15 **Abstract**

16 Storm surge is a common nature disaster in China southern coastal area, which usually causes  
17 heavy human life and economic losses. With the economic development and population  
18 concentration of coastal cities, the storm surges may result in more impacts and damage in the  
19 future. Therefore, it is of vital importance to conduct risk assessment to identify high-risk areas  
20 and evaluate economic losses. However, quantitative study of storm surge risk assessment in  
21 undeveloped areas of China is difficult, since there is a lack of building characters and damage  
22 assessment data. Aiming at the problem of data missing in undeveloped areas of China, this paper  
23 proposes a methodology for conducting storm surge risk assessment quantitatively based on deep  
24 learning and geographic information system (GIS) techniques. Five defined storm surge  
25 inundation scenarios with different typhoon return periods are simulated by coupled FVCOM-  
26 SWAN model, the reliability of which is validated using official measurements. Building  
27 footprints of the study area are extracted through TransUNet deep learning model and Remote  
28 Sensing Image (RSI), while building heights are obtained through Unmanned Aerial Vehicle (UAV)  
29 measurement. Subsequently, economic losses are quantitatively calculated by combing the  
30 adjusted depth-damage functions and overlay analysis of the buildings exposed to storm surge  
31 inundation. Zonation maps of the study area are illustrated to display the risk levels according to  
32 the economic losses. The quantitative risk assessment and zonation maps can help the government  
33 to make storm surge disaster prevention measures and optimize land use planning, and thus to  
34 reduce the potential economic losses of the coastal area.

35  
36 **Keywords:** Strom surge; Quantitative risk assessment; GIS; Deep learning; Risk zonation map

37  
38 **1. Introduction**

39 Storm surge, defined as the abnormal rise of water over and above the normal astronomical  
40 tide, and is expressed in terms of height above predicted or expected tide levels. Mostly, the surge  
41 is generated by a strong atmospheric disturbance, and it becomes particularly catastrophic when it  
42 happens to coincide with an astronomical high tide. In that case, the surge-driven coastal flooding  
43 may inundate buildings and cropland, cause significant casualties and economic losses. Storm  
44 surges have caused widespread damage worldwide. In 2013, super typhoon Yolanda as the worst

45 typhoon in last 30 years, pounded the Philippines. It caused 6293 individuals reported dead, 28689  
46 injuries and 1061 individuals missing, with estimated damages totaling 864 million US dollars  
47 (Mcperson, 2015). Hurricane Harvey struck Texas in August 2017, resulting in approximately  
48 100 deaths and economic losses exceeding 125 billion dollars (Lee, 2021). In China, storm surges  
49 also pose a frequent threat in the coastal cities. In the last decade, China has experienced an  
50 average of 8.5 storm surge disasters annually, with an average damage amount of 6815.8 million  
51 yuan per year, where Guangdong and Zhejiang Provinces are the most affected coastal areas  
52 (China Marine disaster bulletin, 2022). For example, Typhoon Hato in 2017, Typhoon Mangkhut  
53 in 2018, Typhoon Lekima in 2019 has caused significant damage to coastal cities in China, and  
54 resulted great losses of life and property (Zhou et al., 2021; Yang et al., 2019). For the past few  
55 years, as the rapid development of population and economic in China coastal area, the potential  
56 monetary loss grows accordingly (Fang et al., 2021; Ji et al., 2020; Mcgranahan et al., 2007; Seto  
57 et al., 2011). Therefore, it is crucial to implement risk assessment and mapping strategies to  
58 effectively reduce these risks and mitigate the impact of storm surges.

59 Storm surge hazard assessment is an essential component of storm surge risk assessment and  
60 zoning, aiming to evaluate the hazard intensity of disasters, through numerical simulation of storm  
61 surge processes, estimation of storm surge for selected return periods, and computation of the  
62 probable maximum storm surge (Shi et al., 2013). Therefore, the numerical simulation of storm  
63 surge is a key step for storm surge risk assessment. Because of the limitation of historical storms  
64 and the nondeterminacy of future storm, numerical simulation of storm surges is usually used to  
65 determine storm levels. Hydrodynamic model such as Advanced Circulation Mode (ADCIRC),  
66 Delft3D and Finite Volume Coastal Ocean Model (FVCOM) have been widely used (Vijayan et al.,  
67 2021; Wang et al., 2021a; Liu and Huang, 2020; Hu et al., 2022; Lyddon et al., 2019; Zhang et al.,  
68 2020; Zhu et al., 2022). It has been demonstrated that it is critical to include tide and sea-water-  
69 level variations in shelf and nearshore wave simulations (Masson, 1996). Furthermore, the sea  
70 water level could be significantly affected by strong tide and typhoon-induced wind in complex  
71 coastal seas and then modulate the wave properties (Yang et al., 2020). Coupled FVCOM-SWAN  
72 model, with the foundation of FVCOM's finite volume method, unstructured grid, and adaptable  
73 boundary condition handling capability, integrating the hydrodynamic and wave processes of  
74 SWAN, possesses the ability to provide simulation result more quickly and accurately. In this  
75 circumstance, coupled FVCOM-SWAN model is used in this research for simulating the  
76 inundation of storm surge.

77 Coastal risk assessment can be categorized into two primary classifications: qualitative and  
78 quantitative. In the realm of qualitative assessment, entropy weight method, Analytic Hierarchy  
79 Process (AHP) and other methods are widely used. Ramkar and Yadav (2021) used AHP in  
80 combination with Geographic Information Systems (GIS) for proposing a flood risk map, which  
81 can identify the high-risk areas efficiently. Malekinezhad et al. (2021) combined the entropy  
82 weight method and GIS, and conducted a flood vulnerability analysis for Hamadan city. The  
83 results highlighted the advantages of entropy weight method comparing to normal spatial overlay  
84 method. Besides, Pathan et al. (2022) and Rafiei-Sardooi et al. (2021) made use of Technique for  
85 Order Preference of Similarity by Ideal Solution (TOPSIS). The former pointed out the  
86 advancement of TOPSIS by comparing with AHP, and the latter combined machine learning and  
87 TOPSIS to analyze urban flood vulnerability. Unlike qualitative risk assessment, quantitative risk  
88 assessment enables the quantification of damages and risks in monetary terms. The most

89 commonly used approach to assess direct damages is based on depth-damage curves (De Moel and  
90 Aerts, 2011; Merz et al., 2007; Smith, 1994). Thielen et al. (2008) presented the Flood Loss  
91 Estimation Model for the private sector (FLEMOPs) through using the Germany flood losses data  
92 in August 2002, and the group further established model for commercial sector in 2010 (Kreibich  
93 et al., 2010). Zhai et al. (2005) derived multi-factor loss functions for buildings in Nagoya, Japan  
94 using empirical data from Tokai flood in 2000, and Grahn and Nyberg (2014) established  
95 functional relationships utilizing the house insurance claims data caused by lake flooding. Except  
96 for buildings, Yazdi and Salehi Neyshabouri (2012) and Hess and Morris (1988) respectively built  
97 several uni-variable functions and multi-factor functions for kinds of crops and grassland. In  
98 recent years, machine learning is also introduced in quantitative loss assessment, for example,  
99 Merz et al. (2013) developed a tree-based approach using Regression Tree and Bagging  
100 Regression Tree as machine-learning methods to analysis of direct building damage to private  
101 homes. Paprotny et al. (2020) proposed a Bayesian Network damage model (a supervised-  
102 machine-learning method), and reached a good accuracy of predictions of building losses.

