence intervals come from 1000-fold bootstrapping.

#### 480 4.5 Conditional event attribution

A full understanding of an observed extreme event requires addressing the question of how the event relates to anthropogenic influences. This is particularly important with respect to climate-change communication with stakeholders and the general public.

For conditional attribution, the modelling approach involves simulating an event under present-climate conditions and then  
 485 repeating the simulation with modified boundary conditions. This modification consists of subtracting the vertical thermodynamical climate-change signal (Lackmann, 2015; Pall et al., 2017) and is, thus, particularly amenable to high-resolution (convection-permitting) regional-model experiments, which have many advantages for modelling extreme precipitation (Meredith et al., 2020, 2021; Stevens et al., 2020). The modelling approach is, in essence, an adaptation of the surrogate global-warming method (Schär et al., 1996; Hibino et al., 2018; Kröner et al., 2017). The results presented here are based on the  
 490 model simulations described in Section 3.6, where the analysis is performed over an area of  $81,520\text{ km}^2$  centred on the event location (Fig. S3). Model evaluation and technical details are found in the Supplementary Material.

The thermodynamical climate-change signal is vertically heterogeneous, with stronger warming in the mid and upper troposphere (Fig. 12a). Based on a mean tropospheric (1,000 – 300 hPa) temperature of  $\sim 269\text{ K}$  and warming of  $1.36\text{ K}$ , this implies an increase in saturation vapour pressure of  $\sim 10.5\%$  (Bolton, 1980), which exceeds the  $7.5\%$  increase in precipitable water  
 495 (time average; not shown) which we find over our eastern-Germany analysis region (Fig. S3).

**Figure 12.** (a) Vertical warming signal and (b) response of event precipitation to warming signal. The warming is based on a subset of 17 CMIP6 models. The x-axis in (b) shows precipitation bins which are delineated by quantiles of the precipitation intensity distribution; the changes in area and volume represent the changes associated with precipitation in these bins. Based on the Wilcoxon-Mann-Whitney test, the total changes given within (b) are all statistically significant with at least  $p < 0.02$ . Shading denotes the 95 % confidence intervals based on 1,000 bootstrap resamples.

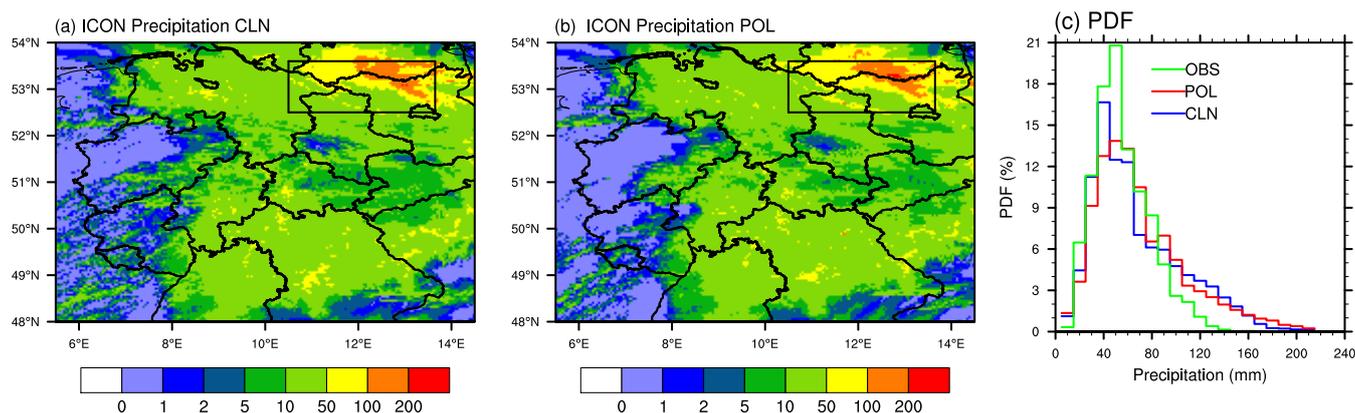

In our present-climate simulations, we find a low, though statistically significant ( $p < 0.02$ ), increase in total precipitation volume of 4 %. This can be better understood by analysing both changes in the precipitation distribution and physical characteristics of the convective system (Fig. 12b). Changes in total precipitation volume associated with a given quantile of precipitation intensity increase as the quantiles become higher. Indeed, at the lowest intensity quantiles, the associated precipitation volumes are found to decrease, which partly offsets the volume increases associated with the higher intensity quantiles (Fig. 12b). By breaking the total precipitation volume into its area and depth components, it can be seen that the change in precipitation intensity shows a signal very similar to that of the total precipitation volume. The spatial extent of the precipitation, meanwhile, decreases (-2 %) in the warmer climate, in line with the results of Wasko et al. (2016) and Armon et al. (2022). It is thus clear that it is not changes in the spatial extent of the system, but rather higher local intensities which drive the increase in total precipitation volume. The intensities increase for, approximately, the upper half of the precipitation distribution, peaking at a 10.4 % increase for the highest quantiles. This increase exceeds the increase in precipitable water (see above), implying that local moisture convergence was an important factor for the most extreme intensities.

