Abstract. The Mediterranean Basin is one of the regions most affected by climate change which poses significant challenges to agricultural efficiency and food security. While rising temperatures and decreasing precipitation levels already impose great risks, the effects of compounding extreme events (CEEs) can be significantly more severe and amplify the risk. It is therefore of high importance to assess these risks under climate change on a regional level to implement efficient adaptation strategies. This study focuses on False Spring Events (FSEs), which impose a high risk of crop losses during the beginning of the vegetation growing period, as well as Heat and Drought-based CEEs (HDCEs) in summer, for a high-impact future scenario (RCP8.5). The results for 2070-2099 are compared to 1970-1999. In addition, deviations of the near-surface atmospheric state under FSEs and HDCEs are investigated to improve the predictability of these events. We apply a multivariate, trend-conserving bias correction method (MBCn) accounting for temporal coherency between the inspected variables derived from EUR-CORDEX. This method proves to be a suitable choice for the assessment of percentile threshold-based CEEs. The results show a potential increase in frequency of FSEs for large portions of the study domain, especially impacting later stages of the warming period, caused by disproportionate changes in the behavior of warm phases and frost events. Frost events causing FSEs predominantly occur under high-pressure conditions and northerly to easterly wind flow. HDCEs are projected to significantly increase in frequency, intensity, and duration, mostly driven by dry, continental air masses. This intensification is multiple times higher than that of the univariate components. This study improves the understanding of the unfolding of climate change in the Mediterranean and shows the need for further, locally refined, investigations and adaptation strategies.

1 Introduction

The latest Assessment Report by the Intergovernmental Panel on Climate Change (IPCC) on the current climate status has yet again made strikingly clear, that the consequences of human actions significantly impacted weather and climate on a global scale and continue to do so (Eyring et al., 2021). Among the most significant impacts of ongoing climate change is the intensification of extreme events, especially in terms of temperature and precipitation (Seneviratne et al., 2021). These

changes are projected to include a significant increase in the frequency and intensity of heat-related extremes, as well as intensified heavy precipitation events, but also an amplified risk of agricultural drought. Additional consequences of human-induced global warming also include negative impacts on agriculture. As stated by Bezner Kerr et al. (2022), there is high confidence that climate change is imposing stress on, among others, agriculture and forestry. Furthermore, the authors point out extreme events to significantly impair food security and heat and drought to be among the main drivers exacerbating the risk of production losses.

While the general understanding of these changes is high on a global level, the level of confidence in these projections varies on a regional to local level. Giorgi (2006) conducted an investigation of regions with the highest exposure to the effects of climate change (Climate Change "Hot-Spots") and demonstrated the Mediterranean, which includes southern Europe as well as parts of northern Africa and western Asia, to be among the two most vulnerable regions worldwide. As this region is characterized by a high population density and high socioeconomic importance, the effects of climate change must be monitored closely to enable suitable protective and mitigative measures.

To assess the potential effects of climate change, general circulation models (GCM) have been extensively used in the past. These models, driven on a global basis, are capable of providing large-scale information on changes in atmospheric predictors, although their spatial resolution is generally low. While GCMs are able of providing reasonable results under specific circumstances, the quality of GCM output proves to be too low to be applied on a sub-global scale (Di Virgilio et al., 2022; Yang and Villarini, 2021; Wang et al., 2021; Hardiman et al., 2008). To improve the quality of these projections, regional climate models (RCM) driven by the GCM output can be consulted, by conducting simulations on a regional to local level and in a higher temporal and spatial resolution (Giorgi, 2019). While this procedure, also known as dynamical downscaling, can improve the quality of climate projections, systematic model bias may still be inherited, originating from both, the GCM and RCM (Eden et al., 2012). To overcome this limitation, the inherited bias from climate models can be statistically corrected according to a reference data set of a higher quality. This method is referred to as bias correction and can, for example, be performed using station observations, satellite data, or reanalysis. As Cannon (2018), Vrac and Friederichs (2015) and Gudmundsson et al. (2012) have proven, performing statistical bias correction can significantly reduce deviations of one or multiple predictors from a reference data set and therefore improve the reliability of climate projections.

Compound extreme events (CEE) have moved more and more into the scientific focus, as the joint effects of multiple hazards may surpass those of univariate extremes (Zscheischler et al., 2020). In the context of extreme events potentially exacerbating risks to agriculture, water availability, and food security (Bezner Kerr et al., 2022), high demand for robust projections of CEE in regions with a high vulnerability regarding these aspects becomes evident. Therefore, this study aims at investigating two types of compound events with detrimental effects on agriculture and vegetation in the Greater Mediterranean Region (GMR), a global climate change "Hot-Spot". The types of CEE analyzed in this study include False Spring Events (FSEs), which are defined as a freezing event occurring after the start of the crop-related growing season (SGS) (Ault et al., 2013; Gu et al., 2008). Freezing during this highly vulnerable period in the early stages of plant development may cause significant damage, resulting in yield loss or failure. Recently, FSEs have been investigated mostly in moderate, mid-latitude climate zones. For example, disproportionate changes in the last day of frost (LDF) during spring and the SGS have been shown for Central Europe (Vitasse

et al., 2018; Zohner et al., 2016) and the United States (Peterson and Abatzoglou, 2014). Chen et al. (2021) demonstrated a negative correlation between the SGS date and mean air temperature over temperate China, indicating an earlier SGS under warmer conditions. Therefore, if the risk of spring freezing events does not proportionally decline, the risk of FSEs increases (Labe et al., 2017; Inouye, 2008; Gu et al., 2008). Less focus has been put on subtropical climate zones, where the risk of frost events is considerably lower than in moderate climate zones. However, as the GMR is characterized by complex topography, with high mountain ridges adjoining wide lowlands that represent a transition zone between the GMR and cool-temperate Central Europe, the effects of freezing conditions may potentially reach out to the subtropical parts of the domain. A variety of methods to estimate the LDF and SGS exist. One example is to collect and assess crop-specific empirical data, where specific thresholds for freezing and growing conditions can be taken into account (Chamberlain et al., 2019). This is often applied in regionalized studies or for specific plant species. In terms of heat-and-drought compound events (HDCEs), many studies investigated historical periods and demonstrated an increasing trend regarding the frequency and intensity of HDCEs (Ionita et al., 2021; Vogel et al., 2021). Fewer studies have investigated whether these changes will be persistent under future climate. For example, Ruffault et al. (2020) demonstrated heat-and-drought-related weather conditions favoring the ignition of wildfires to likely be increased under climate change.

In this study, we aim at presenting a large-scale overview of the potential of FSEs occurring in the GMR. Therefore, we apply a simplified method derived from Peterson and Abatzoglou (2014) and Leeper et al. (2021) that uses generalized thermal thresholds to determine the LDF and SGS. In terms of HDCEs, we adopt an approach by Ionita et al. (2021), using the 3-monthly standardized precipitation index (SPI-3) for drought indexing and percentile-based thresholds for daily maximum temperature. By conducting this study, we seek to increase the knowledge of how the effects of global warming will unfold in terms of FSEs and HDCEs in the GMR, regarding both the frequency and duration of these events.

Next to the projected changes in FSEs and HDCEs, we also investigated the deviations of crucial near-surface atmospheric predictors from the mean state during these events, in order to improve the level of knowledge on what conditions act favorable towards the occurrence of FSEs and HDCEs. Similar works have been done by Ionita et al. (2021) and Mastrantonas et al. (2021), who investigated connections between extreme/compound events and large-scale atmospheric patterns. The inclusion of weather patterns, however, is aggravated in the context of multivariate bias correction, as the conservation of spatial and temporal coherence of multiple variables requires a significantly higher computational effort (Cannon, 2018). By considering sea level pressure as well as zonal (u) and meridional (v) wind speeds in an only temporally coherent bias correction setup, we seek to reduce the computational cost while preserving the ability to assess the origin of air masses and estimate pressure deviations under FSEs and HDCEs.

To obtain these results, we apply a multivariate bias correction method based on the N-dimensional probability density function transform (MBCn) presented by Cannon (2018). 13 GCM-RCM combinations were obtained from CORDEX, as well as ERA5 data as reference for the bias correction procedure. We inspect a late-century future period (2070-2099) under the high-impact RCP scenario 8.5 and compare the results to 1970-1999. The choice of scenario was made to demonstrate potential changes in FSEs and HDCEs on the higher end of the range of emission scenarios (Riahi et al., 2011). These research questions are addressed in the following sections:

- a) To what extent can the quality of climate model output be improved, in the context of reproducing threshold-based metrics for a multivariate and interdependent task? b) Are FSEs relevant in the GMR, and how is their occurrence projected to change towards the end of the 21st century? What deviations in the near-surface atmospheric state are connected with FSEs?
- 95 c) How will the frequency, intensity, and duration of HDCEs change towards the end of the 21st century? What deviations in the near-surface atmospheric state are connected with HDCEs?
- d) What implications will the projected changes in FSEs and HDCEs potentially have on vegetation and crop efficiency?

2 Study domain

In this study, we investigate the potential effects of climate change on the Greater Mediterranean Region (GMR). The domain margins are given as 10° W - 37° E and 27.75° N - 50° N and are displayed in Figure 1. It is important to note that the domain definitions were selected to resemble the Mediterranean domain provided within the MED-CORDEX framework. The label "GMR" as given in this study therefore refers to a model domain definition, rather than a climatic classification of the Mediterranean. The GMR within the context of this study includes most parts of the southern European continent, as well as portions of northern Africa and western Asia. As a result of the Alpine orogeny, this region is characterized by a variety of mountainous formations that merge directly into the Mediterranean Sea. Some of the most prominent ridges are the Alps, the Apennines, and the Pyrenees on the European side, the Atlas formation on the African side, and the Taurus on the Western Asian side. However, these mountain ranges are separated by wide lowlands, where large river systems drain precipitated water from the mountains toward the sea. These lowlands, e.g. the valleys of Ebro, Rhône, and Po, substantially differ from the mountain ranges in terms of climatic characteristics, adding even more to the diversity and complexity of the GMR.

110 This climatic complexity is also reflected in the Köppen-Geiger Climate Classification (Kottek et al., 2006). The northern parts of the study domain are under the influence of the interplay between the polar front and subtropical highs within the zone of Westerlies (Cf climate, see Fig. 1). This causes a constant alteration between moderate temperatures and a high likelihood for precipitation under the maritime influence and dry air masses of continental origin, causing hot temperatures in summer and the opposite in winter. With decreasing latitude, the influence of the Westerlies recedes and the subtropical ridge becomes dominant. This persistent high-pressure system causes calm, warm, and dry conditions under descending air masses. Due to the southward shift of the subtropical ridge following the annual cycle of the Intertropical Convergence Zone (ITCZ), the influence of the Westerlies becomes stronger in winter, causing precipitation levels to increase. The resulting warm and summer-dry climate (Cs climate), which is most common on the west sides of continents, is also often referred to as Mediterranean Climate. The southernmost area of the study domain, where the subtropical ridge is persistently dominant throughout the year and precipitation is rare, is classified as dry-arid, or dry-semi-arid (BW and BS climate). With increasing elevation in the northern mountainous regions, the climate is cooler and more continental, with increased temperature spans and persistently high precipitation (Df climate). The highest portions of the Alps, where the mean temperature of the warmest months is below 10 °C, fall under the Polar-Tundra class (ET, Beck et al. (2018)).

Figure 1. Study domain covering the Greater Mediterranean Region (GMR) outlined in red and classification of the local climate according to an updated version of the Köppen-Geiger Climate Classification. Data and visualization obtained from Kottek et al. (2006).

3 Data and Methods

125 3.1 Data

To perform bias correction, a reference data set must be obtained, e.g. reanalysis or in-situ observations, next to the climate model output. Initially, climate model output data for a historical period must be obtained, next to the corresponding projection data for a future period under a specific scenario. To optimize the quality of the model output, the reference data set must inherit a higher accuracy regarding the "true" atmospheric state. Depending on the research aim this can be, for example, observational station data, satellite data, or reanalysis. The latter is especially relevant in regions with a low density of observations, for example, regions with no or very low population density or regions over the ocean. While a variety of observational data sets is available for the land portions of our study domain, we aimed at specifically including areas over the ocean, thus excluding all purely land-based data sets. Therefore, the latest global reanalysis data set published by the European Centre for Medium-Range Weather Forecasts (ECMWF), ERA5 (Hersbach et al., 2023, 2020), was obtained for this study. Out of the wide variety of variables included in ERA5, hourly 2 m air temperature, precipitation sum, sea level pressure, as well as 10 m u- and v-components of wind speed (eastward and northward, respectively) were obtained for this study and aggregated to daily mean values, respectively daily sums for precipitation. Hourly 2 m temperature was aggregated to maximum and minimum daily values. ERA5 data was obtained for the period 1970-2020, however, the 30-year period 1970-1999 is used

as historical reference data within the bias correction process and denoted as HIST in the following. There exist weaknesses
140 of the ERA5 data set, as discussed by Velikou et al. (2022) and Xu et al. (2022), for example spatial quality disparities and
misrepresentation of extreme events. Nevertheless, as also confirmed by these authors, the overall quality is high, making
ERA5 a justifiable choice as reference.

In terms of climate model output, a total of 13 different combinations of GCMs and RCMs was obtained from the **CO**ordinated
Regional Climate **D**ownscaling **E**Xperiment (CORDEX), consisting of dynamically downscaled realizations driven by GCMs
145 obtained from the fifth phase of the Coupled Model Intercomparison Project, CMIP5, initiated by the World Climate Research
Programme (WCRP, Taylor et al. (2012)). For this study, EUR-CORDEX (Cinquini et al., 2014), in the highest available spatial
resolution of 0.11 x 0.11 km and on a daily temporal resolution was obtained. While multiple RCP scenarios are provided, we
focus only on the high-impact scenario RCP 8.5 (Riahi et al., 2011), and the distant future period 2070-2099. Before being
handed to the bias correction procedure, the model data was bilinearly interpolated to match the 0.25 x 0.25 km spatial resolu-
150 tion of the ERA5 data. The 13 model combinations consist of 6 GCMs, including CNRM-CERFACS-CNRM-CM5 (Voldoire
et al., 2013), ICHEC-EC-EARTH (Hazeleger et al., 2012), IPSL-CM5A-MR (Dufresne et al., 2013), MOHC-HadGEM2-ES
(Collins et al., 2011), MPI-ESM-LR (Jungclaus et al., 2013; Stevens et al., 2013), and NCC-NorESM1-M (Bentsen et al.,
2013). As well as 4 RCMs, including DMI-HIRHAM5 (Christensen et al., 2007), GERICS-REMO2015 (Jacob et al., 2012;
Jacob, 2001), KNMI-RACMO22E (van Meijgaard et al., 2008), and SMHI-RCA4 (Strandberg et al., 2014; Samuelsson et al.,
155 2011). The data sets were downloaded from the DKRZ node of the ESGF data portal (Cinquini et al., 2014) All data utilized
for this study is described in detail in Table 1.