103 The essence of quantitative risk assessment lies in analyzing the interaction between  
104 exposure factors and hazards (Adnan et al., 2020; Armenakis and Nirupama, 2013; Granger, 2003;  
105 Kron, 2005). Therefore it's crucial to quantify the direct tangible damage of elements at risk.  
106 Buildings are important exposure elements, as they are the gathering place of population and  
107 property. Building footprint data is necessary for evaluating the vulnerabilities of a building, as it  
108 provides essential information about the buildings, including spatial location, distribution, and  
109 boundaries and so on (Mharzi Alaoui et al., 2022). It's also of great significance in risk assessment,  
110 primarily due to its ability to identify high-risk areas, assess building vulnerability and estimate  
111 potential damage (Gacu et al., 2023; Wu et al., 2019). Extracting building footprints from remote  
112 sensing images has been widely used in many fields, such as urban management, disaster  
113 management, navigation (Zhou et al., 2004; Tang et al., 2006; Liu et al., 2019; Liu et al., 2020;  
114 Rousell and Zipf, 2017; Chen and Gao, 2019). However, there is a lack of building footprints  
115 extraction and application in the realm of storm surge assessment.

116 When the building is inundated, there are a variety of factors that may influence the amount  
117 of monetary loss. For example, building type, building structure, private precaution, maintenance  
118 status, and others (Marvi, 2020; Thielen et al., 2008). Taramelli et al. (2022) pointed out that  
119 building's height is one of the factors for determining the susceptibility due to flooding and  
120 evaluate the buildings' potential damage by flood hazards. Hasanzadeh Nafari et al. (2016)  
121 developed a new loss model, in which building with different story were divided into different  
122 categories in the modelling process. To conclude, height is an important factor that affecting the  
123 vulnerability of buildings when they serve as inundation-exposed elements. Therefore, in the  
124 process of quantitative storm surge risk assessment, it is necessary to adjust the depth-damage  
125 functions to make buildings of different heights correspond to different functions.

126 Besides, different from the field research and statistics required for other data acquisition, the  
127 data of buildings' height is more accessible from multiple sources. For example, public data DSM  
128 data has been utilized for building height estimation (Huang et al., 2022), some satellite companies  
129 also offer services to customize DSM data for selected regions. Nonetheless, they respectively  
130 suffer from a lack of precision and high costs. Building height can also be obtained via remote  
131 sensing technique, such as Synthetic Aperture Radar (SAR) (Li et al., 2020; Frantz et al., 2021), or  
132 take advantage of shadow in remote sensing images (Comber et al., 2011; Shao et al., 2011).

133 However, in addition to the lack of precision, the absence of data necessary for modelling and the  
134 crowded character of rural buildings in China make the above methods difficult to be implemented.  
135 Compared to methods above, acquiring building height through UAV ensures high accuracy while  
136 being relatively efficient, and the method is quite simple, which also reduces the required costs.

137 In view of the aforementioned information, regarding storm surge qualitative risk assessment,  
138 there is a stringent requirement for both the quality and timeliness of land use data, which means  
139 that the risk assessment cannot be generated in real time, and the qualitative risk assessment also  
140 can't evaluate the risk level through the intuitive value of economic loss. In the realm of  
141 quantitative risk assessment, building a uni-variable or multi-factor empirical model requires  
142 complete and substantial data, and the published models generally only provide uni-variable  
143 functions ignoring the building height as a factor, or have regional limitations. Additionally, for  
144 the coastal regions of China, which are often affected by storm surge disasters, they tend to have  
145 relatively low levels of economic development. Under the circumstances, the data needed to  
146 conduct flood risk assessment is generally in a state of absence.

147 In response to the challenges mentioned above, the scientific goal of this paper is to propose a  
148 quantitative storm surge risk assessment method for underdeveloped areas based on deep learning  
149 and GIS techniques. First, on the basis of high-resolution DEM and seawall data measurement,  
150 five defined storm surge inundation scenarios with different typhoon return periods are simulated  
151 by employing the coupled FVCOM-SWAN model. Subsequently, TransUNet is introduced as a  
152 deep learning method to extract building footprint, and building's height data is acquired through  
153 UAV measurement. Since data on relevant disaster losses in underdeveloped regions are lacking,  
154 empirical modeling was deemed impractical. Therefore, the adjustment of the JRC's depth-  
155 damage curves by the HAZUS is chosen to take the impact building's height into consideration,  
156 thus to conduct a quantitative assessment with more accuracy. Finally, combining hazard map,  
157 exposure elements and adjusted depth-damage curves, the quantitative risk zoning maps are  
158 conducted. The risk zoning maps can assist decision-makers in identifying high-risk sub-zones and  
159 planning disaster prevention measures. Accordingly, the novelty can be seen in obtaining refined  
160 exposure elements data through deep learning and UAV, addressing the lack of historical storm  
161 surge economic loss data and considering the effect of building height on economic loss through  
162 the adjustment of existing depth-damage curves.

## 163 **2. Study area and datasets**

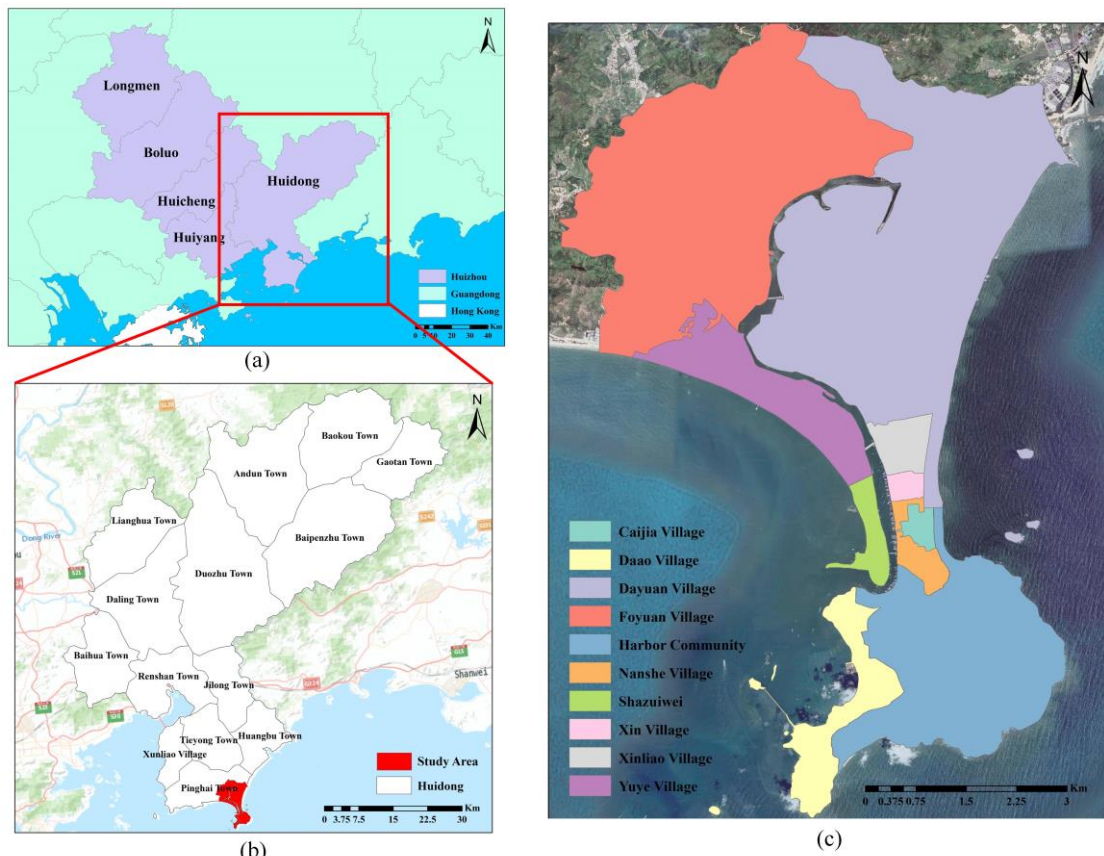

### 164 *2.1. Study area*

165 Being the shipping hub in the South China Sea, Guangdong province, located in southern  
166 China, has become the largest economic province in China since 1989, with a GDP of 129118.6  
167 billion yuan in 2022. Due to the seaborne trade, Guangdong has been the largest economic  
168 province in China since 1989, which reached a GDP of 129118.6 billion yuan in 2022. However,  
169 just as mentioned above, Guangdong is relatively vulnerable to storm surges, such as Typhoon  
170 Hato and Typhoon Mangkhut, due to its geographical characteristics.