It is worth noting that, based on the average tropospheric warming signal (see above), the intensification of the highest quantiles corresponds (almost exactly) to what would be expected from the Clausius-Clapeyron relation. Had the precipitation-temperature scaling been computed using the lower troposphere or the 2-m temperature instead, a super Clausius-Clapeyron increase would have been found. Currently, it is still a matter of debate as to which temperature is most appropriate to use when computing the scaling rate (Drobinski et al., 2016; Formayer and Fritz, 2017). It is plausible that the total precipitation would not have shown an attributable change but that the most intense quantiles would have. This insight is also of relevance for impact studies: the effect of climate change was found to be dependent on the spatial scale of interest. We conclude by stating

515 that climate change since the pre-industrial era served to increase the magnitude and, in particular, the highest precipitation intensities of the event.

#### 4.6 Sensitivity to aerosol loading

Another influence of anthropogenic activities, transport, industry, etc. on heavy precipitation is via cloud-active aerosols. Aerosols may affect deep convection in various ways (Rosenfeld et al., 2014; Fan et al., 2015) and thus exert an anthropogenic  
520 effect beyond the impact of global warming. For instance, an increased aerosol number reduces droplet size by increasing the condensation nucleae and the droplet concentration leading to enhanced precipitation (Guo et al., 2022).

**Figure 13.** Results from the 635 m ICON simulations. Distribution of precipitation ( $\text{mm d}^{-1}$ ) from (a) the factual CLN simulation and (b) the counterfactual POL simulation. (c) PDF of precipitation intensities in the region of interest denoted by the rectangle in a) and b), for the factual (CLN) and polluted (POL) simulations and the observations (OBS) from the RADKLIM precipitation observations.

We study the role of cloud-active aerosols within the 29 June 2017 HPE through sensitivity experiments with the ICON model at 625 m resolution, comparing two scenarios (Sect. 3.7). The first one has factual concentrations representative of the 29 June 2017 HPE, which is a comparatively clean situation (CLN). The second one, has aerosol concentrations representative  
525 of the peak-aerosol conditions in the mid-1980s, or polluted scenario (POL). The simulated distribution of precipitation is compared with RADKLIM for the period from 06 UTC 29 June 2017 to 06 UTC 30 June 2017 (Fig. 13), in order to assess the importance of aerosols for this extreme event.

The results show that POL simulates an increased cloud number and cloud mass due to the larger aerosol loading (not shown) with the corresponding heavy precipitation increase. This is especially so for intensities exceeding  $150 \text{ mm d}^{-1}$  (Fig. 13c). We  
530 quantified this increase in probability to be of 70 % in the high-aerosol conditions the 1980s compared to the factual case (CLN) during the 29 June 2017 HPE. In POL 4.3 % of grid points exceeded  $150 \text{ mm 24 d}^{-1}$  in the high-aerosol case compared to 2.3 % in the low-aerosol simulation (CLN).

## 5 Conclusions and outlook

Multi-disciplinary analyses are a powerful means to gain full understanding of heavy precipitation events with high impact such as the Ahr flooding events in northern Europe in 2021 (Kreienkamp et al., 2021; Mohr et al., 2022). In this work we implemented analytical methods from impact, meteorological, and climate sciences using state-of-art observational and modelling data sets to provide a comprehensive assessment of the 29 June 2017 HPE in the metropolitan area of Berlin (Germany).

The 29 June 2017 event occurred under the influence of a mid-tropospheric trough over western Europe (TrW pattern), with two principal short-wave surface lows located east of the British Isles (Rasmund) and over western Poland (Rasmund II) between 29 and 30 June. Rasmund II induced a southwesterly flow bringing warm and moist air ( $\theta_e^{850} = 306$  K, IWV = 42 mm), accompanied by moderate ML-CAPE over the Berlin area. Low-level wind convergence along the German-Polish border initiated convection, inducing more than 11000 convective cells and lightning, starting 5 UTC (29 June) displacing northwards slowly due to the weak tropospheric horizontal winds ( $10 \text{ m s}^{-1}$  at 500 hPa). Total extreme precipitation amounted to 196 mm in 24 h, especially impacting the Berlin area and the southern limit of the Mecklenburg-Western Pomerania state. A climate index, based on precipitation intensity, coverage, and persistence, classified this event as the 29<sup>th</sup> most severe on record since 1951 in Germany.