3.2 Methods

To obtain optimized climate model output, we apply a multivariate and dependency-preserving bias correction method (MBCn).
This method is presented below, as well as the definitions of FSEs and HDCEs, for which we adopted threshold-based ap-
160 proaches that have been applied in former studies (Peterson and Abatzoglou, 2014; Leeper et al., 2021; Ionita et al., 2021).
We additionally aimed at offering insights into the prevailing near-surface atmospheric conditions during these events. There-
fore, in addition to minimum/maximum temperatures and precipitation, we included sea level pressure into the bias correction
procedure, as well as u- and v-components of near-atmospheric wind, to calculate the mean wind direction. The additional
information on pressure deviations can give hints on the prevailing type of action center (i.e. high pressure or low-pressure sys-
165 tems) and the characteristics of the influencing air masses can be derived by means of their origin, i.e. the predominant wind
direction. To inspect the statistical significance of near-atmospheric deviations under CEEs from the mean state, we applied
a Mann-Whitney U test (Mann and Whitney, 1947; Student, 1908). As the 13 included models are independent, this test is
applied separately to each of the models. The sum of models indicating statistical significance is obtained for both, positive and
negative deviations from the mean, and presented in the results. As the inspection of mean wind directions is aggravated, due
170 to a break in the scale between 359° and 0°, we inspect the mode instead of the mean, i.e. the predominant wind direction with
the highest frequency within the sample. The statistical significance of the deviations of wind direction is obtained by applying

Table 1. Description of all obtained data sets for this study, including 13 GCM-RCM combinations from EUR-CORDEX for historical and future periods, as well as ERA5 reanalysis data for reference purposes.

a Fisher Exact test (Fisher, 1935) to the occurrence count distributions of the 8 wind directions N, NE, E, SE, S, SW, W, and NW. For each test, we consider statistical significance at a significance level of 5%.

3.2.1 Univariate bias correction

175 When aiming at an optimization of climate model output, multiple approaches of differing complexity exist. For example, if a linear bias towards a reference data set is to be removed, a delta (additive), or a factor (multiplicative), can be added to the model output (Deque, 2007). In general, the bias-corrected time series of a variable x_{bc} can be obtained, when a statistical transformation function f is applied to the raw model output $x_{m,p}$, expressed as

$$x_{bc} = f(x_{m,p}), \quad (1)$$

180 by Piani et al. (2010). However, complex climate models often inherit a more complex bias structure, when e.g. trends and instationarities come into play. To specifically account for differing bias within the distribution of a simulated climate variable, the method of empirical quantile mapping (EQM) was introduced (Piani et al., 2010; Boé et al., 2007; Gudmundsson et al., 2012). Within EQM, the cumulative distribution function (CDF) F of the raw model output m within a historical calibration

period c is matched to the corresponding CDF of the reference data (e.g. reanalysis) o within c , given as

$$185 \quad F_{m,c}(x_{m,c}) = F_{o,c}(x_{o,c}) \quad (2)$$

by Gudmundsson et al. (2012) and Tong et al. (2021). In the next step, the CDF of the raw model output within the projected period p is matched to the inverse CDF of the reference data in c , $F_{o,c}^{-1}$, as given in

$$x_{bc} = F_{o,c}^{-1}[F_{m,p}(x_{m,p})], \quad (3)$$

in order to receive the bias corrected model data x_{bc} (Gudmundsson et al., 2012; Tong et al., 2021). In a more general sense, the additional "knowledge" of the reference data regarding the distribution structure of the "true" atmospheric state is applied to the raw model output for a known, historical period. By doing so, information on the performance of the correction can be evaluated. If the correction performance is deemed as satisfactory, and under the assumption that model bias is stationary within the historical and projection periods (Maraun, 2012; Maraun et al., 2010), the same additional "knowledge" of the reference data is applied to the projection period.

195 Trends within the raw model output may have a negative effect on correction performance and, respectively, trends infused by the correction method may not represent the "true" atmospheric changes, as pointed out by Maurer and Pierce (2014) and Maraun (2013). To account for this, the method of EQM was adjusted to initially extract trends from the raw model output, then perform the correction process, and afterward apply the trend back to the corrected model output, as introduced by Cannon et al. (2015). Within this Quantile Delta Mapping (QDM) procedure, the linear trend Δ_m regarding each time step t , defined
200 as

$$\Delta_m(t) = \frac{x_{m,p}(t)}{F_{m,c}^{-1}[F_{m,p}^t[x_{m,p}(t)]]}, \quad (4)$$

is returned to the corrected model output by applying

$$\hat{x}_{bc,\Delta}(t) = \hat{x}_{bc}(t)\Delta_m(t). \quad (5)$$

3.2.2 Multivariate bias correction

205 All previously described methods are applied independently to each variable. While these methods are not capable of specifically adjusting the day-to-day variability to match that of the reference data, the temporal physical coherence is nevertheless upheld, allowing for long-term climatological inspections (Olschewski et al., 2023). However, the independence of the correction process for multiple variables, where each variable is corrected on its own, aggravates the investigation of multivariate matters such as compound events (Zscheischler et al., 2019; Rocheta et al., 2014). Therefore, methods accounting for the
210 dependency of multiple variables become necessary. As for univariate bias correction, a variety of approaches towards multivariate bias correction has been developed, each differing, for example, in the statistical metric that is used to adjust the dependence, or the level of restriction due to specific assumptions (Vrac and Thao, 2020; Cannon, 2016; Vrac and Friederichs, 2015; Bürger et al., 2011). This study applies a multivariate bias correction procedure (MBCn) developed by Cannon (2018),

based on an image processing technique using the N-dimensional probability density function transform (N-pdf) presented
215 by Pitie et al. (2005) and Pitié et al. (2007). Within MBCn, a random orthogonal rotation is first applied to the input climate
data. Subsequently, QDM is applied to the marginal distributions of the rotated input data as described in the previous section.
Finally, the rotated and QDM-adjusted data is inversely rotated to receive the corrected multivariate output (Cannon, 2018). As
the author describes subsequently, this process is iterated until the distributions of the model data and the reference data match.
In this study, we carried out 100 iterations, which has proven sufficient in previous studies (Dieng et al., 2022; Cannon, 2018).
220 Within the framework of this study, this procedure included the six atmospheric variables listed above and was individually
carried out for every grid cell. The suitability and potential of this method in terms of climate data and its application have
been proven in multiple studies, including Cannon (2018), Dieng et al. (2022), Lemus-Canovas and Lopez-Bustins (2021),
Singh et al. (2021), and Meng et al. (2022). Additionally, next to MBCn, Cannon (2016) explored other ways of correcting
the multivariate dependence structure, based on the Pearson and Spearman correlation dependence structure. However, these
225 approaches are accompanied by pronounced restrictions, making MBCn the preferable choice.

3.3 Compound event definitions

A comprehensive overview of types and definitions of compound weather and climate events is provided by Zscheischler
et al. (2020). In general, the authors discriminate four different types of compound events, based on their temporal and spatial
characteristics. FSEs, as defined for this study, are representative of preconditioned compound events, in which the precondition
230 is the warm anomaly of daily minimum temperature, which is beneficial towards the onset of the growing season, and the
hazard is a subsequent frost event, potentially causing damage to crops within the early stages of plant development. Due to
its subsequent nature, FSEs may also be categorized as temporally compounding events. FSEs consist of anomalies of one
variable only, i.e. daily minimum temperature, and are therefore considered as univariate compound events. Heat-and-Drought
compound events (HDCEs), by definition in this study, consist of multiple hazards occurring simultaneously, which is classified
235 by Zscheischler et al. (2020) as a multivariate compound event. However, if persistent drought is considered a precondition,
HDCEs may also be treated as a preconditioned compound event.

Percentile-based thresholds are a crucial component in this study. These thresholds were calculated for the historical period
and subsequently applied to the future period. By applying historical thresholds to future data, the results show changes in
extremes that have already been experienced and can therefore be better assessed by potential users. All included variables, as
240 well as extreme event and compound event definitions, are summarized in Table 2 and described in detail below.

3.3.1 False Spring Events

To define FSEs, we take three thresholds into account, including the start of the growing season (SGS), the number of days
between SGS and the frost event, as well as the thermal definition of frost events. In terms of the SGS, Robeson (2002)
suggested the period within spring and fall freezes, i.e. the SGS to correspond to the day of the year (DOY), from which daily
245 minimum temperatures are persistently above 0 °C. Leeper et al. (2021) built upon this definition and suggested the use of

Table 2. Variables, extreme events, and compound event definitions utilized in this study.

Name	Abbr.	Description	Source
Variables			
Day of year	DOY		
Daily maximum temperature	T_x		
Daily minimum temperature	T_n		
Daily precipitation sum	PR		
Daily mean sea level pressure	SLP		
Daily mean wind direction	DIR		
Metrics			
Last day of frost	LDF	Last DOY in spring period with T_n below $-2.2\text{ }^\circ\text{C}$	Peterson and Abatzoglou (2014)
Start of growing season	SGS	First DOY in spring period with T_n above $0\text{ }^\circ\text{C}$, $5\text{ }^\circ\text{C}$, $10\text{ }^\circ\text{C}$ for seven consecutive days	Leeper et al. (2021)
Standardized Precipitation Index	SPI-3	3-monthly Standardized Precipitation Index	McKee et al. (1993)
Heatwave event	HWE	Six or more consecutive days with T_x above 90., 95., 99. percentile	Perkins and Alexander (2013) Ionita et al. (2021)
Compound events			
False Spring Event	FSE	DOY of SGS minus DOY of LDF < 0	Peterson and Abatzoglou (2014)
False Spring Event Index	FSEI	Number of years within HIST with an FSE	Peterson and Abatzoglou (2014)
	FSEI ₀	FSEI with SGS threshold of $0\text{ }^\circ\text{C}$	
	FSEI ₅	FSEI with SGS threshold of $5\text{ }^\circ\text{C}$	
	FSEI ₁₀	FSEI with SGS threshold of $10\text{ }^\circ\text{C}$	
Heat-Drought Compound Event	HDCE	Day under HWE conditions and SPI-3 < -1	Ionita et al. (2021)
	HDCE ₉₀	HDCE with HWE threshold at the 90. percentile	
	HDCE ₉₅	HDCE with HWE threshold at the 95. percentile

multiple thermal thresholds, i.e. $0\text{ }^\circ\text{C}$, $5\text{ }^\circ\text{C}$, and $10\text{ }^\circ\text{C}$, and these thresholds are also applied in this study. These thresholds can be considered representative of different phases within the period of continuous warming.

Applying a time delay between the SGS and the FSE-defining frost event is an attempt to consider the most vulnerable time of leaf tissue, in the phase between budburst and full leafout (Chamberlain et al., 2019). In this context, Peterson and Abatzoglou (2014) applied various numbers of days between 0 and 15, of which the authors found no sensitivity of the results to lag times above 7 days. We adapted the time lag of seven days, as well as the definition of daily minimum temperatures below $-2.2\text{ }^\circ\text{C}$ for frost events.

Based on Peterson and Abatzoglou (2014), we investigate changes in the False Spring Event index (FSEI), which indicates the portion of years with an occurrence of FSE within a selected period. A year is counted towards FSEI, when the SGS, which is defined as a period of at least seven days in which the daily minimum temperature does not fall below 0 °C, 5 °C, or 10 °C, happens before the last frost event, defined as a daily minimum temperature below -2.2 °C. The considered variants of FSEI are therefore dependent on the definition of the SGS and include FSEI₀, FSEI₅, and FSEI₁₀. In general, the data from January through June was considered in the calculation of FSE. However, the occurrence of FSEs is dependent on the DOY of the SGS, which lies within this range of months for the predominant part of the region (see section 4.2.1).

3.3.2 Heat-and-Drought compound events

Ionita et al. (2021) investigated historical compound hot and dry events over Europe and their approach is adopted in this study. Initially, drought conditions are defined using the Standardized Precipitation Index (SPI, McKee et al. (1993)). The SPI takes the standardized accumulated monthly rainfall amount into account and fits it to a Gamma distribution, resulting in a mean of 0 and a standard deviation of 1. Values below zero, therefore, describe conditions with below-average accumulated rainfall, whereas values above zero depict wetter-than-average conditions. As we focus on agricultural drought, we choose the 3-monthly aggregated version, i.e. SPI-3. According to Edwards and McKee (1997), drought conditions are present when the SPI-3 is lower than -1, respectively when the precipitation level of the preceding 3 months is at least one standard deviation lower than average. This is also applied to this study. We define drought conditions to end with the first day for which the SPI-3 is greater than -1.

Regarding the definitions of heatwave events, as the requirements are diverse and depend on the user and the research question, multiple approaches exist with no general specification. Derived from Perkins and Alexander (2013) and Ionita et al. (2021), we apply a percentile-based threshold to define heatwave events (HWE). We define an HWE to be present when the daily maximum temperature exceeds the monthly 90th, 95th, 99th percentiles for at least six consecutive days. I.e., the sixth day of a period for which this condition is true counts as one towards the HWE statistic. If the heat period has a duration of nine consecutive days, days number six, seven, eight, and nine will count towards HWE, as the precondition is given for all of these days. Correspondingly, a Heat-Drought Compound Event (HDCE) is defined as the joint occurrence of HWE and an SPI-3 below -1, and every calendar day, for which the HWE and SPI-3 conditions are given, counts towards the HDCE statistic. As the hazard potential of HDCEs is highest during the summer months, we analyzed HDCEs for June, July, and August.

4 Results

Firstly, the performance of the MBCn method regarding the overall long-term climatology and specifically the estimation of percentile-based thresholds is evaluated. This is a crucial component in estimating the quality of the projections of FSEs and HDCEs. Subsequently, the prerequisites, the historical and projected frequencies of FSEs and HDCEs, and the corresponding near-surface atmospheric deviations linked to these events are presented.