171 Huizhou is one of the cities in Guangdong province, and also one of the central cities of Pearl  
172 River Delta region. It's located at on the east coast of Guangdong-Hong Kong-Macao Greater Bay  
173 Area, the GDP reached 540.1 billion yuan in 2022, with the highest growth rate in Guangdong.  
174 Pinghai Town located at the southernmost of Huizhou, and has a registered population of about  
175 forty thousand. Its economic source mainly depends on various crops and seafood products. Due  
176 to its coastal geographical characteristics and the presence of Pinghai Ancient City, the town has

177 become a cultural tourist destination and can therefore be defined as a cultural tourist town.

178 In this paper, the chosen study region is the coastal area of Pinghai town, named the Double-  
179 Moon Bay Zone. It covers ten villages in total, including Foyuan, Dayuan, Yuye, Xinliao, Xin  
180 village, Shazuiwei, Cajia, Nanshe, Dao, and Harbor community. These years, the region has been  
181 developed in tourism and real estate project development including construction of hotels, resorts,  
182 and high-end business districts, which vastly prompt the financial development. It is foreseeable  
183 that the population and economy of the region will growth rapidly. However, the economic status  
184 of the region remains relatively low, which presents a challenge due to data scarcity and limited  
185 accessibility. In addition, the region is susceptibly affected by the tropical cyclones during the  
186 season running from April to November (Wang et al., 2021b). Recent years, more than ten  
187 typhoons have affected the study area, including Typhoon Lekima, Typhoon Haishen, Typhoon  
188 Kanuni etc. The general location and information about the study area is shown on Fig. 1.

189  
190 **Fig. 1.** The maps of locations in the study: (a) The map of Huizhou; (b) The map of study area in  
191 Huidong, the base map is obtained from ESRI; (c) The village map of study area, the base map is  
192 obtained from © GoogleMaps (map data © 2023 Google).  
193

## 194 2.2. Data source

195 In order to accomplish the research, the data used is obtained from various sources, here is  
196 the describe of different data:

197 (1) Land Cover Types data: the data is obtained from the Department of Natural Resources of  
198 Huizhou Bureau. It contains multiple land cover types including forest, cropland, residential land,  
199 etc. It is used to calculate vulnerability level.

200 (2) Remote sensing images: the remote sensing images are obtained from Chang Guang Jilin-

201 1 satellite. Chang Guang Satellite technology CO., LTD was founded on December 1st 2014,  
202 which is the first and the largest commercial satellite corporation in China. Jilin-1 is the first self-  
203 developed commercial high-resolution satellite. The images from Jilin-1 satellite have a resolution  
204 of 50 cm, and have five spectral channels: Panchromatic band; Blue band; Red band; Green band;  
205 Near Infrared band. The images consisting of blue band, red band, green band are utilized to  
206 combine deep learning method, thus achieve the extraction of buildings.

207 (3) Unmanned Aerial Vehicle (UAV) data: the UAV data is generated by oblique photography,  
208 and is organized by Open Scene Graph Binary format. The UAV data is obtained from Department  
209 of Natural Resources of Huizhou Bureau, and the data is utilized for buildings' height calculation.

210 (4) Digital elevation model (DEM) data: the DEM data is captured by manual observation in  
211 2018, with the resolution of 0.3m. The coordinate system and file organization are originally  
212 CGCS 2000 and txt file, and further transformed to WGS 1984 and raster format to make use of  
213 these data in the research. The data contains the elevation information for the study region.  
214 Besides, the seawall data is also obtained manually. Both data are used in modeling of storm  
215 surges for simulating the hazard maps.

216 (5) Hybrid wind field: ERA5 is the fifth generation of the European Reanalysis dataset  
217 produced by the European Centre for Medium-Range Weather Forecasts (ECMWF), and it  
218 provides the comprehensive and high-resolution atmospheric and climate data. Holland typhoon  
219 wind field model was proposed by Holland in 1980, which introduced Holland B parameter on the  
220 basis of the Schloemer exponential pressure distribution model (Holland, 1980). In this study, the  
221 two data are fused to generate hybrid wind field data, which is subsequently utilized for storm  
222 surge simulations.

223 (6) Historical typhoon data: the historical typhoon data including typhoon track, typhoon  
224 pressure, and velocity are obtained through China Meteorological Administration Typhoon  
225 Network Website. The historical data is employed to assess the reliability and validity of the  
226 model.

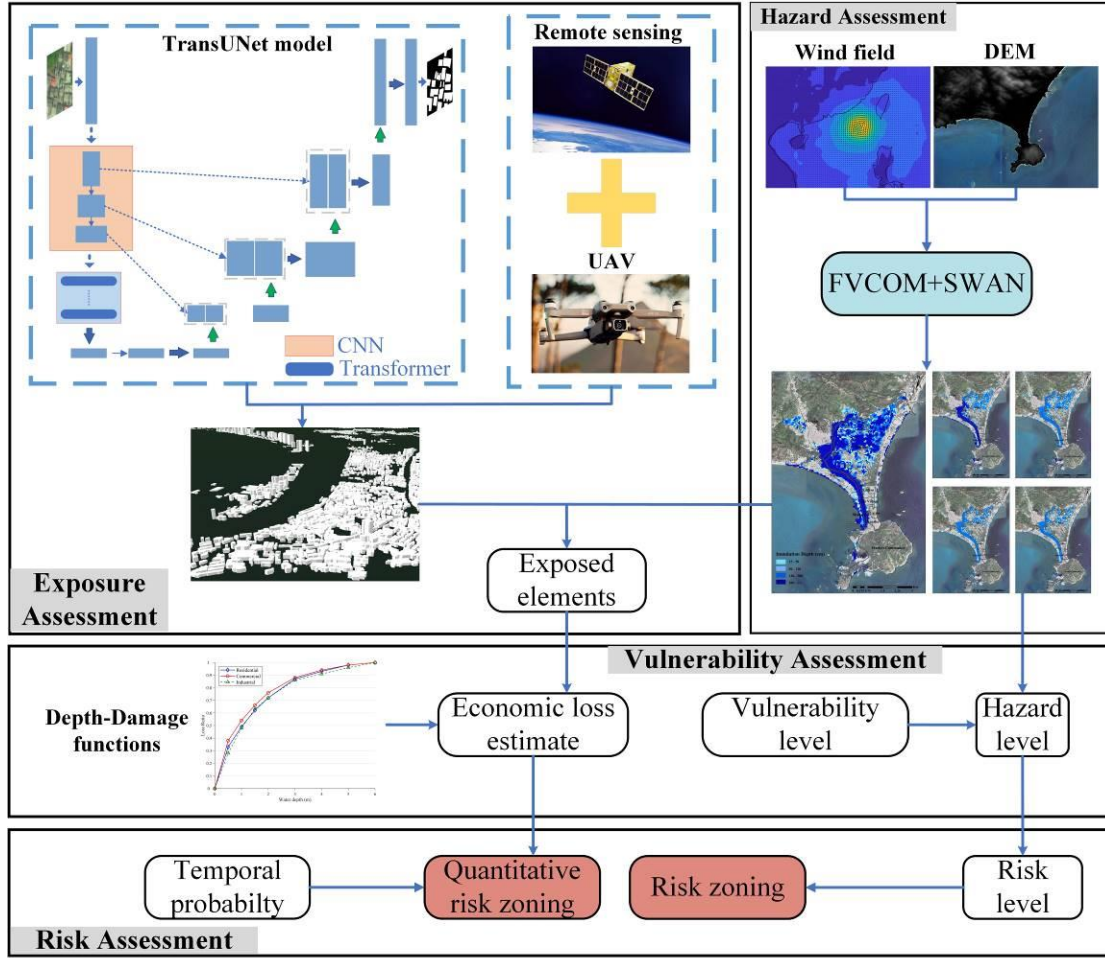

227 (7) Administrative Boundary data: the data is obtained from National Platform for Common  
228 Geospatial Information Services, and it contains administrative boundaries at village level. There  
229 are ten villages in the study area.