Total insured losses in properties amounted to €60 Mill. due to widespread inundation, traffic disruptions and basement flooding. This made the 29 June 2017 HPE the costliest event between 2002 and 2017 in the greater Berlin area. A set of unique surveys estimating the losses at the household level allowed us to compare the 2017 HPE in Berlin and Brandenburg with previous historical cases in Hersbruck and Lohmar in 2005, Osnabrueck in 2010 and Muenster in 2014. The 2017 HPE stands out in terms of median inundation duration, which was up to 100 h; 4 to 12 times longer than the other surveyed events. While surveyed flood attributes (inundation depth and duration) can be linked to household losses, it is difficult to establish a link between these attributes and the meteorological characteristics of the event. This is because the impact at the household level is not only caused by the meteorological characteristics, but also by the conditions on the ground.

Lagrangian backward trajectories determined that land masses, instead of water bodies were the main sources of atmospheric moisture feeding the systems, accounting for 82.9 % of the identified precipitating moisture. In particular, the continental region between southern Poland and northern Italy was the major moisture source, with uptakes up to 4.6 mm in 240 h. It is hypothesised that this moisture was recycled from an earlier event, impacting Slovenia, Austria and Poland on the 28 June.

Three different approaches using Generalized Extreme Value (GEV) models (Gumbel, standard, and duration-dependent) quantified the return period of this event to be over 100 years for daily precipitation aggregations. For higher temporal resolution observations, the return periods were reduced to intervals between 10 and 100 years for 8-hour aggregations, and between 1 and 10 years for 1-hour aggregations. For spatial averages over an area of the scale of the event ( $11,100 \text{ km}^2$ ), return periods were of 75 years. While these techniques provided a good estimation of the probability of exceedence and return periods of such events, our analysis highlighted the large uncertainty of obtaining large return periods (> 100 years) from temporally 'short' databases (< 70 years in our case). To overcome this problem, we suggested using station data, which is usually available for longer periods, at different temporal resolutions with a duration-dependent GEV model. Thereby we were able to increase the

sample size and shrink the confidence intervals. Other interesting approaches to be tested in further research are, considering the climate change signal for  $d$ -GEV estimation (Ganguli and Coulibaly, 2017), or using spatial models (Ulrich et al., 2020; Berghäuser et al., 2021) that combine information from several stations into one model using spatial covariates.

570 The attribution experiments for this case study showed that the thermodynamic climate change signal since the pre-industrial era caused a small, but significant increase in heavy precipitation for this event. While total precipitation increased by 4 %, the heaviest precipitation rates showed an intensification of over 10 %. Moreover, in addition to the thermodynamical effect of climate change, anthropogenic aerosol emissions could increase the probability of heavy precipitation rates over 150 mm d<sup>-1</sup> for this event as shown by hectometer scale model sensitivity experiments with different aerosol loadings.

575 The combined use of impacts, meteorological and climate methods allowed us to relate diverse aspects of heavy precipitation. We found, for the 29 June 2017 HPE, that large amounts of moisture from continental evaporative sources added to the slow motion of the convective systems to cause one of the most extreme events to date. Furthermore, we related the meteorological extremeness to the impacts for this case, provided the event's large return periods and severity and the reported losses of up to (€60 Mill.). This relationship, however, should not be understood trivially, since precipitation severity is a necessary but not  
580 sufficient condition for high precipitation damages. For the 29 June 2017 event, the state of the ground conditions, i.e. blocking of the sewer system in Berlin and Leegebruch was determinant in inducing the high costs. Finally, the climate attribution experiments demonstrated that a part of the severity of one of the most extreme events of the last 70 years in Germany was attributable to the already-observed changes in the thermodynamical environmental conditions.

Notwithstanding the advantages of multidisciplinary studies, they can suffer from methodological and data inconsistencies.  
585 An example of this, is the use of different numerical models. We decided to use different models to profit from the techniques best known to the different working groups. Moreover, we are confident that our results are model independent since all models showed a similar dynamical evolution of the event. Whereas discrepancies in the methods are to a large extent unavoidable as they are intrinsic to the synergistic approach used in this study, the validation of observations provides a powerful means to reduce uncertainty regarding data biases. Our validation of precipitation data sets in Section 2 showed a high degree of  
590 agreement and accuracy between the different products, providing confidence in the conclusions drawn. Among the used products, the accuracy was especially high for REGNIE, followed by RADKLIM.