4.1 Bias correction performance

285 In terms of long-term climatology for the spatial mean, it becomes clear from Fig. 2 that the regionally downscaled output from CORDEX still inherits a substantial amount of bias regarding ERA5. For the annual mean of daily maximum temperature, (Fig. 2a), the raw output of the 13 models lies within a range of roughly 2.5 °C, with most of the models underestimating the value indicated by ERA5. After applying MBCn, the 30-year mean value of all models, and therefore also the model mean, align with the ERA5 mean at 19.5 °C. As the daily minimum temperature inherits a close statistical relationship to the daily
290 maximum temperature, the performance of bias correction is similar, and the results were moved to Appendix A. For the annual precipitation sum (Fig. 2b), the uncertainty range of the raw output spans almost 200 mm, with an equal number of models over- and underestimating the sum given in ERA5. However, the bias of overestimating models is higher than the bias of underestimating models, leading to a slight positive bias in the model mean of around 75 mm. After performing MBCn, the bias is significantly reduced for all models. While some models show a slight underestimation of the annual rainfall amount
295 after MBCn, the uncertainty range of all models is reduced to under 10 mm.

As absolute and percentile-based thresholds are crucial components of the CEE definitions used in this study, we also inspected the ability of MBCn to align the distribution of percentiles derived from the daily data to that of the reference data. As can be seen in Fig. 2c for daily maximum temperature, the quality of raw CORDEX varies between models. In extreme cases, the mean absolute error is more than 1.5 °C. After MBCn percentile distributions of the models are aligned perfectly,
300 which may also be expected from a quantile-fitting method. The indicated percentile values for the MBCn-corrected projection data (illustrated by colored circles) demonstrate the significant changes in daily maximum temperature that are projected by the models, with increases of up to 7 °C. For daily precipitation, the error margin of the raw model output spans up to 0.4 mm. After MBCn, the bias is significantly reduced and lies within a range between 0 and 0.01 mm. The projection data for the future period indicates no clear direction of change, but the majority of models shows a reduction in daily precipitation for
305 moderate precipitation events and an increase in precipitation intensity for extreme precipitation events.

4.2 False Spring Events

4.2.1 Last day of frost (LDF) and start of growing season (SGS)

Crucial indicators for changes in the possibility of FSEs are changes in the LDF and the SGS, which are displayed in Fig. 3. In general, three gradients can be derived. Firstly, LDF and SGS tend to happen earlier in the year with decreasing latitude,
310 which is consistent with an increasing temperature level under a decreasing solar zenith angle. In addition, LDF and SGS tend to happen earlier in the year in maritime regions under a moderate, oceanic influence, whereas more continental areas show a later occurrence. Also, LDF and SGS tend towards later occurrences with increasing altitude, due to decreasing temperature levels. Throughout the low-level areas of southern Europe, the LDF mostly occurs in March or early April. Moving southward, the LDF occurs earlier, around early February, and reaches late January in southern Portugal/Spain, northern Africa, and
315 western Asia. In mountainous areas, depending on altitude, the LDF tends to occur between May and early June. All areas have a projected decrease in the DOY of the LDF within the future period in common. This decrease is mostly around 20 to 30

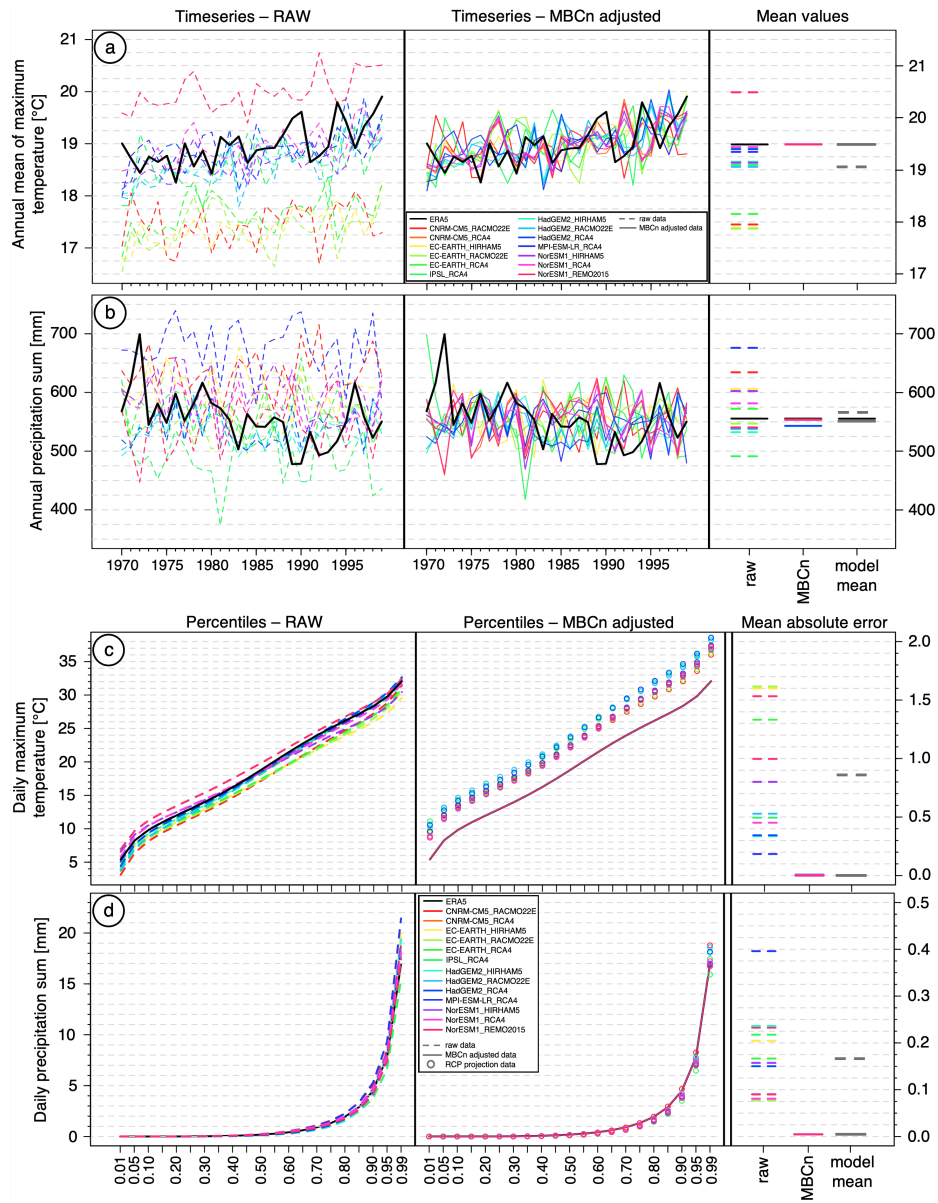

Figure 2. Evaluation of MBCn performance for long-term climatology and daily-based percentiles. a) Long-term time series of annual mean maximum temperature for ERA5 and 13 CORDEX models in raw (left), MBCn-corrected output (middle), and 30-year mean values (right). b) same as a), but for annual precipitation sum. c) percentile-based distributions of daily maximum temperature for ERA5 and 13 CORDEX models in historical raw data (left), MBCn-corrected historical and projected output (middle), and mean absolute error (right). d) same as c), but for daily precipitation.

days, or around one month, for most parts of southern Europe, corresponding to increasing temperature levels (Fig. 2). With increasing altitude, the DOY decrease reaches its spatial maximum of around 1.5 months. In coastal southern European areas, northern Africa, and western Asia, where frost events are in general rare, the reduction is less prominent.

320 The SGS with a temperature threshold of 0 °C (SGS_0 , Fig. 3b and f) occurs particularly early in the year in most western and southern parts of the domain, except for mountainous regions. Moving east, the date increases from mid-to-late January to early March. In elevated areas, the SGS_0 starts between April and June, depending on latitude. The projected changes in the SGS_0 show the largest decrease in mountainous areas, with reductions in the DOY of up to two months. An exception is the Alps, for which the highest situated areas still show a remarkable decrease, but are less dominant than in the Alpine
325 foreland. In terms of low-level regions, especially the continental European and Turkish regions east of 10°E appear striking, with reductions of more than 30 days.

The spatial characteristics of SGS_5 are similar to SGS_0 . However, corresponding to the higher thermal threshold, the occurrence is later within the year. For most regions, the SGS_5 occurs around 1.5 to 2.5 months after the SGS_0 . Within high-elevation areas, the time difference between SGS_5 and SGS_0 is smaller. The projected changes of the SGS_5 , however, substantially differ. Throughout the domain, the decreases in the DOY reach 30 to 50 days, with larger decreases in the western parts. While
330 mountainous areas are projected to experience a decrease as well, it is less dominant than in the lower elevated regions. This is particularly true for the Alps.

The spatial characteristics of the SGS_{10} closely resemble those of the SGS_5 . The shift between the two is around one to 2.5 months and therefore almost linear, when comparing SGS_0 , SGS_5 , and SGS_{10} . The highest elevated parts of the Alps show no
335 occurrence where nightly temperatures do not remain above 10 °C within the inspected period. In terms of projected changes, the spatial structure of the continental regions resembles that of SGS_5 , although the decrease is in general on a lower level, reaching from 20 to 30 days. Most noticeable here are most of the coastal regions, where the projected decrease is the highest, with reductions of up to two months.

It becomes apparent from Fig. 3 that the reductions in the DOY for the LDF are disproportional to the reductions in the
340 DOY of the SGS. The level of disproportionality is dependent on the thermal definition of the SGS as well as on regional characteristics such as latitude, altitude, and distance from the sea. From a statistical point of view, only the SGS_0 tends to occur before the LDF, leading to a potential expectancy that the $FSEI_0$ may be high in the study domain, but not the $FSEI_5$ or the $FSEI_{10}$. However, due to disproportional reductions of the SGS compared to the LDF and with many regions projected to experience a larger reduction in the DOY of the SGS than for the LDF, the risk of an increased FSEI rises.

345 **4.2.2 False Spring Event Index (FSEI)**

The historical and projected changes of the FSEI are displayed in Fig. 4. Following the assumed distributions described above, the $FSEI_0$ is high in almost all of Southern Europe and Western Asia, as well as in some parts of northwestern Africa, and lies mostly in a range between 15 and 25 (Fig. 4a). By definition, this equals an occurrence ratio of 50-83%. Over the ocean, northeast Africa, and mountainous regions, the FSEI is low. On the contrary, the $FSEI_5$ (Fig. 4e) and $FSEI_{10}$ (Fig. 4i) are in
350 general low within the study domain, with the former reaching around 5 in many parts of the domain and the latter mainly

Figure 3. Historical DOY (left) and projected changes in the DOY (right) of the last day of frost (LDF) and the start of the growing season (SGS). First row shows LDF, second row SGS_0 , third row SGS_5 , and fourth row SGS_{10} .

not occurring over land areas in the historical period. An exception within $FSEI_5$ are the coastal areas of western Europe and Turkey, where the occurrence is highest at around 10 to 15, equaling 33-50% of all years.

Regarding the projected changes in the future period, Fig. 4b), f), k) display the difference between the decrease in the DOY of the SGS and LDF. In areas marked red, the SGS is projected to retract more quickly towards the beginning of the year

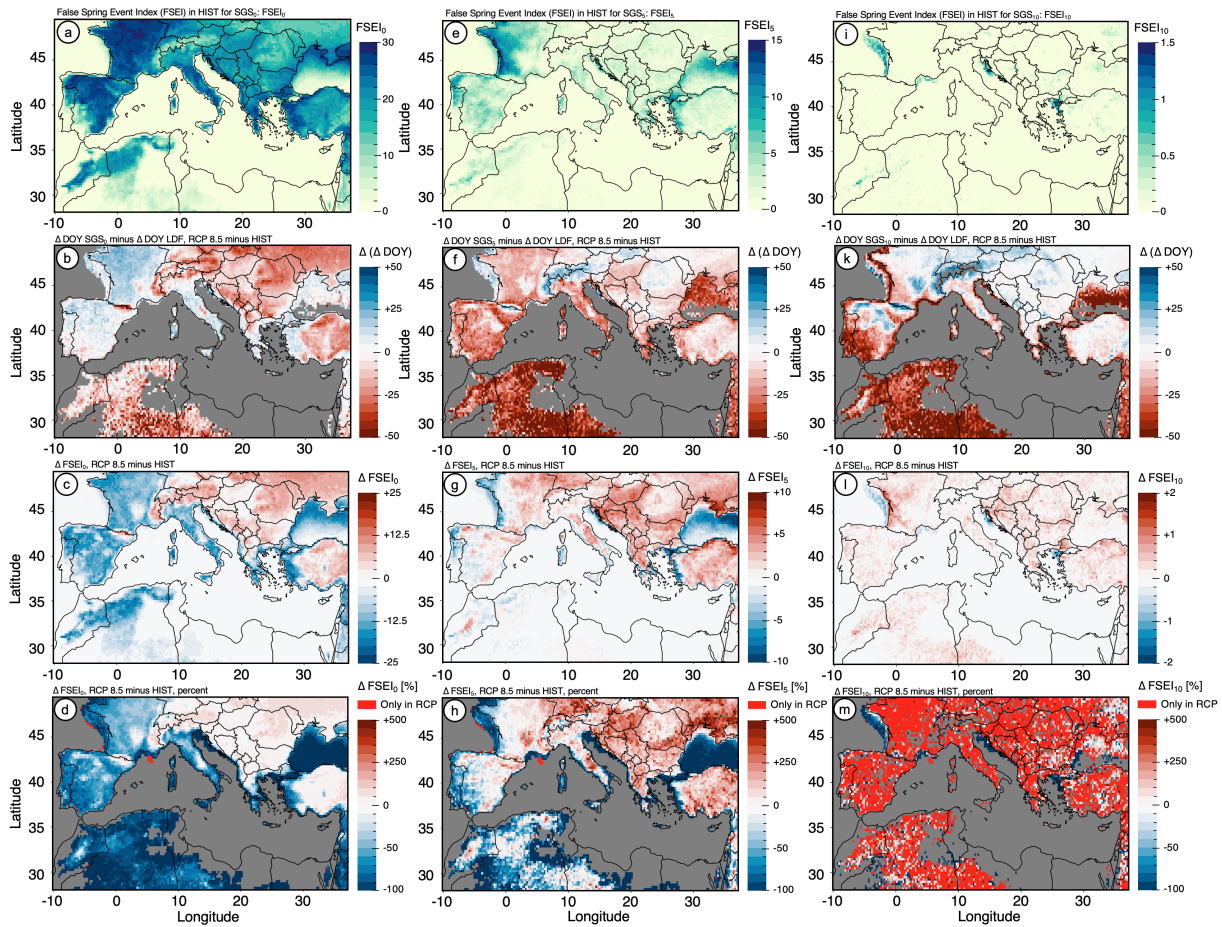

Figure 4. Historical occurrence and projected changes of the False Spring Event Index (FSEI). FSEI₀ in first column, FSEI₅ in second column, FSEI₁₀ in third column. Historical occurrence in the first row (a), (e), (i)), the difference in projected changes in the DOY of LDF and SGS in the second row (b), (f), (k)), projected changes in the FSEI in the third row (c), (g), (l)), and projected changes in the FSEI in percent in the fourth row (d), (h), (m)).