230

### 231 **3. Method**

232 The methods in this study aim to assess quantitative direct tangible damage over the study  
233 area consists of following steps: hazard assessment; exposure assessment; vulnerability  
234 assessment; risk assessment, and the flowchart of the procedure is illustrated in Fig. 2.

235 First, with respect to hazard assessment, five storm surge scenarios are defined. After  
236 constructing wind field through Holland model, the inundation area and depth of different typhoon  
237 return periods are simulated by utilizing the coupled FVCOM-SWAN model. In exposure  
238 assessment, building footprints and heights are extracted by introducing a deep learning method  
239 TransUNet and shadow calculation. Then the hazard maps are overlaid to identify the elements at  
240 risk. Considering the effect of building's floor in flood monetary loss estimation, the JRC's depth-  
241 damage functions are adapted representing the vulnerability of different exposed elements.  
242 Eventually, the economic loss of different typhoon scenarios can be summarized and the risk  
243 assessment is conducted through multiplying the temporal probability. Moreover, the quantitative  
244 zoning maps of four risk levels are generated through zonal statistic.

245

246 **Fig. 2.** The flowchart of the presented storm surge quantitative risk assessment method. The base  
 247 map is obtained from © GoogleMaps (map data © 2023 Google).

248

249 **3.1. Storm surge inundation simulation**

250 Finite Volume Coastal Ocean Model (FVCOM), is a coastal ocean circulation model, which  
 251 was originally developed by Chen et al. (2003), and further improved by the University of  
 252 Massachusetts and the Woods Hole Oceanographic Institution. The following are the governing  
 253 equations of FVCOM, comprising momentum, continuity, temperature, salinity, and density  
 254 equations:

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} + w \frac{\partial u}{\partial z} = -\frac{1}{\rho_o} \frac{\partial P}{\partial x} + \frac{\partial}{\partial z} \left( K_m \frac{\partial u}{\partial z} \right) + F_u \quad (3.1)$$

$$\frac{\partial v}{\partial t} + u \frac{\partial v}{\partial x} + v \frac{\partial v}{\partial y} + w \frac{\partial v}{\partial z} + fu = -\frac{1}{\rho_o} \frac{\partial P}{\partial y} + \frac{\partial}{\partial z} \left( K_m \frac{\partial v}{\partial z} \right) + F_v \quad (3.2)$$

$$\frac{\partial P}{\partial z} = -\rho g \quad (3.3)$$

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z} = 0 \quad (3.4)$$

$$\frac{\partial T}{\partial t} + u \frac{\partial T}{\partial x} + v \frac{\partial T}{\partial y} + w \frac{\partial T}{\partial z} = \frac{\partial}{\partial z} \left( K_h \frac{\partial T}{\partial z} \right) + F_T \quad (3.5)$$

$$\frac{\partial S}{\partial t} + u \frac{\partial S}{\partial x} + v \frac{\partial S}{\partial y} + w \frac{\partial S}{\partial z} = \frac{\partial}{\partial z} \left( K_h \frac{\partial S}{\partial z} \right) + F_S \quad (3.6)$$

$$\rho = \rho(T, S) \quad (3.7)$$

255 Where  $x$ ,  $y$  and  $z$  respectively represent the east, north and vertical coordinate axes in the  
 256 Cartesian coordinate system;  $u$ ,  $v$  and  $w$  are the velocity components in  $x$ ,  $y$ ,  $z$  directions;  $T$ ,  
 257  $S$  and  $\rho$  are the temperature, salinity and density;  $P$  is the pressure and  $f$  stands for the  
 258 Coriolis parameter;  $K_m$  is the vertical eddy viscosity coefficient and  $K_h$  is the vertical eddy  
 259 diffusivity coefficient for heat;  $g$  is the gravitational acceleration;  $F_u$ ,  $F_v$ ,  $F_T$ , and  $F_S$  are the  
 260 horizontal diffusion terms.

261 Simulating Waves Nearshore (SWAN) is the third-generation offshore wave model developed  
 262 by Delft University of Technology and it was originally proposed by Booij et al. (1996). The  
 263 governing equation of the model is shown as

$$\frac{\partial}{\partial t} N + \frac{\partial}{\partial x} C_x N + \frac{\partial}{\partial y} C_y N + \frac{\partial}{\partial \gamma} C_\gamma N + \frac{\partial}{\partial \theta} C_\theta N = \frac{S}{\gamma} \quad (3.8)$$

264 Where  $N$  is the wave action density;  $\theta$  is the propagation direction;  $C_x$ ,  $C_y$  are respectively  
 265 the  $x$ ,  $y$  components of propagation speed and  $C_\gamma$ ,  $C_\theta$  are the  $\gamma$ ,  $\theta$  components of propagation  
 266 cospeed;  $\gamma$  and  $S$  respectively represent the frequency and the source term for the wave energy.

267 The potential storm surge inundation maps in different typhoon scenarios have been  
 268 conducted by institutions such as the National Oceanic and Atmospheric Administration (NOAA),  
 269 National Hurricane Center, and other departments since the 1990s (Glahn et al., 2009). In the field  
 270 of risk assessment research, it is common to set up different typhoon scenarios using storm surge  
 271 simulation models to obtain various scenarios of typhoon induced inundation (Zhang et al., 2023;  
 272 Rizzi et al., 2017). The hazard maps of under various typhoon intensity scenarios are helpful for  
 273 decision-makers and researchers in analysing multiple aspects of potential hazards in the study  
 274 area.

275 Typhoon Mangkhut, as one of the largest typhoons to affect South China Sea region in recent  
 276 years, has a strong representative. It is characterised by high intensity, wide area of influence, high  
 277 wind speed, etc. In this study, the path of Typhoon Mangkhut is shifted to pass through the  
 278 Huizhou tidal station as the input typhoon path of the coupled model to maximize the impact area  
 279 of the simulation result. In terms of the center pressure, Wang et al. (2021b) presented statistical  
 280 analyses of historical typhoon data in Huizhou, and designed five typhoon scenarios, which are  
 281 respectively the typhoon minimum central pressure of 880, 910, 920, 930 and 940 hPa. Therefore,  
 282 these five parameters are introduced as the setup for five typhoon scenarios.

283 FVCOM and SWAN both use the unstructured triangular grid to subdivide the South China  
 284 Sea, and the latitude and longitude range of the region is 13°N - 29°N, 109°E-122°E. The SWAN  
 285 parameters are set as follows: wind input growth term and whitecap dissipation term are the  
 286 Komen scheme; Bottom friction dissipation is parameterized using the Madsen vortex viscosity  
 287 model; The nonlinear interactions are implemented using three-wave and four-wave nonlinear  
 288 interaction schemes. The input wind field is the fusing wind field derived from ERA5 and the  
 289 Holland method. The open boundary forced tidal elevation of FVCOM is conducted by calculating  
 290 the harmonic constants for the eleven major astronomical tidal constituents, namely M2, N2, S2,  
 291 K2, K1, O1, P1, Q1, MS4, M4, and M6. The forcing field is the fusing wind field and the wave  
 292 data generated by SWAN. The external model time step for the model is set to 0.75 second, while  
 293 the internal model time step is set to 7 seconds.