Finally, the multidisciplinary collaboration has created powerful connections that will be exploited in up-coming research. For instance, the authors of this paper will form an expert task force in the framework of ClimXtreme to assess future precipitation events of high interest for the media and the general public, such as the Ahr event in 2021, shortly after their occurrence.

595 *Code availability.* The WRF model source code can be obtained from <https://github.com/wrf-model/WRF/archive/refs/tags/v4.2.1.tar.gz>. The COSMO-CLM model is accessible to members of the Climate Limited-area Modeling Community, and access is granted upon request. Parts of the model documentation are freely available at <https://doi.org/10.1127/0941-2948/2008/0309> (Rockel et al., 2008)

*Data availability.* REGNIE, RADKLIM, German precipitation station and CatRaRe data from the DWD used in this paper are freely available for research under the Open Data Portal (DWD, n.d.-a). Lightning EUCLID data are not freely available but can be requested from the Blitz-Informationdienst von Siemens (<https://new.siemens.com/de/de/produkte/services/blids.html>). ERA5 data are available via the Copernicus Climate Change Service (C3S; <https://climate.copernicus.eu/>; last access: 01 January 2022)(Hersbach et al., 2018). ECMWF analysis data can be obtained from <https://apps.ecmwf.int/archive-catalogue/?type=an&class=od&stream=oper&expver=1> (last access: 24 August 2021) (ECMWF, 2021). The user's affiliation needs to belong to an ECMWF member state. The WRF model simulation data can be made available by TS upon request. The COSMO-CLM simulations have been deposited in an open-access repository at the World Data Centre for Climate (WDCC) under the permanent link [https://cera-www.dkrz.de/WDCC/ui/cerasearch/entry?acronym=DKRZ\\_LTA\\_1152\\_ds000301](https://cera-www.dkrz.de/WDCC/ui/cerasearch/entry?acronym=DKRZ_LTA_1152_ds000301). The survey data of the Lohmar (2005), Hersbruck (2005) and Osnabrück (2010) events are available via the German flood loss database HOWAS21 at <https://doi.org/10.1594/GFZ.SDDB.HOWAS21> (German Research Centre for Geosciences GFZ, 2022). The data of the Münster (2014) event will be added to HOWAS21 by the end of 2023 and can currently be provided upon request. The Leegebruch (2017) and Berlin (2017) surveys are available upon request. ICON simulations (aerosol attribution) are archived in long-term storage at DKRZ and as redundant copy at Leipzig University, please send data requests to RC.

*Author contributions.* All authors collaborated and contributed to drafting, reviewing and editing the paper. In particular, ACA and JQ coordinated the effort and wrote the abstract and conclusions of the manuscript; KB, LD, MH, EPM, SM, JQ, LS, TS and JST wrote the introduction; SS, DN and FK provided support for data management and precipitation dataset validation; AK performed the Lagrangian cyclone analysis; MA, SM, TS and VW analysed the synoptic and mesoscale conditions; FR and SP performed moisture backward trajectory analysis; GA, LD, MH, HK, LS and AHT provided the impact analysis and household surveys; JST, SM and FF implemented the generalized extreme value models and estimated the return periods; HF, EELE and ACA implemented the precipitation severity index; KB implemented the Lagrangian cell tracking algorithm; EPM contributed the conditional event attribution experiment; JQ and RC performed the aerosol sensitivity experiments.

*Competing interests.* The authors declare that they have no competing interests.

*Acknowledgements.* This study is the outcome of collaborative work in the "ClimXtreme" project funded by the German Ministry of Education and Research (Bundesministerium für Bildung und Forschung, BMBF) in its strategy "Research for Sustainability" (FONA). The following subprojects have been funded by ClimXtreme. ACA and HF (project SEVERE) and SM and MA (project VarCLuST) sincerely thank the BMBF for funding the two projects (grant number 01LP1901A). TS is funded by the project LAFEP (grant number 01LP1902D); EM is funded by the project XPreCCC (grant number 01LP1902H). RC and JQ gratefully acknowledge PATTERA (FKZ 01LP1902C). KB is funded by the project DCUA (grant number 01LP1905A). AK sincerely thanks the project B3.6 LAMCoX (grant number 01LP1902F) for their funding and support. HK acknowledges the project FLOOD (01LP1903E). FR and SP are funded by the project MExRain (grant number 01LP1901C). The contribution regarding IDF curves was sponsored by BMBF and the project IDF-AF (grant number 01LP1902H). JST is funded through the project AXE-G (grant number 01LP1902B). EELE is funded by the project CoSoX (grant number 01LP1904C).