355 compared to the LDF, therefore potentially increasing the risk of FSEs. The opposite is projected for areas marked blue, i.e. a faster retraction of the LDF compared to the SGS, thus potentially lowering the risk of FSEs. The third row of Fig. 4 shows the actual projected changes in the FSEI₀, FSEI₅, and FSEI₁₀, and a comparison of the two metrics shows a close agreement for most of the inspected regions. In terms of FSEI₀, a decrease of up to 20 events per 30-year period is projected for most of the western and southern parts of the domain. For most of the eastern domain and the mountainous areas except the Atlas, however, up to ten events per 30-year period are projected. For Eastern Europe, a similar picture is apparent for the FSEI₅. However, in the western parts of the domain, the signal is reversed and depicts an increase in FSEs of up to 5. Only the most maritime parts of France, as well as parts of Spain and Portugal, show matching signals for FSEI₀ and FSEI₅. For FSEI₁₀, especially the non-mountainous areas of the study region show a potential increase in the number of events, with mostly one additional

360

event per 30-year period. Low-level southwestern France, where FSEI₀ and FSEI₅ and projected to predominantly decrease, becomes most dominant for FSEI₁₀, however, with the highest increase of up to 2 events. It should be noted, especially for FSEI₅ and FSEI₁₀, that some regions appear blue regarding the disproportionate retraction of LDF and SGS, but already show no occurrence of FSEs in the historical period. Therefore, no further decline in the FSEI can be detected.

The percentage change of the FSEI, shown in the bottom row of Fig. 4, shows a more pronounced manifestation of changes in FSEI₅, reaching up to a five-fold increase in the number of FSEs, whereas increases amount to around 50-100% for FSEI₀. The decreases projected for FSEI₀ amount up to 50-75% of the historical count. While the occurrence of FSEI₁₀ is extremely rare in the historical period, Fig. 4 m shows that this event is projected to occur in almost every portion of the study domain in the future period.

4.2.3 Atmospheric variations related to FSEs

The deviation from the mean atmospheric state for sea level pressure (SLP) and daily minimum temperature (T_n) for frost events after the SGS₀ is shown in Fig. 5 (SLP a), e), h), T_n b), f), i)). Note, that the deviations in the historical period are shown, whereas the deviations in the future period were moved to Appendix B. In general, frost events after SGS are accompanied by above-average SLP, indicating the potential predominance of high-pressure systems. There is a high level of agreement within the 13 models, as shown by the high number of models indicating this positive SLP deviation (Fig 5e). In addition, these deviations are statistically significant in all 13 models for the majority of areas. A notable exception from this is the high-elevated mountainous regions, where SLP deviations show a negative deviation. As can be expected, T_n deviations are significantly below-average in most low- and mid-elevated areas, where the SGS₀ happens particularly early within the year. In higher elevated areas, where the SGS₀ is closer to summer, the deviations turn towards positive values, as frost events occurring post-SGS tend to be warmer than in winter.

Following the climatology of the study domain (see section 2), the wind most often originates from southwesterly to northwesterly directions in the less elevated areas. This changes northerly to easterly directions with decreasing latitude, where the influence of the westerlies decreases. Over the mountain ridges, however, local anomalies appear dominant in the mode of the wind direction. Here, wind most often blows from the main ridge towards the lowlands, resulting in, e.g., predominant southwesterly winds to the north and east, and northeasterly winds to the south and west of the Apennines. The interplay of large-scale atmospheric flow and local anomalies causes the complex structure shown in Fig. 5c). Under frost events post-SGS, this structure is significantly changed (Fig. 5g), with predominant easterly and northeasterly winds throughout the lowlands (Fig. 5d). Along mountainous areas, the mode of the wind direction appears similar, with winds blowing from the ridge to the lowlands. However, a high number of models still indicate statistically significant shifts in the wind direction distribution.

The general picture is similar for frost events after the SGS₅ (Fig. 6). But with a decreasing number of frost events and therefore a reduced sample size, fewer models indicate statistical significance. For the SGS₁₀, with even fewer events, no clear picture can be derived, and the corresponding plot is therefore moved to Appendix B. The overall picture indicates that frost events after the SGS are most often accompanied by cold, easterly airflow under high-pressure conditions, which all

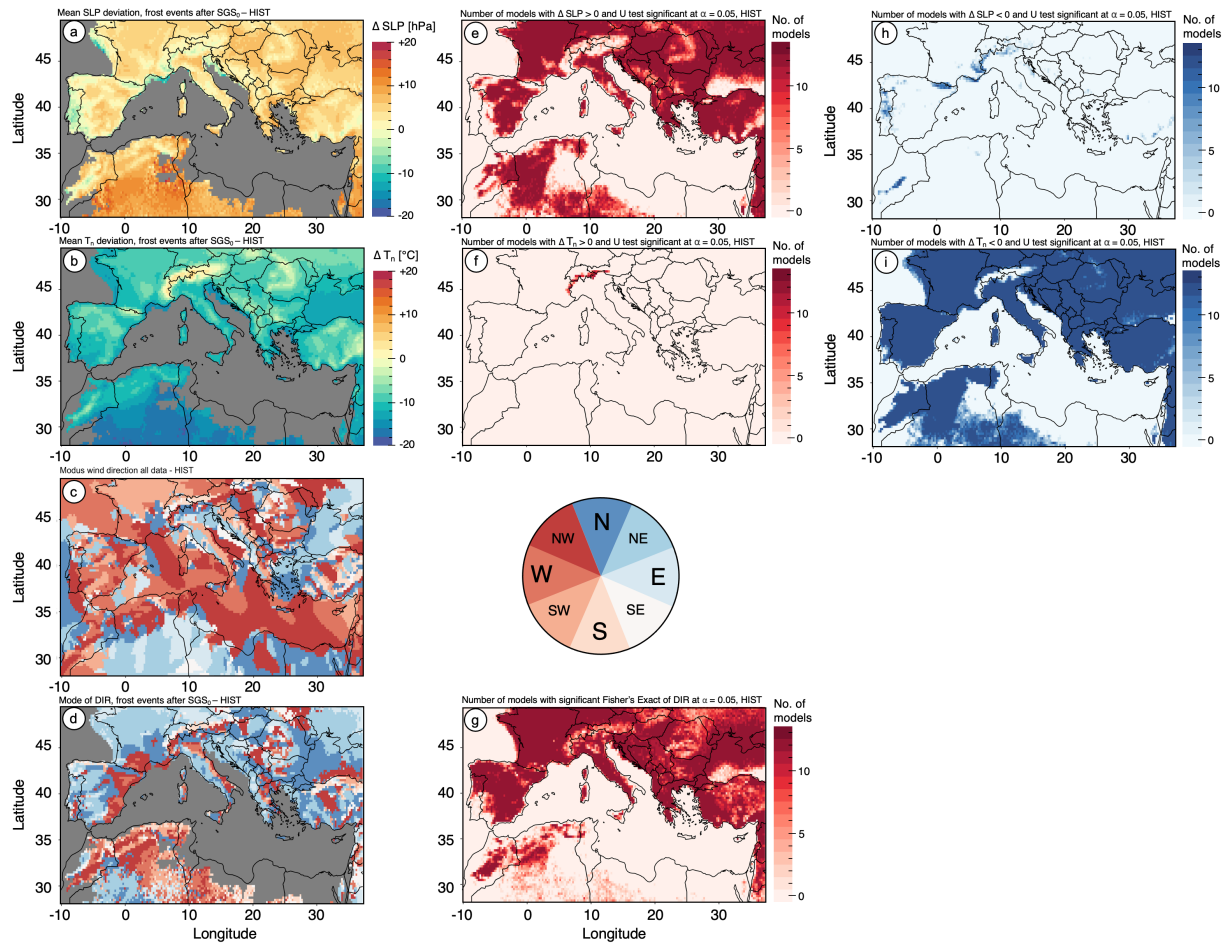

Figure 5. Mean deviation of the near-surface atmosphere from the 30-year mean under frost events after the SGS for sea level pressure (SLP, first row) and daily minimum temperature (T_n , second row). Number of models indicating a statistically significant positive deviation (e, f), and statistically significant negative deviation (h, i). Mode of wind direction within the 30-year historical period (c) and only for frost events after the SGS (d). Number of models indicating significantly different distributions of wind directions (g).

significantly deviate from the 30-year mean. In mountainous regions, descending air masses flowing from the ridge to the lowlands are predominant.

In the future, there is no indication of a change to the general picture of these characteristics. While cold, easterly flows under high pressure are also predominant in the projections, fewer models indicate a statistically significant deviation from the 30-year mean (Appendix B). Comparing the mean atmospheric deviation in the future and historical periods, it can be seen in Fig. 7 that the models project an increase in the positive deviation of SLP from the mean state for most of Eastern Europe and Western Asia.

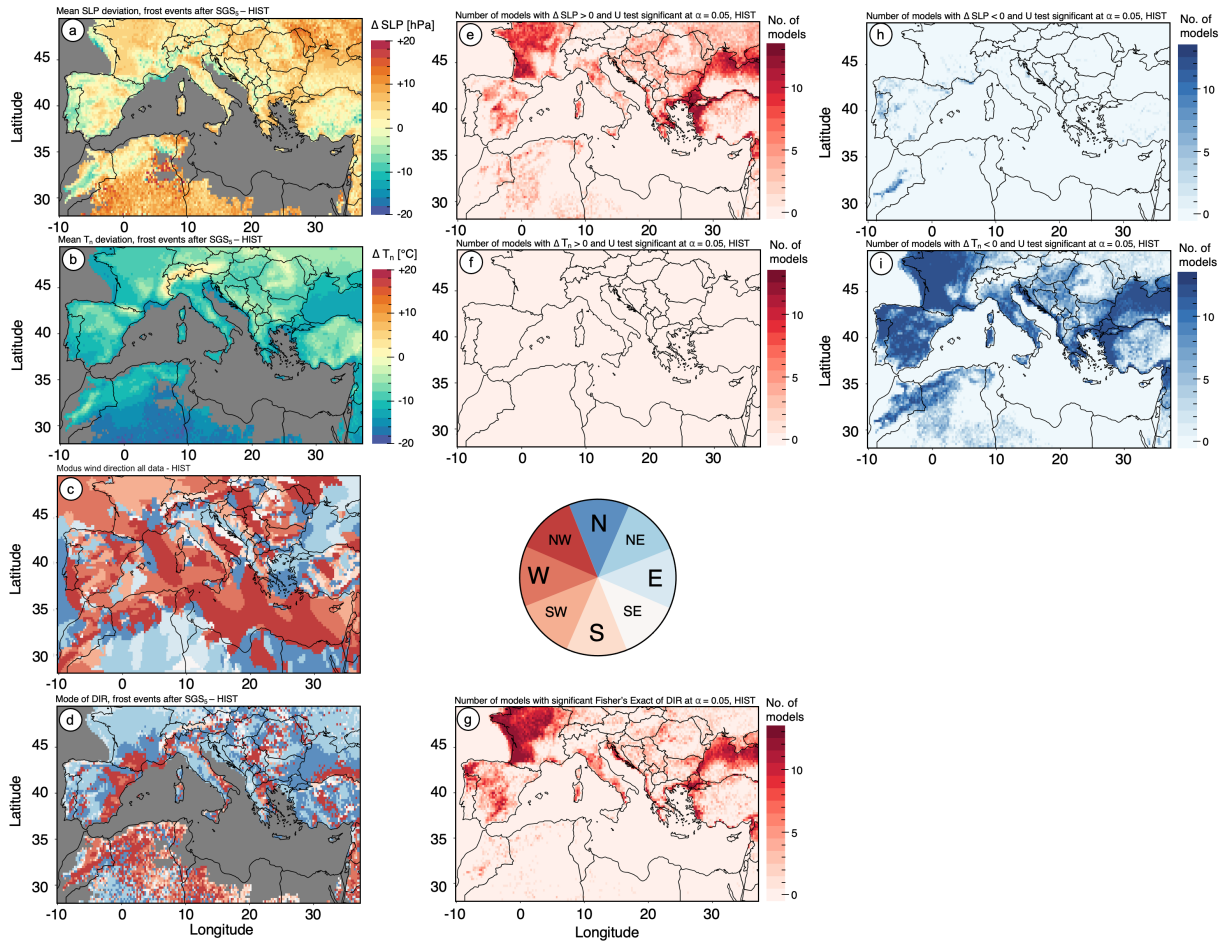

Figure 6. Same as Fig. 5, but for FSEI₅.

The homogeneous spatial indication of this change for SGS₀ is less uniform for SGS₅, where the majority of cells indicate an increase in positive deviation mixed with cells indicating a decrease. In Spain, Portugal, and northwestern Africa, however, the projected development is the opposite, indicating a general decrease in positive SLP deviation. In terms of T_n , regions with varying changes in the deviation mix closely for SGS₀ with no clear spatial distinction. For SGS₅, which is in general projected to occur earlier within a year, the temperature deviation is projected to decrease in correspondence with a higher potential for lower temperatures closer to the winter period. In general, not accounting for regional variations, the projections indicate an intensification of the high-pressure anomaly under frost events post-SGS, with a higher potential for lower temperature anomalies than in the historical period.

Figure 7. Projected changes in the deviations of sea level pressure (SLP, first row) and daily minimum temperature (T_n , second row) from the 30-year mean under frost events after the SGS. SGS_0 (a-b), SGS_5 (c-d), and SGS_{10} (e-f).

4.3 Compound events of heat and drought

4.3.1 SPI-3 and percentiles of T_x

Prerequisites for the investigation of heat and drought-related compound events are changes in the percentiles of daily maximum temperature (T_x) and the corresponding change in the exceedance of these thresholds, as well as changes in drought behavior indicated by the SPI-3. These projected changes are shown in Fig. 8.