294 In summary, FVCOM-SWAN coupling method is utilized for simulating the inundation  
 295 caused by storm surge. Specifically, following the modification of typhoon Mangkhut's central  
 296 pressure, velocity, and track data, the data is utilized as input for the Holland typhoon wind field  
 297 model, subsequently yielding the wind field outcome. The hybrid wind field data generated is fed  
 298 into the SWAN model to generate wave data. Then, both the wind data and wave data are input  
 299 into the FVCOM model to calculate the extent of inundation.

300

### 301 3.2. Buildings extraction

302 The deep learning model used in the research is TransUNet (Chen et al., 2021), which was  
 303 originally proposed for medical images segmentation. TransUNet incorporates transformer in  
 304 encoder within the architecture of U-shape network, consequently makes use of the advantage of  
 305 global information extraction while fusing the superficial and deep features. On the mission of  
 306 building extraction, the target is to segment the building's area precisely. The TransUNet model  
 307 can effectively identify the boundary between buildings and background, which enables the model  
 308 to be competent for extracting the buildings in different size and shape.

309 The following is relevant introduction of the structure of the model.

#### 310 3.2.1. Transformer in TransUNet

311 Transformer was first proposed by Sutskever et al. (2014), which was originally utilized for  
 312 machine translation. However, as more variants of transform were developed, people found  
 313 transform also perform well in multiple tasks, such as natural language processing (NLP),  
 314 computer vision (CV) and automatic speech recognition (ASR).

315 The transformer encoder is composed of L layers of Multi-head Self-Attention (MSA), Layer  
 316 normalization (LN) and Multi-Layer Perceptron (MLP), the structure is shown in the Fig. 3(a), and  
 317 the equations of Query-Key-Value (QKV) self-attention and MSA are shown below:

$$\text{Attention}(Q, K, V) = \text{softmax}\left(\frac{QK^T}{\sqrt{D_k}}\right)V \quad (3.9)$$

$$\text{MultiHeadAttn}(Q, K, V) = \text{Concat}(\text{head}_1, \dots, \text{head}_H) \mathbf{W}^O \quad (3.10)$$

$$\text{head}_i = \text{Attention}(QW_i^Q, KW_i^K, VW_i^V) \quad (3.11)$$

318 Where  $Q, K, V$  are respectively the Query, Key, Value vector.  $\sqrt{D_k}$  is the scaled dot-  
 319 product attention.  $\mathbf{W}^O, W_i^Q, W_i^K, W_i^V$  are respectively the corresponding linear mapping, which  
 320 convert  $Q, K, V$  and the output to the specified dimension.

321 The MSA has a positive effect on helping the model identify the target objects and  
 322 background, thus the neural network can learn more information form the target. LN is deemed to  
 323 stabilize the deep network training, which can prevent unstable gradient, model degradation, etc.  
 324 The module receives the 2d flatted patches from the image's patches. Due to it is different from  
 325 CNN or RNN, apart from map the vectorized patches to D-dimensional embedding space,  
 326 transformer needs to apply additional position encoding for retaining the patch's positional  
 327 information.

#### 328 3.2.2. Structure of TransUNet

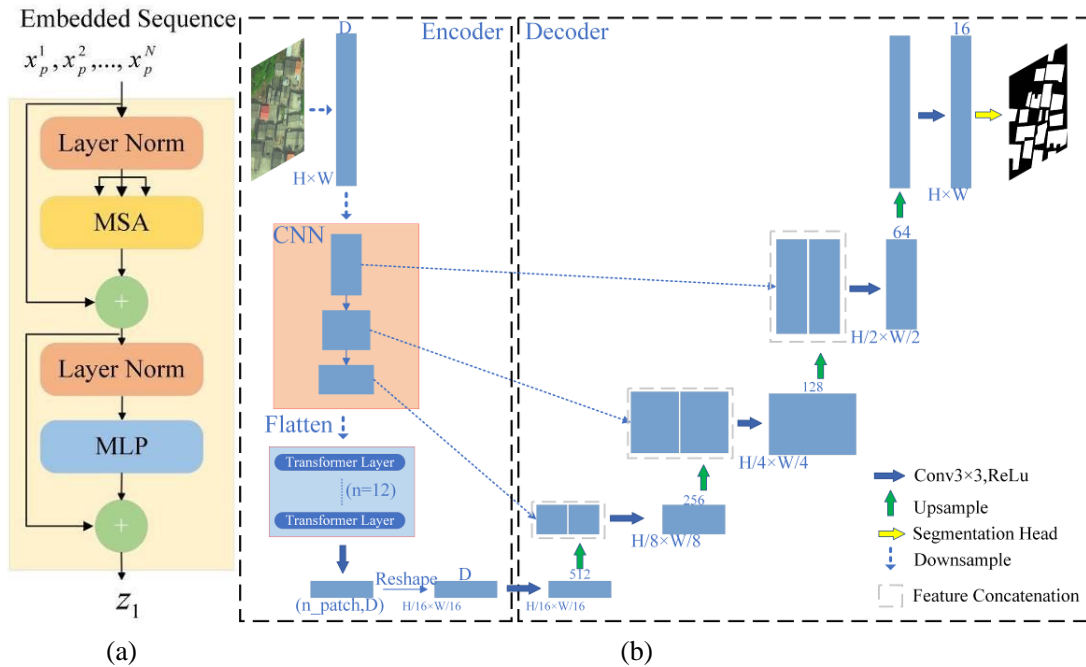

329 The overall structure of TransUNet is reference to U-Net, which is a U-shaped Encoder-  
 330 Decoder structure, and the structure diagram is shown in the Fig. 3(b).

331 Encoder: the origin image is put into the CNN part for feature extraction, after the processing  
 332 of position encoding and flatten, the patches are further put into the transformer module. The

333 transformer module consists of 12 transformer layers. The CNN part is implemented through  
 334 using resnet50, which include 3 blocks in total, and each block output the hidden feature for skip  
 335 connection.

336 Decoder: reshape the output sequence from encoder and then cascade up-sampling after  
 337 transforming the number of channels. During the process, the skip connection is introduced by  
 338 using the feature map hereinbefore. In the end, the segmentation result is generated.

339 In conclusion, TransUNet is the combination of U-Net and transformer, which is designed to  
 340 make use of the advantage from both structures. The Global Attention from transformer can  
 341 contribute to learn the global information, while the skip connection from U-shape network can  
 342 contribute to get more information from shallow feature map output from CNN, and also CNN  
 343 performs better in extracting the local information. In this research, buildings images are similar to  
 344 medical images, with the features like high complexity level, large range of gray values. The skip  
 345 connection structure can simultaneously acquisition of low-level semantic features and high-level  
 346 semantic features, and transformer can conduce identify the buildings from background, thus  
 347 TransUNet achieves a high accuracy in buildings segmentation.