GA and LD are funded by the project CARLOFFF (BMBF, grant number 01LP1903B), LS by the DFG (GRK 2043/2). DN and SS are  
630 funded by CoDaX (BMBF, grant number 01LP1904A). This work used computing resources of the German Climate Computing Center  
(DKRZ) granted by its Scientific Steering Committee (WLA) under project IDs bb1152 and bm1159. We thank the CLM-Community  
(<https://wiki.coast.hereon.de/clmcom>) for maintaining and providing the COSMO-CLM regional climate model. ECMWF is acknowledged  
for providing the operational IFS analysis data on model levels and for providing the ERA5 data. The ERA5 reanalysis data used in this study  
635 contain modified Copernicus Climate Change Service Information 2020. Neither The European Commission nor ECMWF is responsible for  
any use that may be made of the Copernicus Information or the data it contains. DWD is acknowledged for providing the RADKLIM and  
REGNIE data. The WRF simulation was performed on the HPE Apollo Hawk national supercomputer at the High Performance Computing  
Center Stuttgart (HLRS) under the grant number ipm12835. The survey campaigns on extreme precipitation impacts were conducted and  
supported by the following projects/parties: in Lohmar and Hersbruck by the project “URBAS — Urban flash floods” (BMBF; 0330701C),  
in Osnabrueck by the University of Potsdam, the German Research Centre for Geosciences GFZ and the Deutsche Rueckversicherung AG,  
640 in Muenster and Greven by the project “EVUS — Real-time prediction of pluvial floods and induced water contamination in urban areas”  
(BMBF, 03G0846B), in Leegebruch 2017 by the project “ExTrass - Urban resilience against extreme weather events—typologies and transfer  
of adaptation strategies in small metropolises and medium-sized cities” (BMBF; 01LR1709A1) and in Berlin by the project "NatRiskChange  
- Natural hazards and risk in a changing world" (DFG; GRK 2043/2). MA and SM thank the Blitz-Informationsdienst von Siemens (BLIDS;  
namely Stephan Thern) for providing the lightning data. KB gratefully acknowledges the provision of computing time through the Center for  
645 Information Services and HPC (ZIH) at TU Dresden.

## 1005 Comparing the return periods of the 29 June 2017 and 14 July 2021 extreme events

Here, we will discuss the 2017 extreme event in the context of the Kreienkamp et al. (2021) study as the events exhibit similarities regarding the local scale and its convective characteristic. It should be noted, however, that Kreienkamp et al. (2021) has been a rapid attribution study which has not gone through peer-review yet. The July 2021 severe precipitation at the Ahr, Erft and Meuse has been an extremely rare event – so rare that estimation of a return period for the combined Ahr and Erft catchment is challenging. Thus, a pooling approach, whereby tiles of equal size in a wider region around the event are used to estimate the return period and the impact of anthropogenic climate change on the event, was applied. Choosing such an approach was based on the assumption that the given event could have occurred anywhere in a wider region around the event. It was found that in any 130x130km tile within the wider region, one such event can be expected every 400 years, which means that several such events would occur in the wider western European region in 400 years.

1010 To put the event we analyse here into the context of Kreienkamp et al. (2021), we compare the return periods of the events. Table S2 gives the return period of the 2017 event, spatially averaged over regions of different sizes (see also Sect. 4.4). The return period of the 2017 event, which has locally quite long return periods, decreases to 75 years when averaged over an area of 11,100  $km^2$  ( $100 \times 111$  km, yellow box in Figure 5), which is still smaller than the area size selected in Kreienkamp et al. (2021). Thus, the 2017 event has a lower return period than the 2021 event on a regional scale.

**Table S2.** Return period estimates for spatially averaged daily precipitation accumulation for regions of different size. The three regions (pink, grey, brown) are shown in Figure 10.