Following the climatological description in section 2, the thermal gradients regarding latitude, elevation, and distance from the sea become apparent for the historical percentile-based thresholds of T_x including the 90th, 95th, and 99th percentiles in Fig. 8a) and c). The given values all refer to the meteorological summer, including June, July, and August (JJA). The corresponding projected changes under RCP 8.5 are shown in Fig. 8d) and f) and depict a minimum increase of 4.5-5 °C for a majority of land areas in the study domain. Additionally, a southward increase in the deviation can be detected, reaching from around +5 °C in central Europe to over +6 °C in northwestern Africa. Thirdly, some mountainous areas, e.g. the Alps and the Pyrenees, show intensified warming compared to the surrounding lowlands. Next to the spatial gradients, an increase in warming can be detected for increasing percentiles, which is true for most parts of the study domain. In general, when applying the percentile-based thresholds derived from the historical period (see. Fig. 2c) to the future daily T_x , the historical 90th percentile is projected to shift to approximately the 66th percentile. Therefore, while this threshold was historically exceeded on one of ten days on average, one out of three days would exceed the historical threshold in the future. This tripling of the occurrence probability is surpassed by the 99th percentile, for which a fifteen-fold increase is projected.

The SPI-3 indicates an increased probability for drought conditions in the study domain, excluding parts of central and eastern Europe, which is reflected both in the annual (Fig. 8g) and JJA consideration (Fig. 8h). However, lower values for JJA

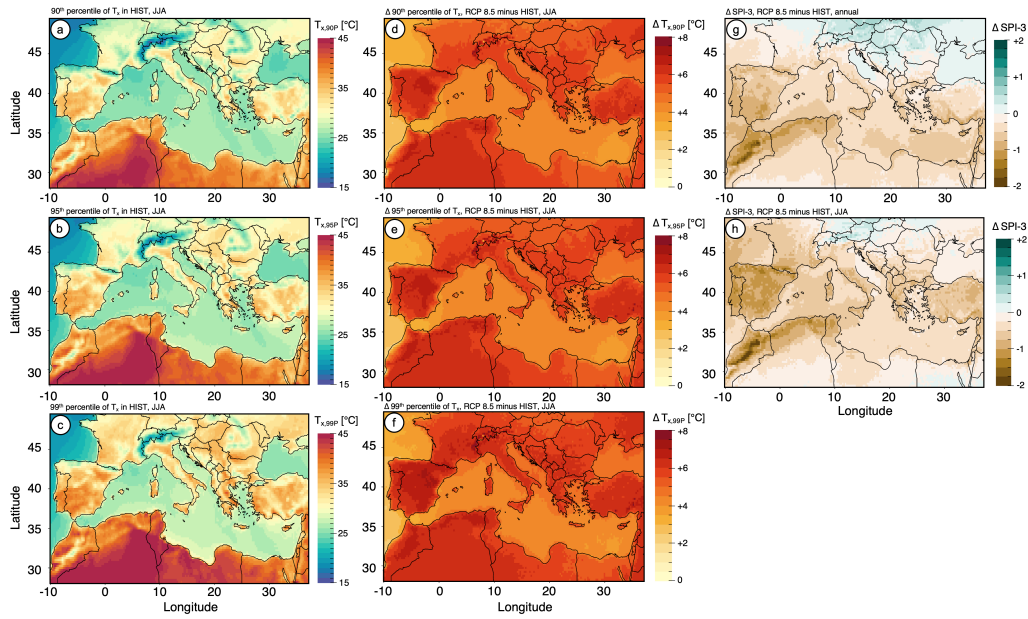

Figure 8. Historical (left column) and projected changes (middle column) in the 90th (a, d)), 95th (b, e)), and 99th (c, f)) percentile of daily maximum temperature. Projected deviation of the SPI-3 from the historical mean in the future period (right column) under annual (g) and summer (h) consideration.

indicate an aggravated drought situation for the summer months, compared to the annual mean. For most regions indicating a decrease in the SPI-3, the reductions are projected at around 0.5. This equals a reduction in the mean precipitation sum of around one-half standard deviation of the historical period. However, in the western parts of the domain, including most parts of Spain, Portugal, and Morocco, the SPI-3 is projected to decrease by more than one standard deviation, indicating prevailing
 435 drought conditions in the future. In the regions where Δ SPI-3 falls below -1, on average, every month is expected to meet the drought-based requisite for the occurrence of HDCEs.

4.3.2 Heat-Drought Compound Events (HDCEs)

The historical and future spatial characteristics of HDCEs, as well as the corresponding length of consecutive days meeting the HWE criteria, are shown in Fig. 9. During the historical period (Fig. 9a), HDCE₉₀ most often occurred in the northern
 440 half of the domain, including Italy, southern France, and the Balkans, reaching occurrence rates of once every three to five years, on average. While the spatial differences are similar for HDCE₉₅, the frequency of events is reduced, mostly occurring less than once every ten years. HDCE₉₉ are virtually not simulated by the models, showing only singular appearances within the 30-year period. Due to the low historical occurrence rates compared to the future period, the absolute occurrences, instead of the Δ , are shown in Fig. 9b), f), k). For every grid cell of the domain, increases in the occurrence of all types of HDCEs are
 445 projected. The largest frequency over land areas appears in regions close to, or bordering, the Mediterranean Sea. For HDCE₉₀,

up to 20–25 days per summer are projected to occur in these regions, with frequencies dropping to around 5–10 events per year in Central Europe and northeastern Africa. As for the historical occurrence, the spatial structure of the projected increases is similar for HDCE₉₅ and HDCE₉₉, with decreasing frequencies for higher thermal thresholds. Within the aforementioned regions with the highest increase, HDCE₉₅ are projected to occur around 10–20 times per summer, and 5–10 times per summer for HDCE₉₉.

Figure 9. Historical occurrence and projected changes of Heat-Drought Compound Events (HDCEs). HDCE₉₀ in the first column, HDCE₉₅ in the second column, HDCE₉₉ in the third column. Historical occurrence rate in the first row (a, e, i)), projected future occurrence rate in the second row (b, f, k)). Average historical length of consecutive days meeting the HWE criteria (HDCE-period) in the third row (c, g, l)) and projected changes in the average length of HDCE-periods in the fourth row (d, h, m)).

In accordance with the definition of HDCEs, the number of consecutive days meeting the HWE criteria (HDCE-period) is at least six. In the historical period, the average HDCE-period has a length of around seven to nine days for HDCE₉₀, with no apparent spatial discrimination (Fig. 9c). The length is reduced to around seven to eight days for HDCE₉₅. The projected

changes of the HDCE-period are highest in the regions with the highest projected increase in HDCEs (Fig. 9d, h, m)). For
455 HDCE₉₀, gains reach up to 15 days, resulting in an overall projected length of around three weeks, on average. Increases in the
length of the HDCE-period reach 10 days for HDCE₉₅, resulting in more than two weeks with consecutive days reaching the
HDCE₉₅ criteria. Most land areas show an increase of six days for HDCE₉₉, which is mostly due to HDCE₉₉ being projected
for the first time within the future period.

4.3.3 Atmospheric variations related to HDCEs

460 For this investigation, all days meeting the HDCE criteria were extracted, and their mean climatology was compared to that of
the entire 30-year period. Due to the low number of events (see Fig. 9) the results on near-surface atmospheric variations during
the historical period were moved to the appendix. The general picture of the variations detected in the future period similarly
applies to the historical period (comp. Fig. 10-12 and Appendix B). As shown by Fig. 10, HDCE₉₀ are accompanied by
below-average SLP conditions over most of the low elevated areas. These negative deviations are often statistically significant,
465 although the number of models varies.

Over mountainous regions, however, the SLP deviations are positive, indicating above-average pressure conditions. Over
the Alps, Pyrenees, and Atlas, these deviations are statistically significant in a majority of models. As expectable, the T_x
deviations are significantly above-average. The mode of the wind direction is similar for both the entire 30-year period and
for HDCEs. As for FSEs, westerly to northerly wind directions are predominant in the eastern half of the study domain. In
470 the low elevated areas of the northwestern parts of the domain, where westerly winds are predominant for FSEs (see Fig. 5),
winds predominantly originate from the north and northeast. Mountainous areas, similar to FSEs, are determined by regional
characteristics depending on the orientation of the main ridge, causing a complex picture in the mode of the wind direction.
Contrary to FSEs, near-surface flows tend to move towards the mountain ridge, as can be seen for the Atlas, Pyrenees, and
the Apennines (Fig. 10c). For many land areas in the study domain, the projected distribution of the wind directions under
475 HDCE₉₀ in the future differs significantly from the total distribution (Fig. 10g).

The overall picture of HDCE₉₅ and HDCE₉₉ is similar to HDCE₉₀, with below-average sea level pressure conditions in the
low-lying areas and above-average conditions over the western mountain ridges (HDCE₉₅ in Fig. 11, HDCE₉₉ in Appendix C).
Winds predominantly originate from northern to eastern directions, excluding regional phenomena in the vicinity of mountain
ranges. While a majority of the 13 inspected models prove the atmospheric variations under HDCEs to differ from the overall
480 mean with statistical significance, the number of indicating models decreases with decreasing sample size, resp. higher thermal
thresholds.

The projected changes in the mean near-atmospheric state under HDCEs are shown in Fig. 12. The results described above
for the future period are therefore the result of a decrease in sea level pressure for most regions. Still, some regions show an
increase in sea level pressure, adding to the complexity of the projected changes. The deviation in mean T_x under HDCEs, as
485 indicated by the general projected warming, is shown to increase by around 2.5-5 °C, and often the projected warming is more
intense for HDCE₉₅ than for HDCE₉₀. Due to the low occurrence rate in the historical period, comparisons for HDCE₉₉ could
not be made.

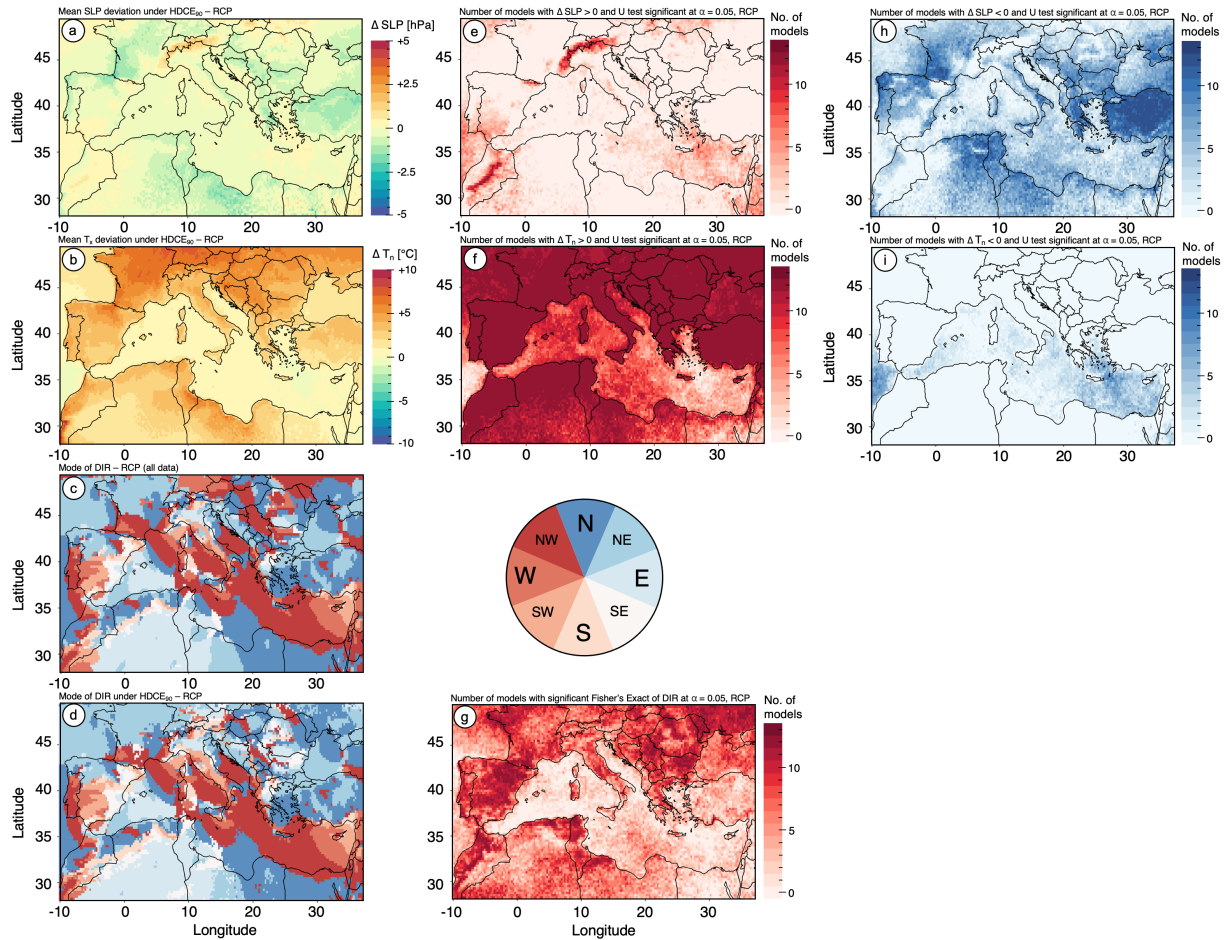

Figure 10. Mean deviation of the near-surface atmosphere from the 30-year mean under HDCE₉₀ for sea level pressure (SLP, first row) and daily maximum temperature (T_x , second row). Number of models indicating a statistically significant positive deviation (e, f), and statistically significant negative deviation (h, i). Mode of wind direction within the 30-year historical period (c) and only for HDCEs (d). Number of models indicating significantly differing distributions of wind directions (g).