350 **Fig. 3.** The overview of TransUNet framework (adapted from (Chen et al., 2021)): (a) Schematic  
 351 diagram of Transformer layer; (b) Structure diagram of TransUNet

### 353 3.3. Building's height acquisition

354 UAV tilt photography modeling technology can combine control points encryption from  
 355 massive image data with a small number of ground control points to obtain accurate external  
 356 orientation elements (Kang et al., 2020). The conducted 3D model reflects the truly condition of  
 357 the ground, and the data is selected to be in the WGS 1984 coordinate system. The ground  
 358 resolution is one of the most intuitive and important parameters in tilt photography, and it's also a  
 359 key factor determining the quality of the 3D modeling. In the process of performing aerial  
 360 triangulation for tilt-image automation, it is necessary to ensure that the resolution of the different  
 361 images is as consistent as possible while taking into account the resolution of the side-view image,  
 362 thus to ensure accuracy and image overlap. Hence, the combinatory analysis of image resolution at

363 tilted viewing angle is required. The tilted image center point, near point and far point resolutions  
 364 are expressed as follows:

$$\text{GSD}_{\text{top}} = \frac{\delta h \cos \beta_y}{f \cos(\alpha_y - \beta_y)} \quad (3.12)$$

$$\text{GSD}_{\text{mid}} = \frac{\delta h}{f \cos \alpha_y} \quad (3.13)$$

$$\text{GSD}_{\text{bottom}} = \frac{\delta h \cos \beta_y}{f \cos(\alpha_y + \beta_y)} \quad (3.14)$$

365 Where  $\delta$  is sensor cell size,  $h$  is flight height,  $f$  refers to the camera focal length,  $\alpha_y$  and  
 366  $\beta_y$  are respectively dip angle and half the angle of view. Normally, the ground resolution at the  
 367 center of the tilted and vertical images should be comparable, and the minimum resolution of tilted  
 368 images should less than three times the resolution of a vertical image.

369 There are multiple formats available for storing 3D models, including OBJ, STL, FBX,  
 370 OSGB, etc. In this study, the generated 3D model is saved as OSGB format. OSGB format is  
 371 originally proposed by Ordnance Survey for storing the geographic spatial data in the British. It  
 372 combines binary encoding and compression algorithms to improve the data storage and  
 373 transmission efficiency. Normally, the OSGB data contains information of geographic coordinates,  
 374 elevations, texture mapping, and geometric shapes, which can be used to GIS application, virtual  
 375 reality (VR), among others.

376 Digital surface model (DSM) is a digital terrain model that contains elevation information  
 377 about trees, buildings, and bridges. Compare to DEM, DSM can reflect the truly surface condition  
 378 of earth, thus DSM has a wide range of application in city management or forest stewardship. In  
 379 this research, the UAV data can be transformed to DSM data by using SuperMap software, and the  
 380 DSM result is shown in Fig. 4(b). After generating the DSM, the elevations of the roof of the  
 381 buildings and the corresponding elevations of the ground around the buildings are extracted by  
 382 manual selection, then the height of buildings can be calculated by using equation (3.15).

$$DSM_{\text{Roof}} - DSM_{\text{Ground}} = H \quad (3.15)$$

383 Where  $DSM_{\text{Roof}}$  is the DSM value of the building's roof,  $DSM_{\text{Ground}}$  represents the  
 384 corresponding DSM value of ground, and  $H$  is the result of building's height.

385 (a) (b)  
 386 **Fig. 4.** Building's height acquisition: (a) The schematic diagram of UAV tilt photography data; (b)  
 387 The generated DSM results for Building height data extraction.  
 388

### 389 3.4. Exposure and vulnerability assessment

390 The process of storm surge risk assessment involves two key components: exposure and  
 391 vulnerability. The exposure represents the elements exposed to hazardous spaces, while the  
 392 vulnerability refers to the level of the exposure elements' susceptibility to damage. When doing  
 393 exposure assessment, the disaster-affected elements can be conducted by overlaying the building  
 394 footprint data and land cover data with the hazard layer, which is the inundation data in this  
 395 research. The process can be accomplished using overlay analysis in ArcGIS software.

#### 396 3.4.1. Adaptation of flood vulnerability functions.

397 Constructing an empirical stage-damage curve is a commonly used method for conducting  
 398 vulnerability assessments. However, as is mentioned above, China lacks of the data about flood  
 399 loss or insurance compensation in flood disasters, as a result, it's not practicable to develop  
 400 exclusive functions for the study region, so the depth-damage functions developed by Huizinga,  
 401 Joint Research Center (JRC) (Huizinga et al., 2017) are introduced. The depth-damage functions  
 402 manifest the loss ratio of the exposure elements in different inundation depth from 0 to 6 m, and  
 403 the ratio range from 0 to 1, which represents no damage to fully damaged. Besides, JRC also  
 404 provides the maximum economic losses per square meter for six different exposure element types  
 405 including residential, industrial, infrastructure, road, agricultural land, and transport. In this study,  
 406 the original functions and maximum loss data for China region are used, and the economic loss  
 407 can be calculated by multiplying the loss ratio, the maximum loss, and the disaster-affected area.

408 However, the JRC's vulnerability functions do not provide the specific function of each  
 409 height category. In this case, the depth-damage functions in HAZUS are introduced. HAZUS is  
 410 first released for earthquakes in 1997 by Federal Emergency Management Agency (FEMA), and  
 411 that's when the HAZUS Flood Model started to be developed (Scawthorn et al., 2006). In 2004, a  
 412 multi-hazard version called HAZUS-MH was a standardized GIS-based model that included the  
 413 earthquake, flood, and hurricane models (Nastev and Todorov, 2013). The HAZUS-MH flood  
 414 model is designed primarily for local and regional hazard planners and emergency managers for  
 415 developing emergency management plans and mitigation strategies (Tate et al., 2015). However,  
 416 the depth-damage functions in HAZUS-MH are restricted to regions within America, hence the  
 417 HAZUS's functions are introduced to adapt JRC's functions.

418 The approach to modifying functions is referred to the method proposed by Dabbeek et al.  
 419 (2020). In the process, the HAZUS loss ratios of each height category (one-story, two-story, three  
 420 and more-story) are averaged, which is shown in equation (3.16). Then the contribution of each  
 421 height category relative to the average loss is calculated as equation (3.17) shows. In the end,  
 422 multiplying the value obtained in the previous step by JRC's vulnerability functions yields the  
 423 adapted functions for each height category.

$$\bar{D}_{i(hazus)} = \frac{d_{i,1} + d_{i,2} + d_{i,3+}}{n} \quad (3.16)$$

$$i(depth) = \{(0, 6)\}$$

$$c_{i,h} = \frac{d_{i,h}}{\bar{D}_{i(hazus)}} \quad (3.17)$$

$$d_{i,h(adapted)} = c_{i,h} \times \bar{D}_{i(jrc)} \quad (3.18)$$

424 Where  $d_{i,h}$  represents to the loss ratio at the inundation depth  $i$  for each height category  $h$ .  
 425  $\bar{D}_i$  is the average loss ratio of all heights.

426

427 *3.4.2. Quantitative risk assessment*

428 The quantitative financial loss estimation is accomplished by overlaying the following data:  
429 the inundation simulation result generated by FVCOM and SWAN modeling, the spatial  
430 distribution of three types of exposure elements, the depth-damage functions of industrial and  
431 commercial elements, and the adapted depth-damage functions for residential elements in three  
432 height categories. The process of loss estimation can be shown in the following equation:

$$C = \sum_{i=1}^{i=n} D_{x(i)} f(d_i) A_i \quad (3.19)$$

433 Where  $C$  stands for the economic loss estimation result.  $n$  represents the total number of  
434 exposure elements.  $x(i)$  is the type of the  $i$ -th element and  $D_{x(i)}$  is the maximum loss of the  $i$ -th  
435 element.  $d_i$  is the depth of submergence of the  $i$ -th element and  $f(d_i)$  is the loss ratio of the  $i$ -th  
436 element.  $A_i$  refers to the area of the  $i$ -th element.

437 Comparing to the 984 euros per  $m^2$  monetary loss of residential buildings in 2010, the  
438 monetary loss of infrastructure and agriculture are respectively 12 euros per  $m^2$  and 0.02 euro per  
439  $m^2$  according to JRC, only account for 1% or less. Therefore, the monetary loss estimate of  
440 infrastructure and agriculture is excluded in the study.