Region	Latitude [°] south corner	Latitude [°] north corner	Longitude [°] west corner	Longitude [°] east corner	Area size [ $km^2$ ]	24-hour precipitation [mm]	Return period [years]
pink	52.47	52.62	13.20	13.50	340	134.5	429
grey	52.25	52.75	12.75	13.75	3.720	99.0	161
brown	52.00	53.00	12.50	14.00	11.100	75.7	75

## 1020 Conditional Event Attribution

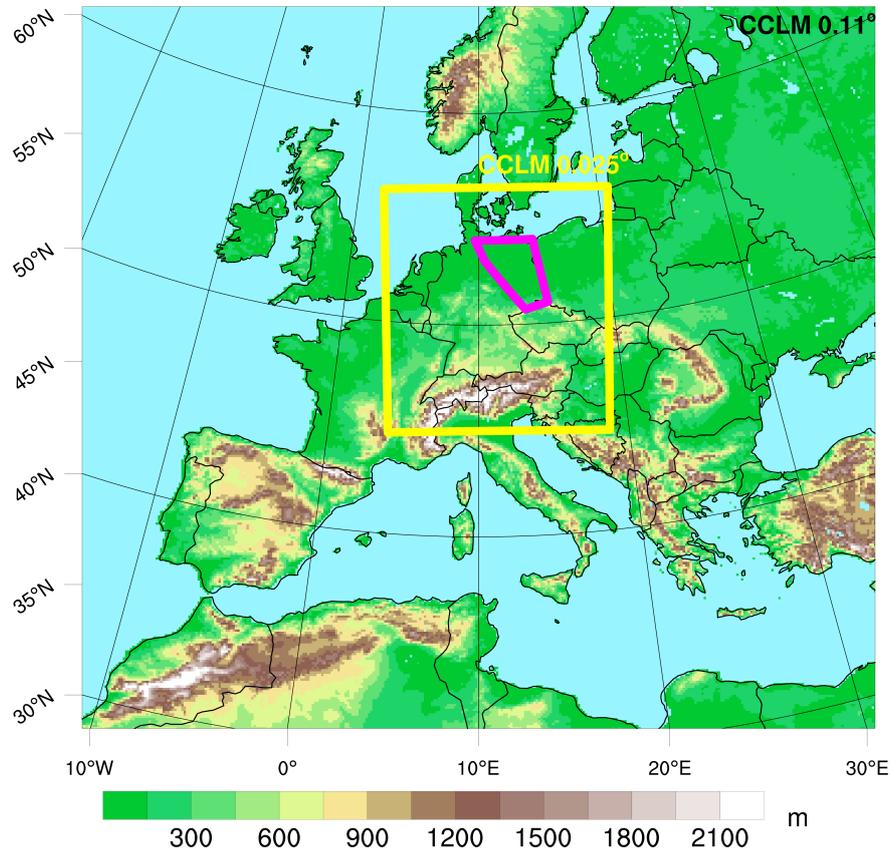

### CMIP6 models and climate-change signal

The CMIP6 models from which we compute the climate-change signal are shown in Table S3. To compute the climate change signal, we first calculate the mean temperature from the CMIP6 pre-industrial simulations from 1850-1859 across all models for the months of June and July (our event occurs on 29<sup>th</sup> June) and average over the  $0.11^\circ$  domain (Figure S3). This is then repeated for the years 2007-2016, representative of the present climate. As the CMIP6 historical simulations end in 2014, the years 2015 and 2016 are taken from the SSP245 scenario. The actual choice of scenario here is not relevant, because the divergence between the different scenarios from 2015-2016 is trivial. The difference between the 2007-2016 and the 1850-

