12

13 **Abstract**

14 The MEMS-based seismic network of Trentino (NE Italy) consists of 76 low-cost accelerometers installed close to inhabited
15 areas. These sensors have a suitable sensitivity to detect moderate-to-strong earthquakes but are able to record even weaker
16 seismicity. The densely distributed peak ground acceleration values recorded by MEMS and other types of stations are
17 integrated within the existing seismic monitoring procedure in order to automatically obtain a complete set of strong motion
18 parameters a few minutes after the origin time. The exposure for resident population and critical buildings is estimated by
19 quantifying the different levels of shaking, which is expressed according to the Mercalli-Cancani-Sieberg intensity scale.
20 These types of results, summarized in synthetic PDF (Portable Document Format) documents, can be useful for civil
21 protection purposes to timely evaluate the state of emergency after a strong earthquake and to choose how and where
22 activate first aid measures and targeted structural monitoring.

23 **1 Introduction**

24 During the last decades seismic monitoring has been greatly improved in order to give precise and even more detailed
25 information for emergency and environmental purposes. Besides permanent seismic networks, a primary role in capturing
26 the increased amount of instrumental data is given by low-cost micro-electromechanical system (MEMS) instrumentation
27 (D'Alessandro et al., 2019). Nowadays, MEMS accelerometers are widely used on different spatial scales to replace or
28 densify permanent networks, in order to improve seismic detection and evaluate with greater resolution the effects of
29 earthquakes (Cochran et al., 2009; Boaga et al., 2018; Vitale et al., 2022). Earthquake early warning systems have also been
30 benefitting greatly from MEMS technology, because targeted timely actions can be automatically taken in case of strong
31 earthquakes (Satriano et al., 2011; Cochran, 2018). For this reason, large earthquake datasets need to be efficiently and
32 rapidly managed (Spallarossa et al., 2021) and related outcomes (e.g., earthquake location and magnitude, strong motion data
33 and maps) shared in real-time with different end users, such as scientists, technicians, politicians, civil protection, decision
34 makers, and citizens.

35 The Trentino region (NE Italy) is currently monitored by a permanent seismic network, which has been managed by the
36 Autonomous Province of Trento (PAT) since 1981 (Geological Survey–Provincia Autonoma di Trento, 1981; Viganò et al.,
37 2021; Fig. 1). According to the Italian building code (Ministero delle Infrastrutture e dei Trasporti, 2018) this area is
38 characterized by peak ground acceleration values lower than 0.18 g (for a return period of 475 years), with highest seismic
39 hazard in southern Trentino (upper Lake Garda and lower Adige Valley) and eastern Trentino (lower Valsugana, Tesino and
40 Primiero) where fault systems are mostly active (Viganò et al., 2015) (Fig. 2). The resident population on 1st January 2022 is
41 540,958 (ISTAT, 2012) and is mostly concentrated in the city of Trento and along the main valleys where principal road
42 networks and infrastructures are located.

43 Here, we present a local network based on MEMS accelerometers in Trentino, aimed at real-time monitoring and automatic
44 generation of exposure maps. Co-seismic recordings are automatically processed and integrated with those from other
45 stations (e.g., belonging to other permanent networks), allowing for a dense distribution of ground motion measurements.

46

47 **2 Method**

48 Maps displaying seismic shaking are widely used during emergency due to their ability to summarize earthquake effects and
49 their potential impact on local targets (Michelini et al., 2020). In order to lead effective emergency actions, it is essential that
50 these maps, named “exposure maps” hereafter, are available in a few minutes after a seismic event. In fact, they provide a
51 first-level overview of the expected damage over the monitored area.

52 The exposure maps of the Trentino civil protection are automatically generated by using all the available seismic data (i.e.,
53 ground motion measurements), with the aim of estimating the asset exposed to an earthquake (Fig. 3). In particular, MEMS
54 recordings are integrated with those from other stations and used to obtain a complete set of strong motion data, in order to
55 quantify the numbers of resident population and buildings subjected to different levels of shaking. A step-by-step description
56 of the method used to generate the exposure maps is given in the next sections.