5 Discussion

The use of dynamically downscaled climate model output offers several advantages over the output of General Circulation
 490 Models, foremost a higher spatial and temporal resolution, as well as a higher data accuracy. However, as the results of this
 study prove for the GMR, a high amount of bias remains in the output of RCMs, when compared to state-of-the-art reanalysis
 data. This bias varies for different variables and is dependent on the underlying GCM and RCM, but it is not distinguishable
 whether the choice of GCM or RCM contributes more bias. With one exception, temperatures are underestimated in the raw
 model output, which is in line with former experiences with CORDEX output (Dosio et al., 2022; Top et al., 2021). Precipitation
 495 sums, on the other hand, show an almost equal number of over- and underestimating models. However, the magnitude of the bias

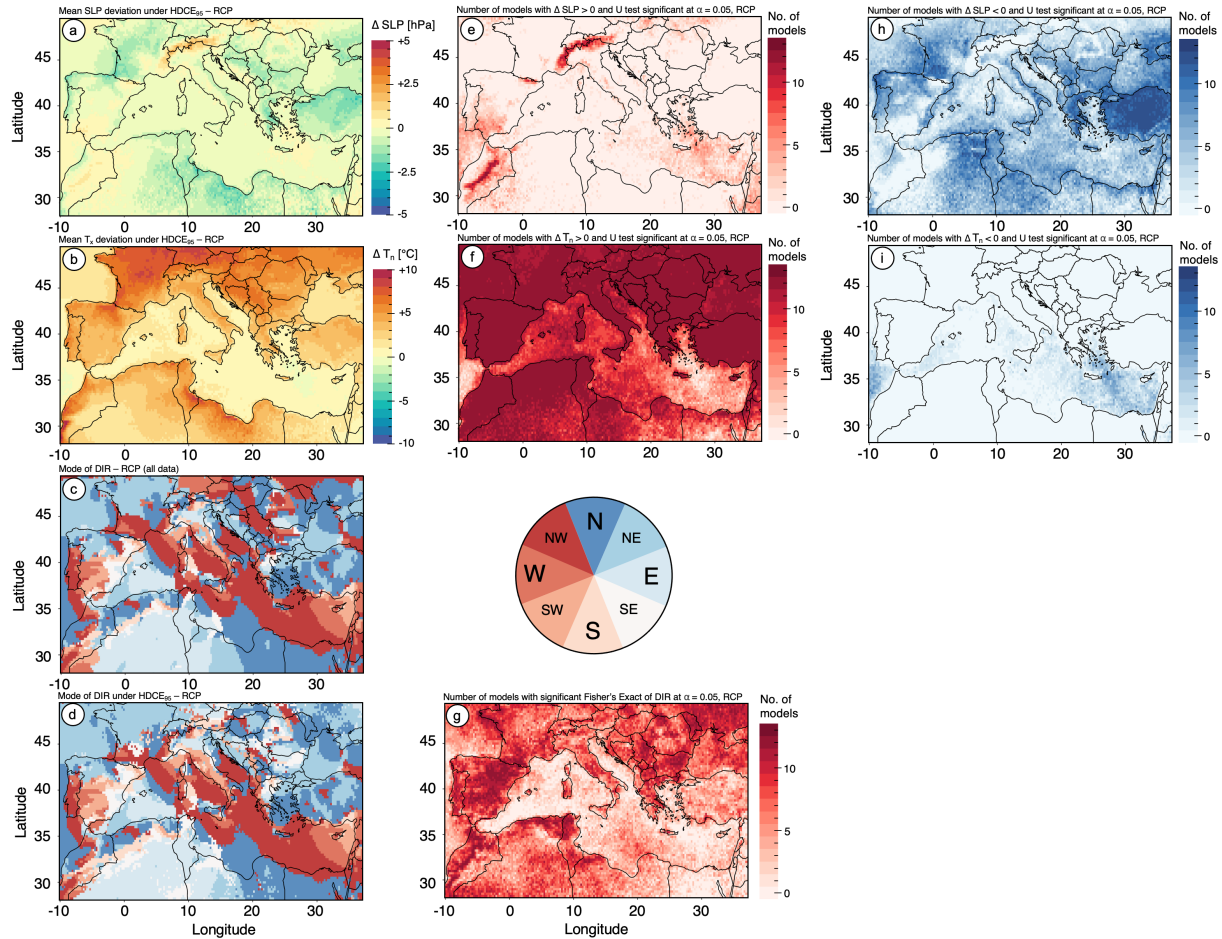

Figure 11. Same as Fig. 9, but for HDCE₉₅.

is higher for models with an overestimation of the precipitation sum. Reasons for the over- and underestimation of precipitation, including the "drizzle-effect", have been discussed before, e.g. by Chen et al. (2021), Demory et al. (2020), and DeMott et al. (2007). A bias is present in both the climatology of daily data, i.e. percentiles, and the long-term climatology. After applying QDM, both mentioned forms of bias are removed to a significant degree, resulting in nearly zero bias in terms of percentiles and minimal deviations in long-term climatology, depending on the selected GCM-RCM combination and variable. Therefore, and by preserving the dependence structure of multiple corrected variables, MBCn proves to be a suitable choice for assessing percentile threshold-based compound events. The performance of several different multivariate bias correction methods could be evaluated in follow-up studies, similar to what has been done before for univariate correction methods applied to CORDEX (Olschewski et al., 2023; Laux et al., 2021). An additional limitation of this study lies in the choice of reference data. While ERA5 is proven to be a suitable state-of-the-art reference for temperature and precipitation (Lavers et al., 2022; Mistry et al., 2022; Velikou et al., 2022; Hassler and Lauer, 2021), some level of uncertainty regarding extreme events remains, especially

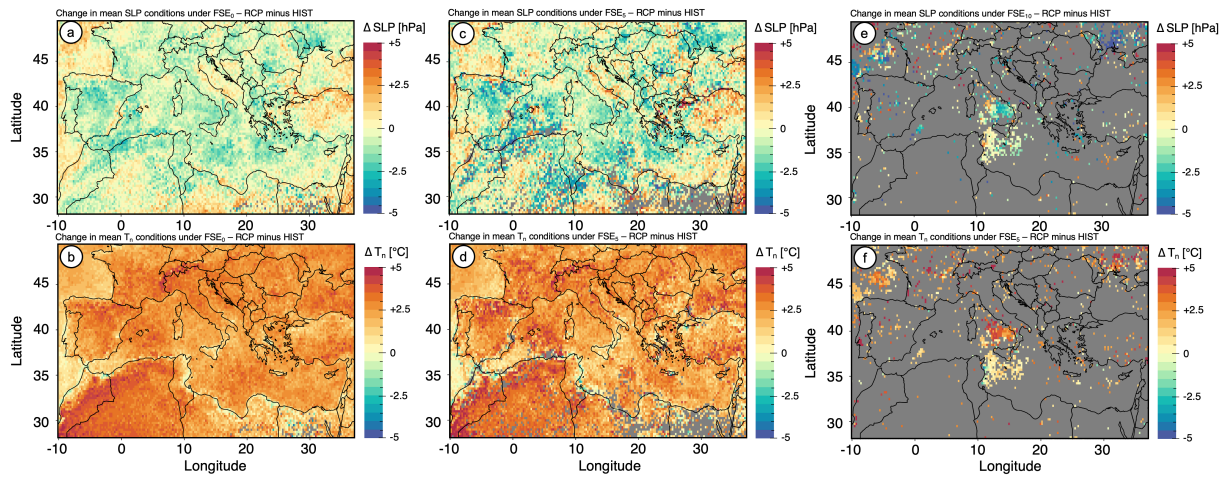

Figure 12. Projected changes in the deviations of sea level pressure (SLP, first row) and daily maximum temperature (T_x , second row) from the 30-year mean under HDCEs. HDCE₉₀ (a-b), HDCE₉₅ (c-d), and HDCE₉₉ (e-f).

for precipitation. When conducting local refinement of the presented results in potential follow-up studies, additional reference data sets, including station-based observations, could be compared to further improve the robustness of the projections.

The disproportionate behavior of the LDF and the SGS shown in this study has also been demonstrated, for example, for the United States (Allstadt et al., 2015; Peterson and Abatzoglou, 2014; Marino et al., 2011). These authors conclude that FSE-related risk varies significantly for different regions. In this context, Chamberlain et al. (2021) discuss potential reasons for the large regional variability, including elevation (Vitasse et al., 2018) and distance from the sea (Ma et al., 2019). The findings of this study also demonstrate these two drivers as decisive when determining the potential future risk of FSEs. However, the nature of the projected change is also strongly dependent on the selected SGS threshold. Regarding the SGS, the presented thresholds are strictly based on atmospheric temperatures and do not include data on, e.g., soil temperatures and observations of vegetation. Apart from highly elevated regions, where the onset of the growing season is generally later in the year, the three selected thermal thresholds for the SGS are proven in this study to represent three different sections within the warming period between January and June. This offers a benefit for a future refinement of the presented results, for example for specific crops with specific thermal characteristics referring to one of the sections. The broad nature of the thermal definitions yet imposes a limitation on the results of this study. A more sophisticated approach, e.g. including crop-related modeling or crop-specific thresholds of budburst and freezing damage, for example, discussed by Allstadt et al. (2015) and Chamberlain et al. (2019), may lead to an increased preciseness and applicability for practitioners. On the other hand, this study aims to provide a general overview of the potential risk of FSEs within a large domain that has not been closely investigated yet in this concern. This was done, using simplified and straightforward thermal definitions. This study proves the spatial resolution to be sufficient to distinguish regional characteristics of FSEs. In terms of agricultural applications on a local level, where crop-specific metrics and local climate characteristics gain in importance, the presented results may be the starting point of local refinement.

The results regarding the atmospheric deviations under FSEs are in line with the general understanding of climatology in the study domain, and this especially applies to the low-lying areas. During spring, air masses originating from westerly and southerly directions are more and more likely to cause warm conditions, as the level of warming closely follows the northward shift of the subtropical ridge (see section 2). However, especially when high-pressure conditions cause clear skies and the nights are still long, a high level of outgoing longwave radiation over land masses causes temperature levels to decrease. Under easterly flows, which this study proves to be predominant under FSEs, these cooled air masses are forced into the study domain and increase the risk of frost events. In a recent study for Europe, Quesada et al. (2023) determined the advection of northerly to easterly air masses to be crucial drivers of cold waves over Europe. These results can be directly linked to the findings of this study, increasing the predictability of FSEs. Over mountainous areas, the predominant winds differ, indicating flows from the mountain ridges towards the lowland. In general, descending air masses are linked to dissolving cloud coverage, resulting in clear skies. As described above, the longwave outgoing radiation can therefore not be retained in the lower atmosphere, contributing to low near-surface temperatures and the occurrence of FSEs. On the other hand, for example, under foehn conditions, descending air masses on the leeward side of a mountain ridge may be linked to warm conditions (Jansing et al., 2022) and therefore contradict the results of this study. To gain further insights into the local conditions caused by the large-scale atmospheric steer flow, additional vertical layers of atmospheric flow that are less sensitive to local orography, e.g. the 500 hPa layer, could be assessed in further studies. For this study, we specifically focused on the near-surface atmospheric conditions, as these are most relevant in the context of crops. A similar gain may also be achieved by considering circulation patterns, for example, based on Jenkinson and Collison (1977) or Hess and Brezowsky (James, 2007). However, the application of large-scale circulation patterns is aggravated in the context of multivariate bias correction, as the spatial coherence, next to the temporal coherence, of all variables must be preserved for the entire study domain. As Cannon (2018) pointed out, this is, in general, possible for MBCn. However, considering the size of the study domain, the additional consideration of spatial coherence required a significantly higher computational effort that was not available within the means of this study.

The nature of compound extreme events including heat and drought over Europe and the GMR has been extensively studied for historical periods (Vogel et al., 2021; Ionita et al., 2021; De Luca et al., 2020; Russo et al., 2019). The results presented in this study embody the continuation of the historical trend of increasing HDCEs that all former studies share. Inspecting the relevant variables independently already shows the tendency of each variable to favor the occurrence of HDCEs in the future. As described above, the projected increase in daily maximum temperature for the spatial mean causes extremes exceeding the 99th percentile to be 15 times more likely. However, as a majority of regions show the potential for persistent drought during summer (JJA), the projected change in the occurrence rate of HDCEs is multiple times higher. To further increase the robustness of these projections, additional metrics and thresholds to define heat and drought could be considered in a follow-up study.

The aggravated risk of compounding extremes has, for example, been indicated by Zscheischler et al. (2018). The potential effects of the projected changes in heat and drought behavior are diverse. An increased risk of crop failure, for example, has been shown by He et al. (2022) on a global level and by Ribeiro et al. (2020) for a Mediterranean domain. While it must be noted, that crop failure risk is highly dependent on the crop type and local climate factors, accumulated drought and

heat nevertheless have negative impacts on the amount of water available for irrigation. Apart from agricultural aspects and natural ecosystems, the projected level of warming will significantly impact human health and mortality (Raymond et al., 2020; Gasparrini et al., 2015). The impact of increased temperatures is also shown to be aggravated in highly urbanized areas (Merkenschlager et al., 2023) and further amplifies socioeconomic disparities (Hsu et al., 2021).

The results of this study depict that below-average sea level pressure conditions and predominantly northeasterly to easterly flows are accompanied by HDCEs. A reason for below-average pressure could be near-surface thermal lows induced by intense surface warming, as previously described by Lavaysse et al. (2016) and Hoinka and Castro (2003). This, in combination with the advection of dry, continental air masses from eastern Europe, may be crucial for the occurrence of HDCEs. The limitations in terms of drawing conclusions on the large-scale atmospheric circulation, as discussed above, similarly apply to HDCEs. While the results clearly depict significantly differing conditions under HDCEs and offer benefits regarding the predictability of these events, a follow-up study including circulations patterns could improve the quality of these predictions even more. This also applies to the mountainous regions, which show different characteristics under HDCEs than the surrounding lowlands. For both, FSEs and HDCEs, the climate projections show an intensification of the pressure anomalies. For FSEs, the already above-average conditions show a projected increase in deviation from the current mean atmospheric state. For HDCEs, there is a less clear picture, although more regions show below-average conditions for historical HDCEs. This below-average deviation is amplified in the future projections for a majority of regions in the study domain. Whether centers of action (Osman et al., 2021) and related blocking systems will intensify in the future is subject to the scientific discourse, as discussed by Kautz et al. (2022).

580 **6 Summary and conclusions**

This study aims at demonstrating characteristics and potential changes in False Spring Events (FSEs) and Heat-Drought Compound Events (HDCEs) in a high-impact future scenario (RCP8.5) for the end of the 21st century. The inspected periods are 1970-1999 and 2070-2099. We applied a multivariate, i.e., a variable dependence-preserving, bias correction method based on the N-dimensional probability density function transform (MBCn) to regional climate model output obtained from CORDEX. The results prove that MBCn can successfully remove biases in the model output and therefore increase the reliability of projections. Due to MBCn representing a percentile-adjusting method, this is specifically true for the percentile distributions of jointly corrected climate variables, making it a valuable method for the derivation and inspection of percentile threshold-based compound extreme events.

The presented results indicate that, while only FSEs of the lowest thermal threshold (SGS_0) are historically relevant on a widespread basis in the Greater Mediterranean Region, FSEs are projected to gain in frequency and relevance in the future period. This is mainly due to a disproportionate reduction in the day of the year (DOY) of the last day of frost (LDF) and the start of the growing season (SGS). Therefore, warm periods have an increased probability of occurring particularly early in the year, whereas the risk of frost events remains. In low-lying areas, FSEs are mostly coupled with high-pressure anomalies and northerly to easterly winds. This is in line with cold, continental air masses flowing into the GMR and causing an increased

595 risk of frost events. For mountainous areas, local winds appear predominant, mostly flowing from the mountain ridge towards
the lowlands.