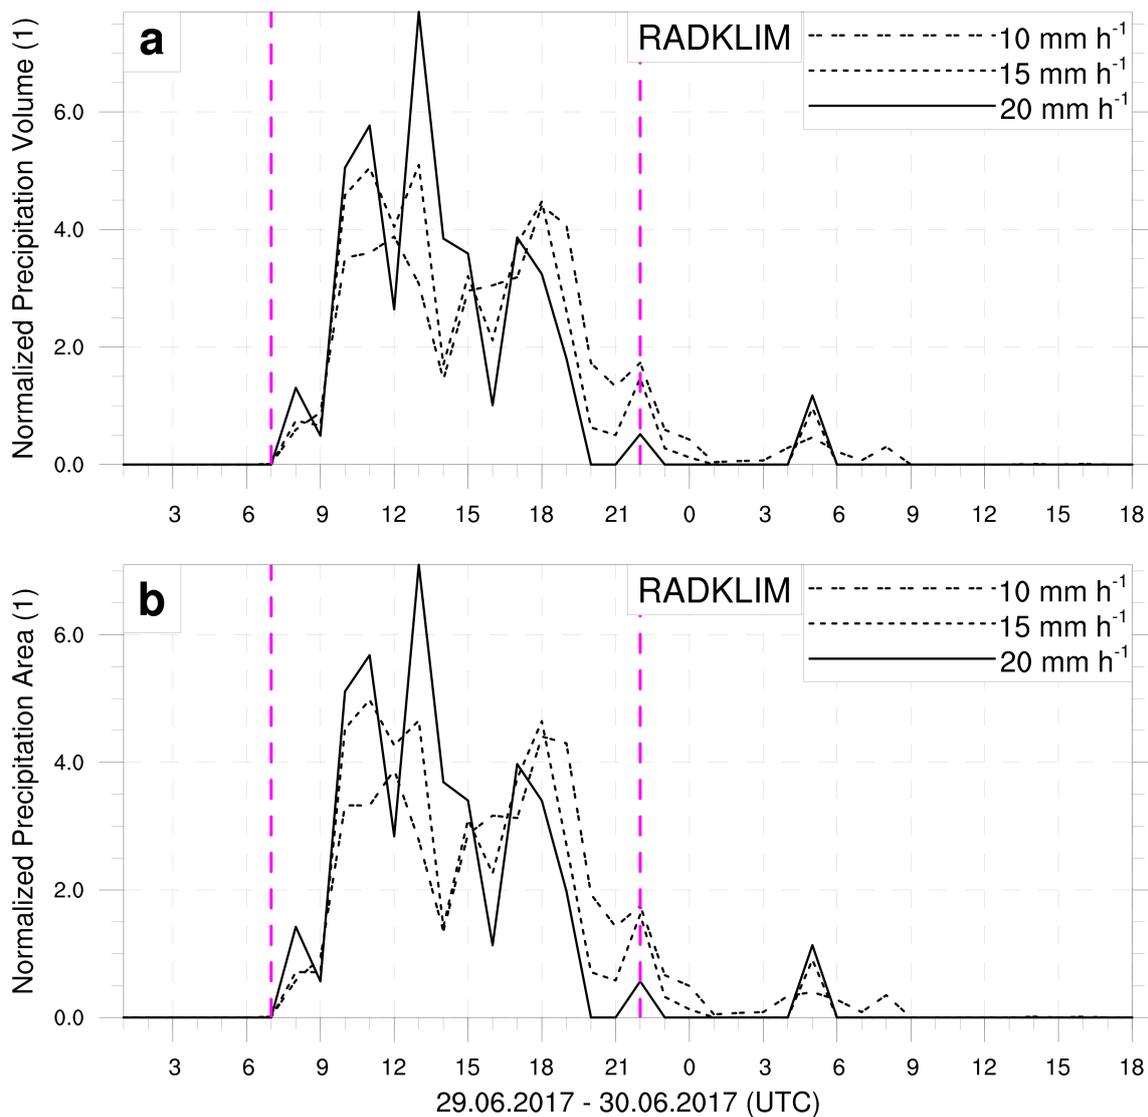

1859 climate is then taken. This difference is the basis for creating the pre-industrial boundary conditions from the observed boundary conditions, as described in the main manuscript.

**Table S3.** CMIP6 GCMs used to compute the climate-change signal used for adjusting the initial and lateral boundary conditions in the conditional event attribution study. The 17 GCMs were selected as they were the only ones for which soil temperature data were also available.

**Figure S3.** Central  $0.11^\circ$  simulation domain used in the conditional attribution study of Section 4.5 (recall from the description in the main manuscript that the ensemble is created using the domain-shift technique (Rezacova et al., 2009), whereby the boundaries and centre of the  $0.11^\circ$  domain are systematically shifted for each member); shading shows the orography of the  $0.11^\circ$  domain. The  $0.025^\circ$  simulation domain is marked in yellow. The magenta polygon marks the analysis region.

**Figure S4.** Normalized hourly time series of (a) precipitation volume and (b) precipitation area for different minimum precipitation intensities, based on the radar-based RADKLIM data set (Winterrath et al., 2018). The times series is based on the analysis region marked in Figures S5 and S6. The precipitation intensities denote the minimum precipitation intensities considered for each time series, i.e. for (a), the  $10 \text{ mm h}^{-1}$  line represents the total precipitation volume based on all grid cells with an hourly rate above  $10 \text{ mm h}^{-1}$ . The vertical magenta lines mark the time period (i.e. accumulation time) chosen for the analysis presented in Section 4.5 of the main manuscript and below.

**Figure S5.** Pre-industrial COSMO-CLM ensemble: event total precipitation accumulations for observations (top left), ensemble mean (top, second from left) and all 17 ensemble members. The magenta box marks the analysis region used in the main manuscript. The accumulation period is as shown in Figure S4. Note that, for fair comparison, the RADKLIM data have been spatially aggregated to the COSMO-CLM 0.025° grid.