57

58 **2.1 MEMS accelerometer design and installation**

59 The low-cost MEMS sensor named “ASX1000” (Fig. 4a), which is adopted in the presented network, is designed and
60 produced by AD.EL. s.r.l., an Italian based telecommunication company. The ASX1000 is a capacitive triaxial
61 accelerometer, conceived to be a platform for data acquisition and recording for long-term measurements. It is equipped with
62 communication channels for remote control and data transmission: a serial channel RS-422 or RS485, a LAN Ethernet
63 10/100 Mbit/s, and an USB 2.0 (Fig. 4b). This sensor operates in high sensitivity mode for an acceleration range of ± 2 g (it
64 supports also the ± 1 g and ± 4 g full scale configurations), with a 250 Hz sampling rate.

65 The noise analysis relative to each component reveals a Power Spectral Density with a general downward trend between -80
66 and -65 dB in the 0.03–10 Hz frequency range (Fig. 5). As shown in Figure 5, the detectability threshold of seismic events
67 corresponds to a moment magnitude of about 3.5. Therefore, this sensor has a suitable sensitivity to detect moderate-to-
68 strong events, those that are of primary interest to public administration for emergency management.

69 The MEMS sensors are installed inside telecommunication infrastructures. Each sensor is firmly coupled with the ground
70 with screws and plugs, at the base of the local server room; the azimuth is carefully measured during installation. Each
71 sensor is plugged into a wall outlet for power. A complete station costs only a few hundred euros, making possible the
72 deployment of dense arrays of accelerometers.

73

74 **2.2 Data integration and seismic processing**

75 Seismic data processing is here performed by using the software CASP – Complete Automatic Seismic Processor (Scafidi et
76 al., 2016; 2018; 2019). By taking advantage of the features of its iterative procedure, this software can effectively manage
77 (during phase picking and location) data provided by different seismic stations with variable signal quality. Contrary to
78 stations of permanent monitoring networks, which are usually installed in remote and quiet areas to ensure seismic signals
79 with low noise levels, signals from seismic stations deployed in urban areas, such as those from our MEMS network, can be
80 significantly affected by high level noise (producing spikes and impulsive signals) due to anthropogenic activities. This may
81 lead to an uncontrolled proliferation of false (i.e., non-seismic triggers). Therefore, their use in automatic phase picking
82 procedures may affect the reliability of the final earthquake location and, in some cases, lead to false events. Hence, noisy
83 stations are often neglected in automatic earthquake monitoring. CASP processes signals by using an iterative procedure
84 within which the phase picking is driven by earthquake location (Spallarossa et al., 2014). On the one hand, this allows
85 identification of false triggers. On the other hand, arrival times are improved at each iteration, leading to an optimization of
86 the earthquake location.

87 With reference to the present application, which integrates data from permanent monitoring networks and data from the
88 MEMS stations, CASP is set not to use MEMS data in the first iteration of the location procedure, thus assuming that they
89 are affected by significant background noise. In this step, the definition of arrival times is not yet driven by location but it is
90 based on an envelope function on signals (Spallarossa et al., 2014). This precaution may not be necessary for local strong

91 earthquakes, for which the seismic signal clearly dominates the background noise, but it is useful when managing signals
92 from weak earthquakes. From the second iteration on, signals from all stations are used and P- and S-wave arrivals are
93 computed by applying the Akaike Information Criterion – AIC (Akaike, 1974) on signal windows centred, for each station,
94 around the expected arrival times obtained by the location code. In fact, these picks are determined (at each iteration) by the
95 location algorithm working in conjunction with CASP, the NonLinLoc software (Lomax et al., 2000). This allows to reliably
96 discriminate between seismic phase arrivals and signal disturbances also in the case of weak-to-moderate earthquakes
97 recorded by different stations, regardless of the type of sensor used.

98 In addition to the computation of hypocentral parameters, for each station with at least one phase picked, CASP returns the
99 values of a number of ground motion parameters (e.g., PGA, PGV, spectral acceleration).

100 In the case of the Trentino region, a fully automated earthquake monitoring has been already operating based on CASP
101 (Viganò et al., 2021). Thus, the great amount of data provided by the 76 installed MEMS stations (see Fig. 1) has been easily
102 integrated within the seismic monitoring procedure as the only requirements for CASP are real-time data transmission in
103 standard SeedLink format and station response metadata in seismological standard format (i.e., Dataless, StationXML, Poles
104 and Zeroes – PAZ file).