All investigated metrics of HDCEs indicate significant changes in the future. These include an increase in intensity, with
more severe phases of agricultural drought and increased daily maximum temperatures of up to 6 °C. Also, the frequency
of HDCEs and the length of consecutive days meeting the HDCE criteria is projected to increase. In general, the changes in
600 HDCEs are multiple times more intense than those of the underlying univariate extremes. Local thermal lows are shown as the
predominant near-surface condition linked to the occurrence of HDCEs, together with the inflow of dry, continental air masses
from northern to eastern directions.

The projected changes will potentially have severe negative effects on vegetation and crop efficiency if no additional adaptive
measures are applied. An increased risk of frost exposure due to an earlier SGS can have adverse effects on crop yield by
605 causing damage in the early stages of development. This is particularly true for plant species with only rare historical exposure,
and therefore a low degree of adaption to frost. The projected level of heat and drought-induced stress could potentially
aggravate the agricultural and socioeconomic stress even more. This could, for example, manifest itself in the form of severe
water shortages for humans, livestock, and vegetation, stress on food security due to the increased risk of crop losses or failures,
increased tree, and forest mortality endangering natural ecosystems, and deteriorated human health and increased mortality.

610 While the public focus often lies on the effects of increased temperature levels due to global warming, this study demonstrates
the additional need for adaptation on the other end of the thermal spectrum. To prevent vegetation and crop damage or loss,
which would further amplify the already aggravated ecological and nutritional stress, the efforts to protect vegetation and crops
should equally focus on heat/drought and frost. The results of this study can offer benefits in this regard to allow for better-
informed adaptation strategies in agriculture. An additional benefit is given by increasing the level of predictability of FSEs
615 and HDCEs. This will allow local actors to react to forecasts indicating a potential occurrence on time. The data sets generated
in this study can additionally be used for further climate change impact analyses, that, for example, focus on a local refinement
or specific crop species in the GMR. By applying more complex definitions of compound extreme events, for example, when
additional predictors or higher resolution data sets are available, potential follow-up studies will be able to further improve the
assessment capability of compound extreme events.

620 *Author contributions.* P.O., B.B., and P.L. conceptualized the study design and aims. P.O. and E.H. downloaded and curated the data. P.O.
and D.D. wrote and implemented the code. P.O. carried out the calculations. P.O., D.D., H.M., B.B., and P.L. evaluated and interpreted the
results. H.K. and P.L. acted as supervisors. P.O. wrote and prepared the draft manuscript. All authors reviewed and approved the final version
of the manuscript.

Competing interests. The authors declare that they have no known competing financial interests or personal relationships that could have
625 appeared to influence the work reported in this paper.

Financial support. P.O. was financially supported by the German Ministry of Education and Research (BMBF), grant number 01LP2005A. H.M. was financially supported by the project Multi-Scale Quantification and Modeling of Spatio-Temporal Dynamics of Ecosystem Processes by Smart Autonomous Sensor Networks (ECOSENSE,SFB 1537).

Acknowledgements. The computations for this analysis were carried out using the programming environment R, version 4.2.2 (R Core Team, 2022). NetCDF data was processed within the R framework "climate4R", provided by Santander Meteorology Group (Iturbide et al., 2018). Bias correction was performed using the "MBC" package (Cannon, 2023, 2018; Cannon et al., 2015). We gratefully acknowledge the public provision of the CORDEX (Cinquini et al., 2014) and ERA5 (Hersbach et al., 2023) data. The study has been performed in the wider context of the research project *BENEFIT-Med: Boosting technologies of orphan legumes towards resilient farming systems in the Greater Mediterranean Region: from bench to open field* (without dedicated funding). Ideas from the project team discussions partly contributed to the conceptualization of this study.

Data availability. All data sets that were obtained for this study are openly accessible. The ERA5 data can be downloaded from the Copernicus Climate Change Service (C3S) Climate Data Store at <https://cds.climate.copernicus.eu/cdsapp#!/dataset/reanalysis-era5-single-levels?tab=overview>, the CORDEX data can be downloaded, for example, via the DKRZ node of the ESGF data portal at <https://esgf-data.dkrz.de/search/cordex-dkrz/>. Both are retrievable upon registration.

640 **Appendix A: List of abbreviations**

Appendix B: Supplementary material for Bias correction performance

Table A1. List of abbreviations used in this study.

Abbreviation	Name
CDF	Cumulative distribution function
CEE	Compound extreme event
CMIP5	Fifth generation of the Coupled Model Intercomparison Project
CORDEX	Coordinated Regional Climate Downscaling Experiment
DIR	Daily mean wind direction
DOY	Day of year
ECMWF	European Centre for Medium-Range Weather Forecasts
EQM	Empirical quantile mapping
ERA5	reanalysis product provided by ECMWF
FSE	False spring event
FSEI	False spring event index
GCM	General circulation model
GMR	Greater Mediterranean region
HDCE	Heat-and-drought compound event
HIST	Historical time period (1970-1999)
HWE	Heatwave event
IPCC	International Panel on Climate Change
LDF	Last day of frost
MBCn	Multivariate bias correction using the N-dimensional probability density function transform
PR	Daily precipitation sum
QDM	Quantile delta mapping
RCM	Regional climate model
RCP	Representative concentration pathway
SGS	Start of growing season
SLP	Daily mean sea level pressure
SPI-3	3-monthly Standardized Precipitation Index
T_n	Daily minimum temperature
T_x	Daily maximum temperature

Figure A1. Evaluation of MBCn performance for long-term climatology and daily-based percentiles. a) Long-term time series of annual mean minimum temperature for ERA5 and 13 CORDEX models in historical raw (left), historical MBCn-corrected output (middle), and 30-year mean values (right). b) percentile-based distributions of daily minimum temperature for ERA5 and 13 CORDEX models in historical raw data (left), MBCn-corrected historical and projected output (middle), and mean absolute error (right).

Appendix B: Supplementary material for FSEs

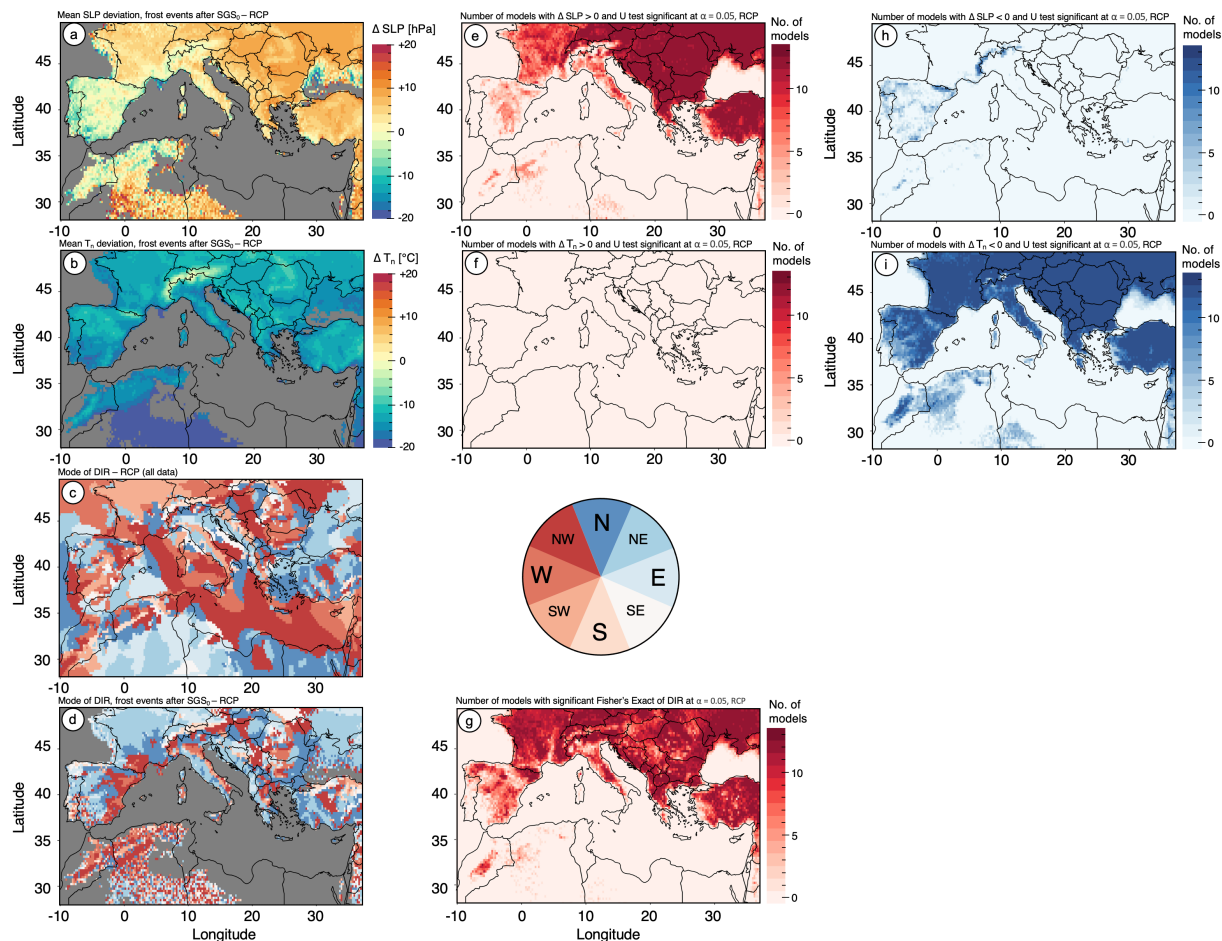

Figure B1. Mean deviation of the near-surface atmosphere from the 30-year mean under frost events after the SGS_0 for sea level pressure (SLP, first row) and daily minimum temperature (T_n , second row). Future deviations under RCP8.5. Number of models indicating a statistically significant positive deviation (e, f), and statistically significant negative deviation (h, i). Mode of wind direction within the 30-year future period (c) and only for frost events after the SGS_0 (d). Number of models indicating significantly differing distributions of wind directions (g).

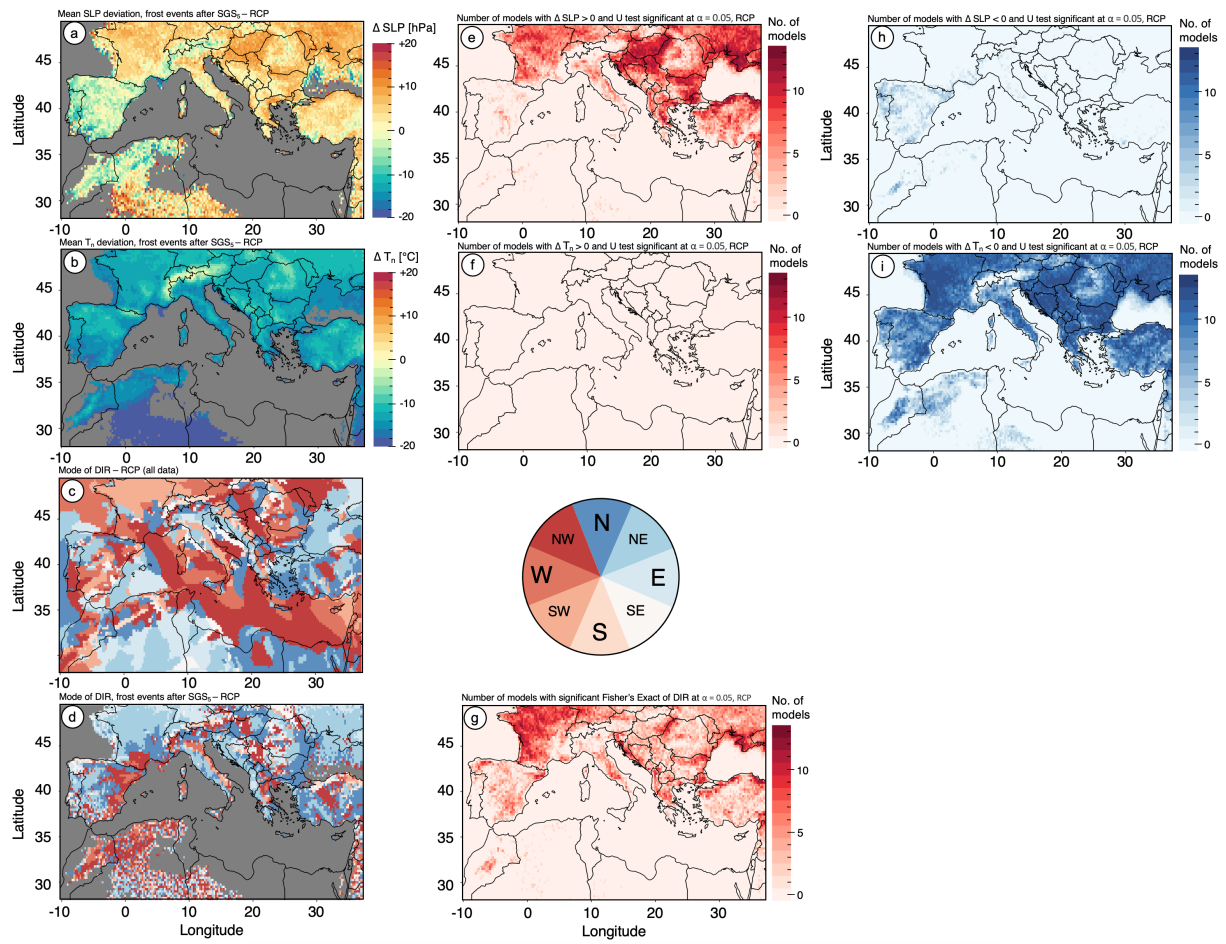

Figure B2. Same as B1, but for SGS₅.

Figure B3. Same as B1, but for SGS_{10} in the historical period.