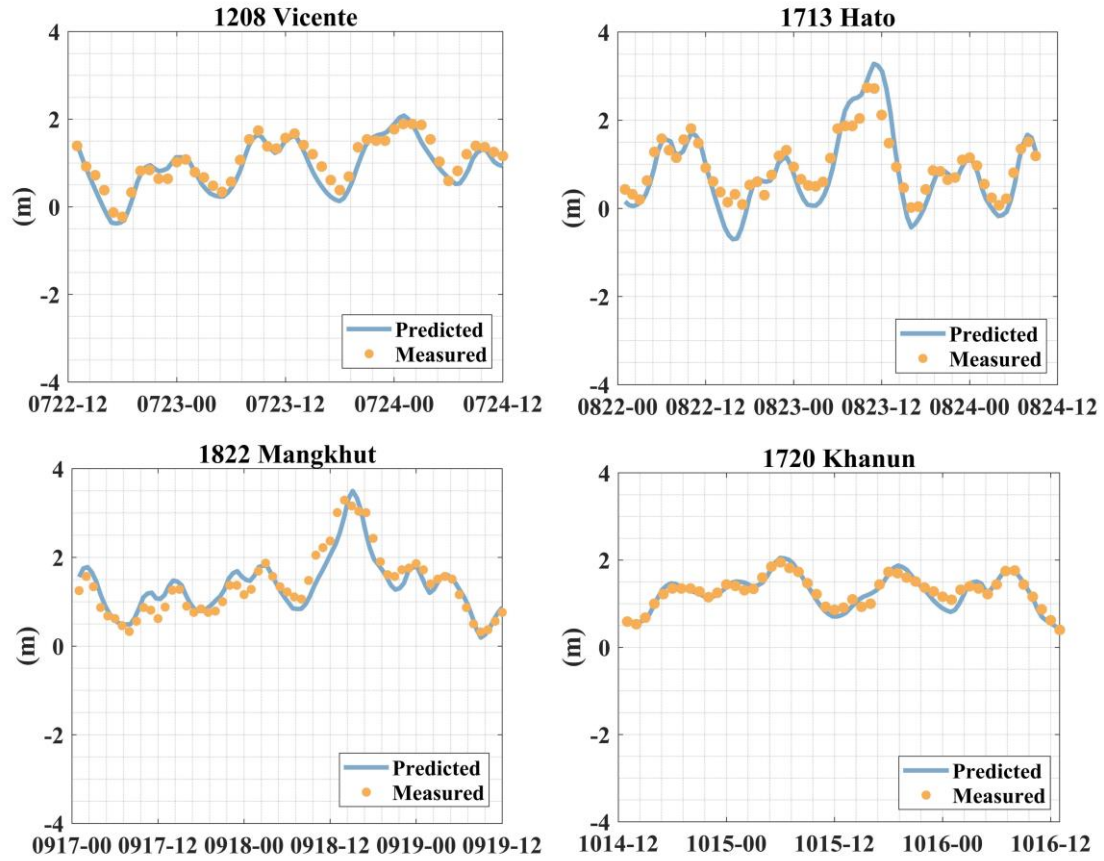

441 In this research, five storm surge scenarios are settled, ten administrative sub-zones are given  
442 four different risk levels for each defined typhoon scenario.

443

444 **4. Results and discussions**

445 *4.1. Validation*

446 The performance of coupled FVCOM-SWAN model is evaluated. Four typical typhoons  
447 (Vicente, Hato, Mangkhut, Khanun) are selected to validate the coupled model for the study region.  
448 The measured data of each typhoon are captured by Department of Natural Resources of Huizhou  
449 Bureau. Fig. 5 shows the maximum predicted water level and highest measured water level of the  
450 chosen typhoons. Relative error and absolute error are introduced to evaluate the model and Table  
451 1 displays the statistical results from Huizhou tidal station. It is seen that the predicted results are  
452 in good agreement with the measurements. The statistic result shows that the relative errors of the  
453 four typhoons range from 2.1% to 19.8%, and the absolute error varies from 4 cm to 54 cm.  
454 Therefore, the coupled FVCOM-SWAN model demonstrates a reliable competence in  
455 accomplishing the storm surge simulation task.

456  
457 **Fig. 5.** The predicted water level and highest measured water level recorded by Huizhou tidal  
458 station during different typhoon event  
459

460 **Table 1.** The Relative error and Absolute error between maximum predicted water levels and highest  
461 measured water levels from Huizhou tidal station during different typhoon events

Typhoon name	Measured data (cm)	Relative error (%)	Absolute error (cm)
Vicente (1208)	189	10.3	19
Hato (1713)	274	19.8	54
Mangkhut (1822)	329	6.5	22
Khanun (1720)	201	2.1	4

462  
463 *4.1. Hazard assessment*

464 In the present research, five storm surge inundation scenarios are defined, which represent  
465 five different typhoon return periods: 10-year, 20-year, 50-year, 100-year, 1000-year respectively  
466 corresponding to minimum central pressure 940hPa, 930hPa, 920hPa, 910hPa, 880hPa, and the  
467 probability of occurrence are 10%, 5%, 2%, 1%, 0.1%. The simulation result is displayed through  
468 ArcGIS 10.8 software, and the inundation area and depth simulation results for each scenario is  
469 shown in Fig. 6. It is seen that the inundation area is spread over the coastal area in southwest of  
470 study area. In particular, for the 1000-year return period scenario, the inundation area exceeds 13  
471 km<sup>2</sup> in the study area. Moreover, the presence of Double-Moon Bay leads to the extension of the  
472 inundation along the bay, contributing to severe disasters inland.

473 From the point of view of different scenarios, the area of inundation is in direct proportion to  
 474 the typhoon's return period, and the proportion of inundation area increases from 14% to 31% of  
 475 study area. When the return period is less than 50 years, most of the flooded area is considered to  
 476 be in a high-level hazard zone, accounting for 75% for a 10-year return period and 67% for a 20-  
 477 year return period, and no zone in very high-level hazard. Basically, the inundation area covers  
 478 land such as grassland, saline land, and some buildings near the estuary as the area is more  
 479 susceptible to flooding because of the lower elevation and drainage from the estuary. As the return  
 480 period goes up to 100 years, 34% and 36% of the flooded area are defined at a high-level hazard  
 481 and very high-level hazard. When it's 1000-year, the situation worsens with approximately half of  
 482 the inundation area being considered in very high-level hazard. Typically, the flood extends from  
 483 the margin of terrene, however, the southernmost region of the investigated area is characterized  
 484 by a knoll covered by forest vegetation, which serves the dual purpose of water absorption and  
 485 flood mitigation. In addition, the construction of embankments on both sides of Double-Moon Bay  
 486 effectively withstands flooding. Nevertheless, because of the presence of the estuary, inadequate  
 487 water absorption ability of coastal saline soil and the hydrological system, the inundation flows in  
 488 through the estuary and spreads inland.

489

490

491 **Fig. 6.** The storm surge inundation simulation results of five different typhoon scenarios: return period  
 492 (a) 1000-year, (b): 100-year, (c): 50-year, (d): 20-year, (e): 10-year. The base map is obtained from ©  
 493 GoogleMaps (map data © 2023 Google).

494

495 *4.2. Buildings' characters extraction*

496 *4.2.1 TransUNet model training*

497 The dataset construction area is chosen at southwest waterfront region of Renshan Town. The

498 specific location is shown in Fig. 7. The chosen area is a typical area of the Huizhou coastal area.  
499 Apart from the seaside bungalows, the area contains some high-rise buildings that are identified as  
500 commercial hotels or resorts, while dense residential area is also widely distributed throughout the  
501 inland region. In conclusion, the chosen area contains different kinds of buildings with strong  
502 representativeness. Since most of the buildings in China coastal towns have the similar characters,  
503 the model trained on the representative region has the ability to identify buildings in other regions  
504 rapidly.