105

106 **2.3 Exposure maps**

107 Exposure maps are automatically created using the GMT software (Wessel and Smith, 1998) and the PHP open-source
108 scripting language. At first, shaking data recorded by each station (i.e., peak ground accelerations) are converted to intensity
109 values (Mercalli-Cancani-Sieberg scale, MCS) using the empirical relationship of Faenza and Michelini (2010) for Italy.
110 Intensity, which is considered more informative than peak ground acceleration for civil protection purposes as it is directly
111 based on earthquake damage and perception, is colour coded according to the ShakeMap palette (Michelini et al., 2020).
112 These densely distributed data are then gridded using adjustable tension continuous curvature splines (“surface” routine
113 command in GMT, with tension set to 0.5), with no pre-processing (e.g., blockmean) or interpolation. This is possible
114 because of the dense distribution of MEMS stations, which are mainly located in the vicinity of inhabited areas. At this
115 stage, a maximum intensity value is assigned to each municipality in Trentino, for which the cumulative number of resident
116 population is known (Fig. 6). Then, the intensity map is compared to the distribution and density of resident population in
117 Trentino (last national census; ISTAT, 2012), where territorial localities are classified as (i) urban area, (ii) small inhabited
118 areas, (iii) productive areas or (iv) wide spread houses. For each locality the procedure automatically calculates the
119 maximum intensity and combines it with the population density. The cumulative population for each intensity level is then
120 computed. In a similar way, the system automatically processes (as polygonal features) the distribution of buildings of
121 interest for the Autonomous Province of Trento (Fig. 6), and the cumulative number of buildings for each intensity class is
122 obtained. Finally, the intensity map is compared to the distribution of instrumented dams (Fig. 6) to determine a list for
123 decreasing measured peak ground acceleration.

124

125 3 Results

126 The estimation of exposure maps in Trentino is usually carried out within 10 minutes from an earthquake. A local magnitude
127 (M_L) threshold for their automatic generation is set to M_L 4.0. The procedure has been activated since June 2022, using a
128 standard workstation equipped with an Intel Core i5 CPU. Even if no strong earthquakes occurred until now (July 2023) in
129 the monitored area, MEMS stations have been used for standard locations and to record the ground motions of low-to-
130 medium energy seismic events. We note that a seismic signal recorded by a MEMS station is commonly clearly detectable
131 for events with M_L greater than about 2.5, considering hypocentral distances of a few tens of kilometres. As an example, we
132 can consider the automatically detected P- and S-phase arrival times (red and blue vertical lines in Fig. 7, respectively) for
133 the M_L 2.7 earthquake occurred on November 10th 2022 in the Fassa Valley (NE Trentino). GAGG is a standard seismic
134 station of the permanent PAT network, while station 003B belongs to the MEMS network (see Fig. 1). Both stations are
135 located in the same area (2 km apart from each other) at about 65 km from the earthquake hypocentre. Even if the P-phase
136 onset for station 003B is masked by the background noise, which is clearly higher than the noise affecting the GAGG
137 recordings, the CASP procedure is able to detect the S-phase arrival time. Thus, both GAGG and 003B can be used to
138 calculate the strong motion parameters for that event (Fig. 8). Few minutes (maximum 5) after the origin time, CASP returns
139 event location, magnitude, and the strong motion table (for all the analysed stations), which includes: Peak Ground
140 Acceleration (PGA), Peak Ground Velocity (PGV), Peak Ground Displacement (PGD), Spectral Acceleration (SA) for
141 different response periods, response spectrum intensity (also known as Housner Intensity, IH) for different period ranges
142 (0.1–0.5 s, IH 0; 0.1–1.0 s, IH 1; 0.1–1.5 s, IH 2), and Instrumental Intensity (I_{MCS} ; Mercalli-Cancani-Sieberg scale).
143 Compared to station GAGG, station 003B shows stronger shaking values that can be attributed to the effect of different
144 subsoils (Fig. 8). As with all stations belonging to the PAT permanent network, GAGG is deployed on bedrock, while 003B
145 is located in the middle of an alluvial valley near the town of Vezzano. Here, alluvial deposits are reasonably assumed to be
146 responsible of the observed shaking amplification. The higher ground motion values of station 003B are used for a site-
147 specific exposure map, which can take into account local seismic effects near towns and populated areas.