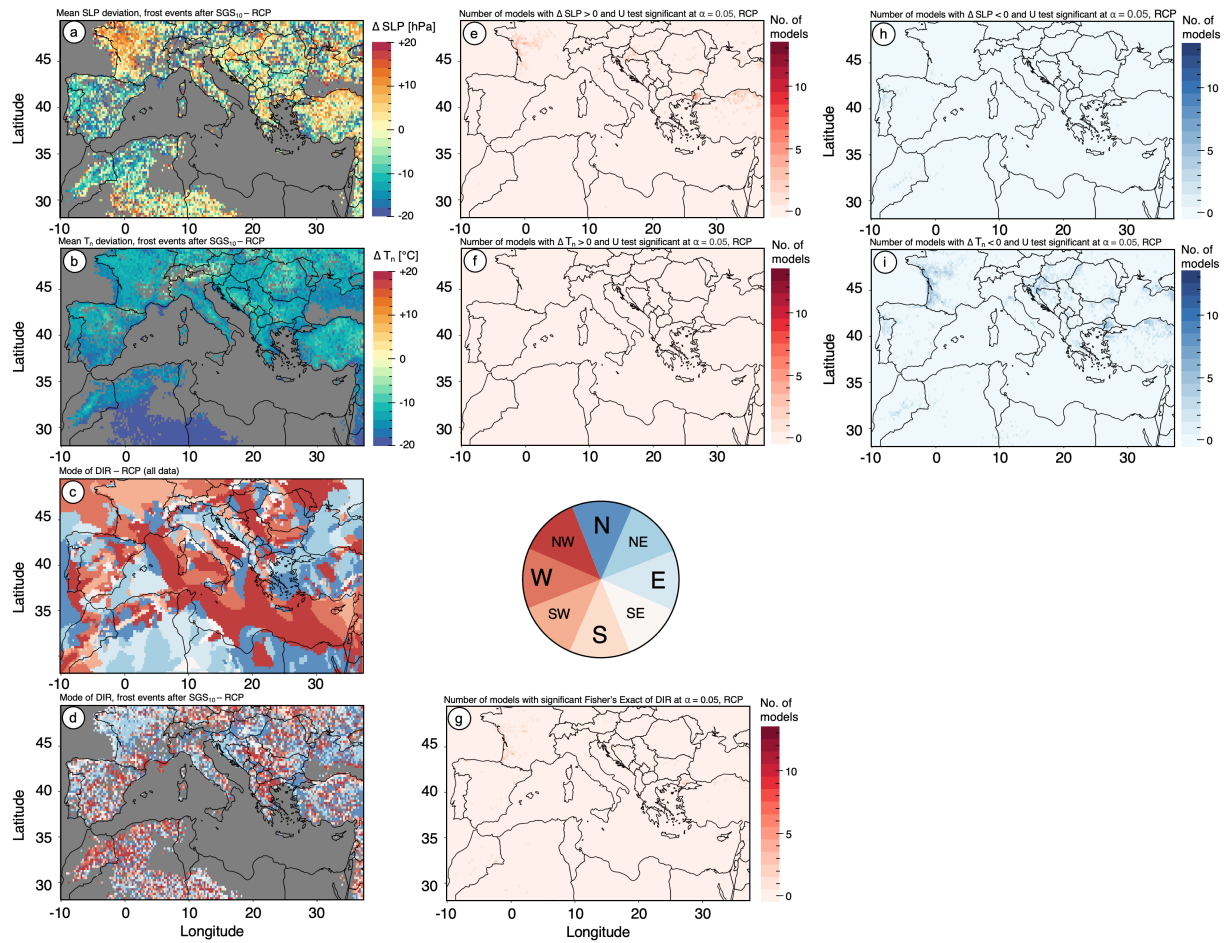

Figure B4. Same as B1, but for SGS₁₀ in the future period.

Appendix C: Supplementary material for HDCEs

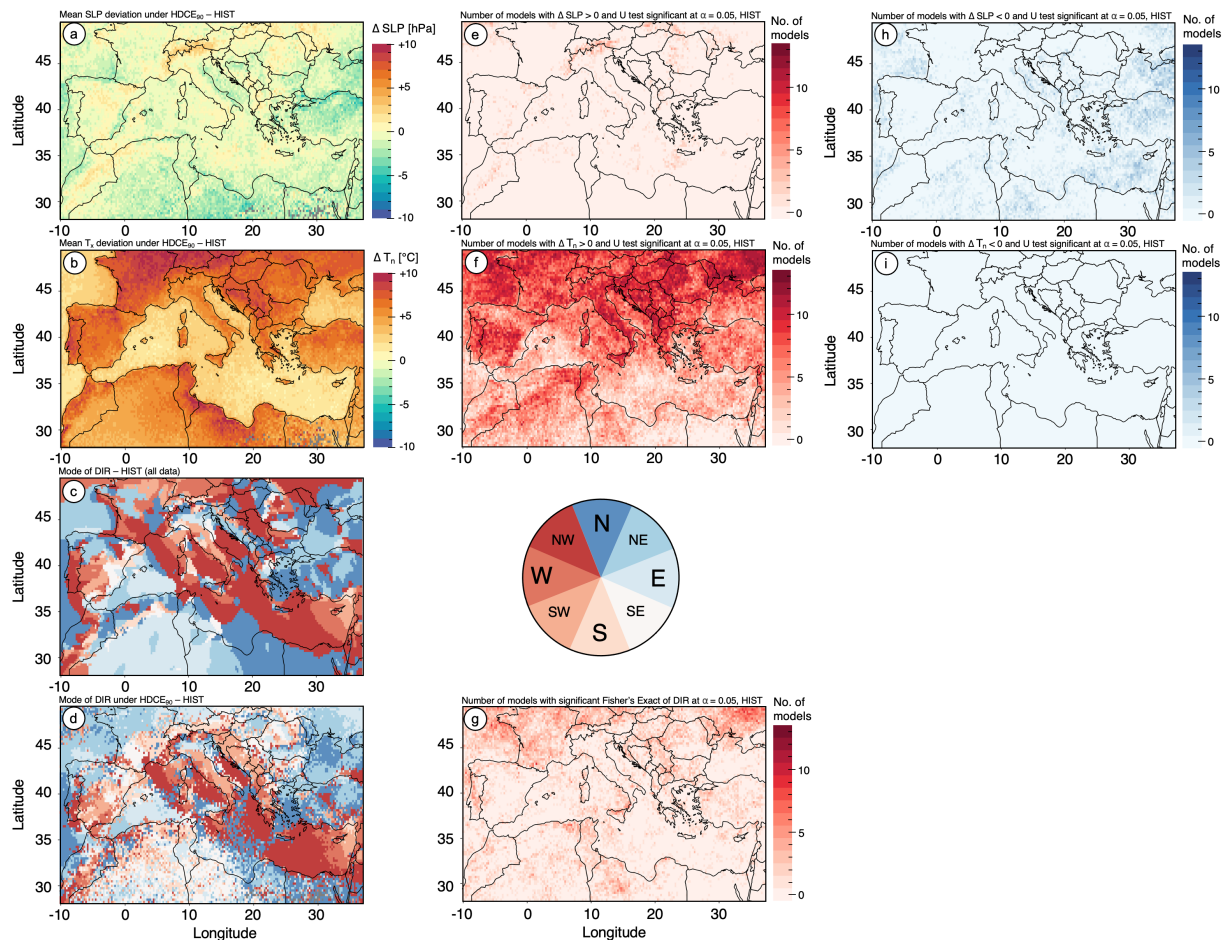

Figure C1. Mean deviation of the near-surface atmosphere from the 30-year mean under HDCE₉₀ for sea level pressure (SLP, first row) and daily maximum temperature (T_x , second row). Future deviations under RCP8.5. Number of models indicating a statistically significant positive deviation (e, f), and statistically significant negative deviation (h, i). Mode of wind direction within the 30-year future period (c) and only for HDCEs (d). Number of models indicating significantly differing distributions of wind directions (g).

Figure C2. Same as C1, but for HDCE₉₅.

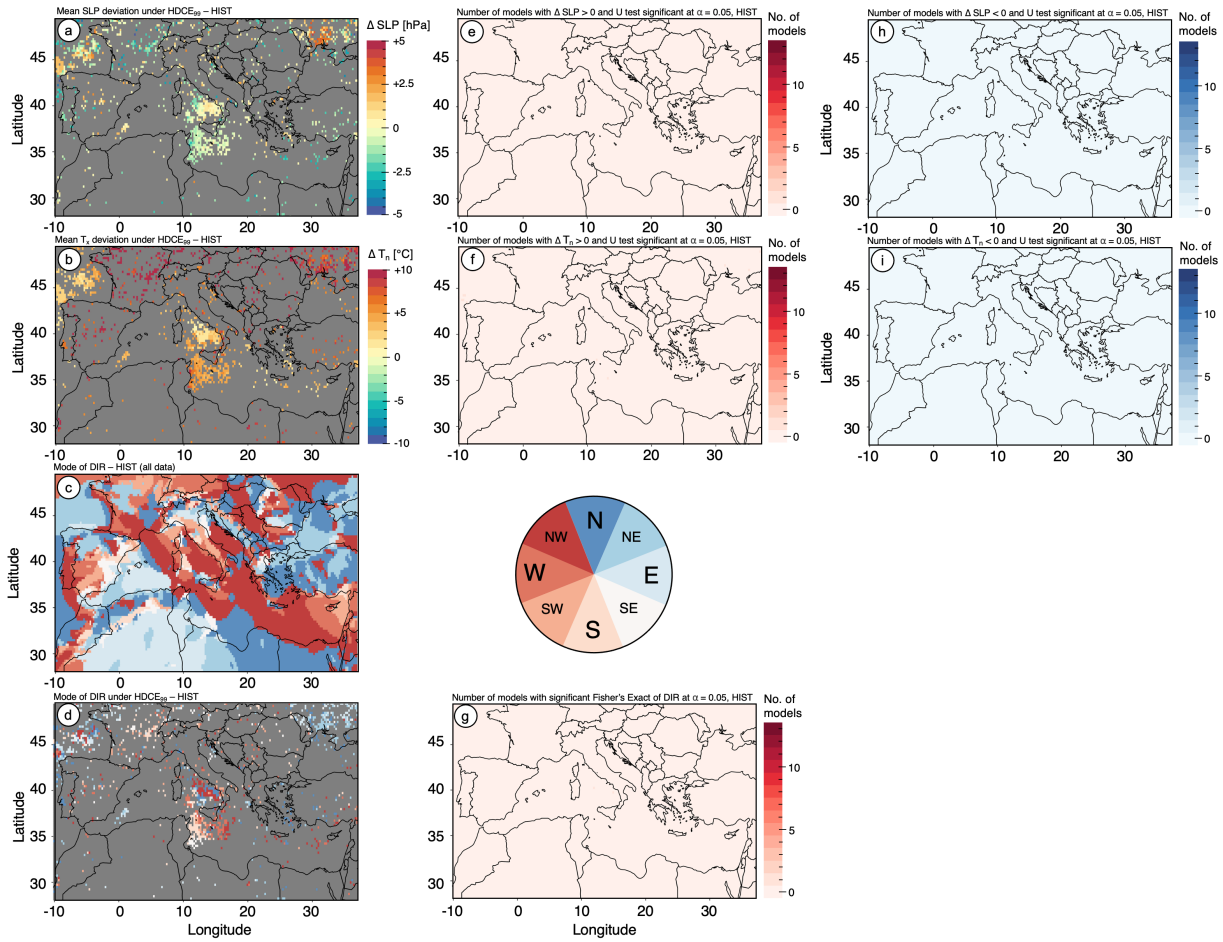

Figure C3. Same as C1, but for HDCE₉₉ in the historical period.

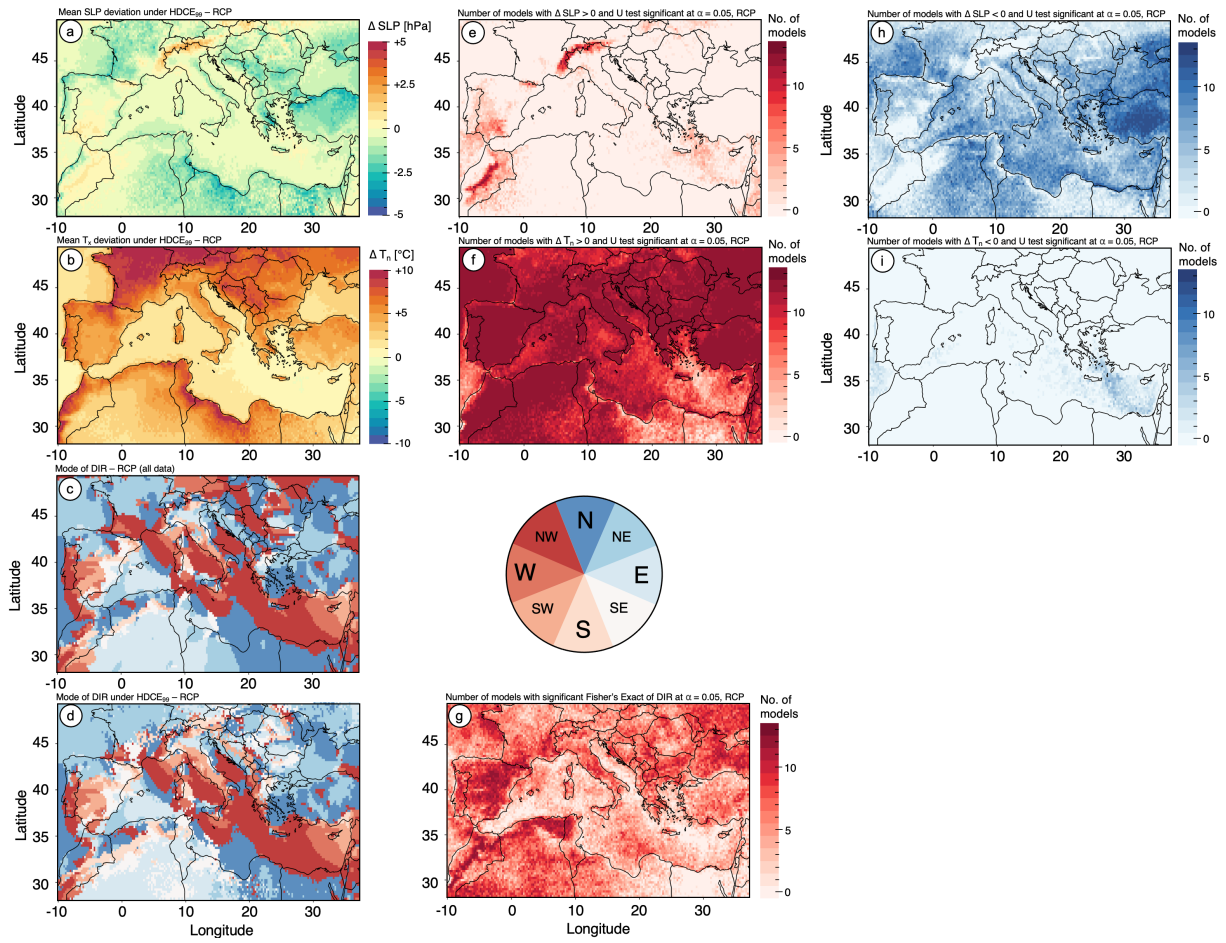

Figure C4. Same as C1, but for HDCE₉₉ in the future period.