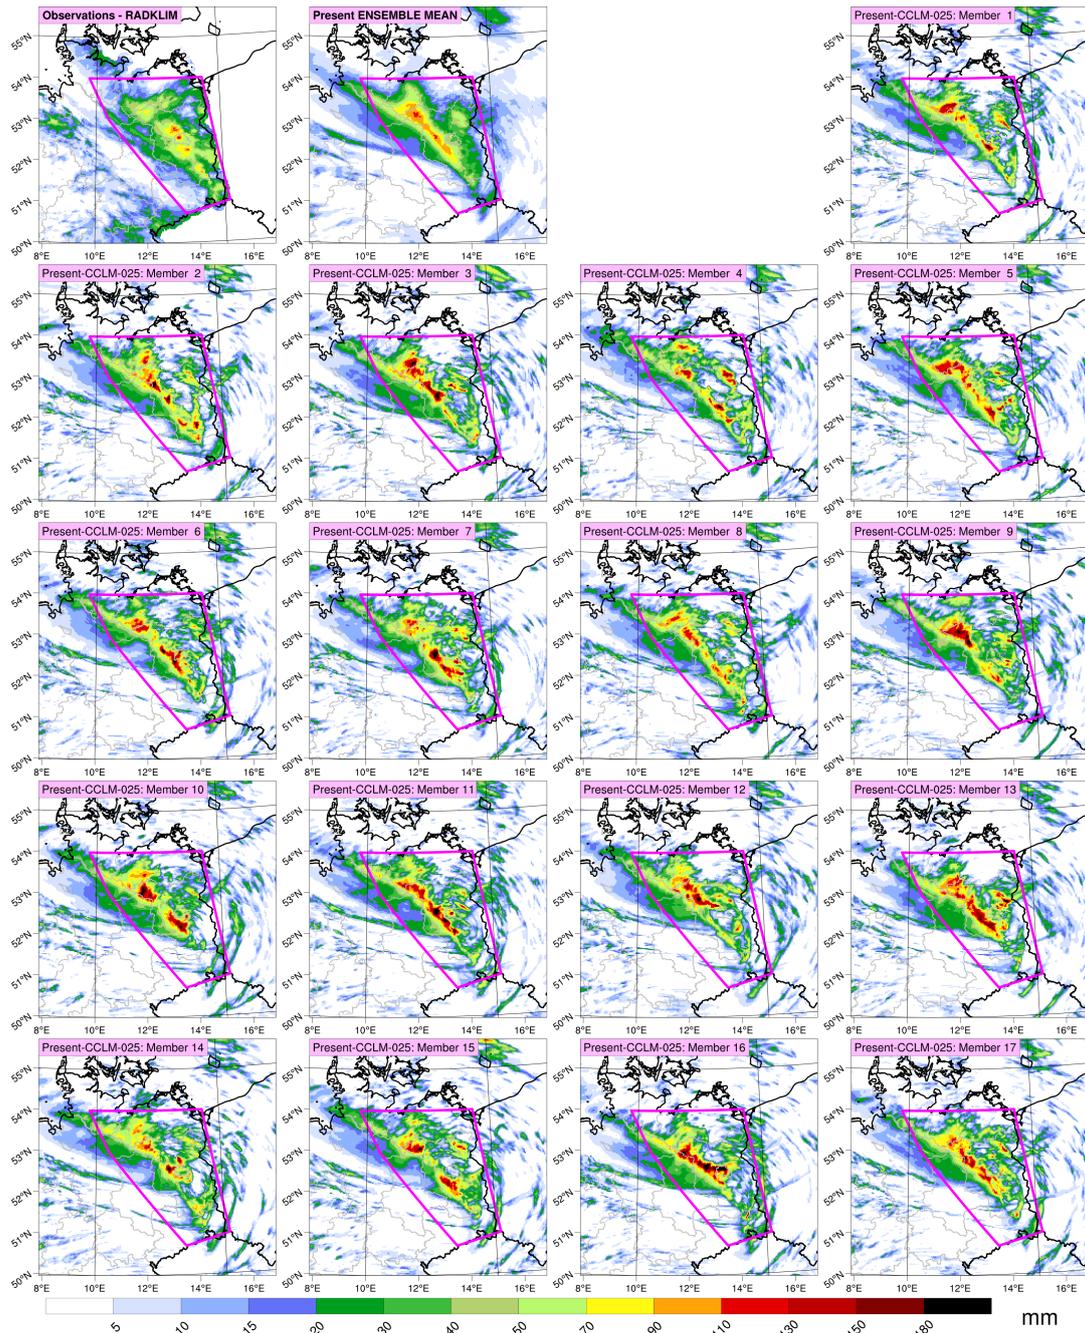

Figure S6. As in Figure S5, except for the present-climate ensemble.