148 The exposure maps and all the relevant seismic results provided by CASP are reported in an automatically generated
149 document in standard PDF (Portable Document Format) format, which also contains links to the high resolutions maps
150 stored online. This summary file represents an easy and user-friendly mean of communications that can be easily
151 disseminated through emails and messaging platforms (e.g., Telegram), read online, or printed. Figure 9 shows the PDF of
152 the exposure map generated for an M_L 2.1 earthquake occurred on July 11th 2023 in Western Trentino. After a synthetic
153 textual and graphical summary of event location (magnitude, area, origin time and hypocentral data), tables and maps
154 relative to the seismic shaking and exposure are displayed. The first table contains a quantification of the population and the
155 number of buildings of interest (A and B levels according to the administrative classification) possibly stricken by the
156 earthquake for each intensity level. The maximum recorded intensity is VI MCS at about 5 km from the earthquake
157 hypocentre (which is only 4.8 km deep). Of note, without the information provided by the MEMS network, we would have
158 significantly underestimated the maximum intensity induced by the earthquake, which would not have exceeded III MCS.

159 The PDF also shows two intensity maps that can be helpful for a rapid inspection of the damaged area. The first one shows
160 interpolated values while the second one displays the values actually observed at each analysed station. Besides the maps,
161 two tables provide further details about the measured shaking levels for both potentially involved population (first 20
162 municipalities sorted according to decreasing intensity) and dams (listed according to both decreasing intensity and PGA
163 values).

164 In order to test the procedure considering a realistic emergency scenario for a moderate event, we have simulated an M_L 5.8
165 earthquake in Southern Trentino (45.834 °N latitude, 11.066 °E longitude, 9.0 km depth). This event has been selected to
166 roughly simulate the so-called “Middle Adige Valley” earthquake, which represents a reference for the seismic potential of
167 the Trentino region, as also evidenced by recent studies (e.g., Ivy-Ochs et al. 2017 and references therein). This earthquake
168 dated to 1046 AD, with estimated epicentral intensity IX MCS and co-seismic shaking responsible for great damage and
169 catastrophic induced events. For each seismic station (MEMS and permanent stations), PGA is computed using the regional
170 attenuation law developed within the framework of the INGV-DPC Project S4 (Michellini et al., 2008). In particular, the
171 regionalized attenuation relation adopted for the Eastern Alps is used. The summary PDF document relative to this
172 earthquake is shown in Figure 10. According to this scenario, about 60 thousand people and 262 buildings of interest are
173 involved in the area with maximum intensity (VIII MCS); the four municipalities with maximum intensity count a total
174 population of about 52,000 people. Concerning dams, two of them reach PGA values greater than 0.3 g; this is important in
175 order to define specific structural monitoring when predetermined PGA thresholds are overcome.

176

177 **4 Summary and conclusions**

178 We have presented an upgrade of the seismic monitoring procedure of the Trentino region through the integration of data
179 provided by 76 low-cost MEMS accelerometers installed in urban areas. This dense MEMS-based network has a suitable
180 sensitivity to detect moderate-to-strong seismic events; weaker earthquakes with local magnitude lower than 3.0 can be even
181 recorded and analysed. The additional data in conjunction with the automatic monitoring procedure currently in use allows
182 us to obtain a densely distributed set of strong motion measurements and, consequently, high-definition shaking maps that
183 relies only on actual recorded data. Integrating these dense MEMS data, though noisy, allows avoiding the use of ground
184 motion prediction equations, thus leading to a more reliable picture of the actual ground shaking (hence, of the expected
185 damage). This is of paramount importance for post-earthquake emergency planning in densely populated, urbanized areas
186 characterized by high seismic risk. The use of the CASP code is crucial to properly manage such noisy data with the aim of
187 getting reliable results in quasi real-time.

188 In addition to shaking data, the procedure presented here provide automatically generated exposure maps that quantifies the
189 resident population and the number of critical buildings in Trentino, subjected to different levels of shaking during an
190 earthquake. Exposure maps are reported in synthetic PDF documents, which are very useful for civil protection in order to
191 rapidly evaluate the local state of emergency after a strong earthquake and to choose how and where activate first aid
192 measures, both for population and buildings of interests like dams.

193 **Code availability**

194 The Complete Automatic Seismic Processor (CASP) is a commercial software.

195

196 **Author contributions**

197 DS, AV, JB and MC conceptualized the project; JB, VC, MC and GDM developed the MEMS sensor; DS, AV, JB and MC
198 followed MEMS installation; DS, AV, MC and GDM performed data integration; DS and GF made the earthquake
199 simulation; DS, AV, JB, GF and SB wrote the manuscript draft; DS, AV, JB, GF, SB and DS_p edited the manuscript.