505 The labels of the buildings in the area are generated by manually annotation, and the image is  
506 cropped into small patches with a size of 256\*256. Besides, some of the images without buildings  
507 are filtered for preventing the effect of imbalance between the building samples and background  
508 samples. In the end, a total of 1200 labeled building dataset is constructed, and the dataset size is  
509 deemed sufficient when compared to previous study (Dixit et al., 2021; Ji et al., 2018). The dataset  
510 is then divided into a training set and a test set, with the ratio of 8:2. Data enhancement techniques,  
511 such as random hue saturation value, random shift scale rotation, flip, and rotation, are  
512 implemented during model training to improve the deep learning model's generalization  
513 performance and prevent overfitting.

514 The training's initial learning rate is set to 1e-5, and the learning rate adjustment strategy for  
515 improved training. The batch size is specified as 4, and the number of training epoch is 100. The  
516 model is trained on a NVIDIA RTX3060 GPUs.

517  
518 **Fig. 7.** The chosen area to make the training samples. The base map is obtained from ©  
519 GoogleMaps (map data © 2023 Google).  
520

#### 521 4.2.2. Extraction result

522 Several effective indicators are introduced, including Recall, Precision, F1-score, and mean  
523 Intersection-over-Union (mIoU), to evaluate the performance of the deep learning model. Recall is  
524 the probability of being predicted as positive among actual positive samples. Precision, on the  
525 other hand, is the probability of being actually positive among samples predicted as positive. F1-  
526 score serves as an indicator that achieves a balance point between precision and recall, essentially  
527 being the harmonic average of precision and recall. mIoU is the mean ratio of the intersection to  
528 the union between predicted and true values for each category. True positive (TP) indicates the  
529 true samples that are predicted correctly by the model. False positive (FP) indicates the positive  
530 samples that the model incorrectly predicted. True negative (TN) and false negative (FN) refer to

531 the number of samples that are correctly and incorrectly predicted as negative by the model. The  
 532 equations of Recall, Precision, F1-score, and mIoU are as follows:

$$recall = \frac{TP}{TP + FN} \quad (4.1)$$

$$precision = \frac{TP}{TP + FP} \quad (4.2)$$

$$F1 = 2 \times \frac{precision \times recall}{precision + recall} \quad (4.3)$$

$$mIoU = \frac{1}{k+1} \sum_{i=0}^k \frac{TP}{TP + FP + FN} \quad (4.4)$$

533 The quantitative evaluation result is shown in Table 2, and the visualization results are  
 534 illustrated in Fig. 8. As Table 2 shows, the recall score reaches 87% indicating that most of the true  
 535 building pixels are predicted correctly, and Precision indicates that 82% of all building pixels are  
 536 correctly detected. Moreover, both the mIoU score and F1-score exceed 80% manifest that the  
 537 model can balance well between precision and recall. These results reflect the strong performance  
 538 of TransUNet in the building extraction task. After post-processing the result, such as boundary  
 539 simplification, the building vectorization results can be used for further research in risk assessment.  
 540 The overall result is shown in Fig. 9 (b,c).

541 **Table 2.** The statistical accuracy assessment of building footprint extraction

Evaluation metric	
Recall (%)	87.03
Precision (%)	82.04
F1-score (%)	84.46
mIoU (%)	83.38

542  
 543 **Fig. 8.** Building footprint extraction result in study area. (a) Remote sensing images obtained from  
 544 Jilin-1 satellite (© Chang Guang Satellite technology CO., LTD); (b) Extraction result; (c) Ground  
 545 truth. The building is marked in white, and the background is marked in black

546

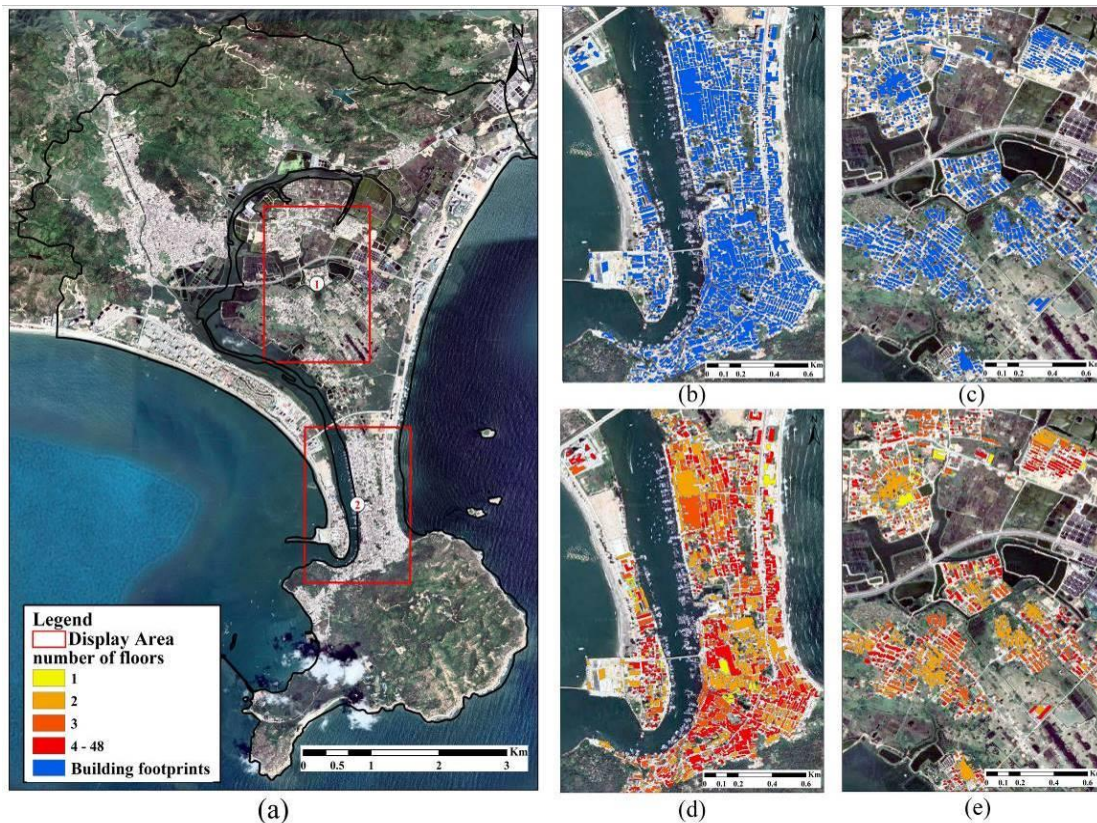

547 *4.2.3. Building height calculation*

548 Through combing two methods mentioned above, the height information is acquired in units  
549 of meters. The number of floors is derived by dividing the acquired height information by the  
550 specified standard height of 3 meters, according to the China residential design standards. The  
551 general condition of building floor is shown in Table 3. Just as mentioned above, the buildings in  
552 study area are mainly for residential and commercial use. Since the study area is undeveloped, the  
553 high buildings and large mansions is relatively less common, and most of them are built for  
554 seaside resort. Instead, buildings with 5 floors or less are the mainstream in study area as respected,  
555 which the proportion can reach 76.5%. The building footprint extraction result and building's  
556 height information extraction result can be found in Fig. 9 (d,e).

557

**Table 3.** Statistical results of building height in the study area

Building floor	Area (m <sup>2</sup> )	Proportion (%)
1-5	17537238.61	76.5
6-10	4996897.08	21.8
11-20	342207.82	1.5
20+	54083.93	0.2

558

559 **Fig. 9.** The building characters extraction result: (a) The schematic of the display area; (b, c)  
560 Building footprint result in area 1 and 2; (d, e) Building height result in area 1 and 2. The base  
561 map is obtained from © GoogleMaps (map data © 2023 Google).

562

563 *4.3. qualitative risk assessment*

564 Risk matrix is a risk assessment approach firstly developed by Electronic System Center,

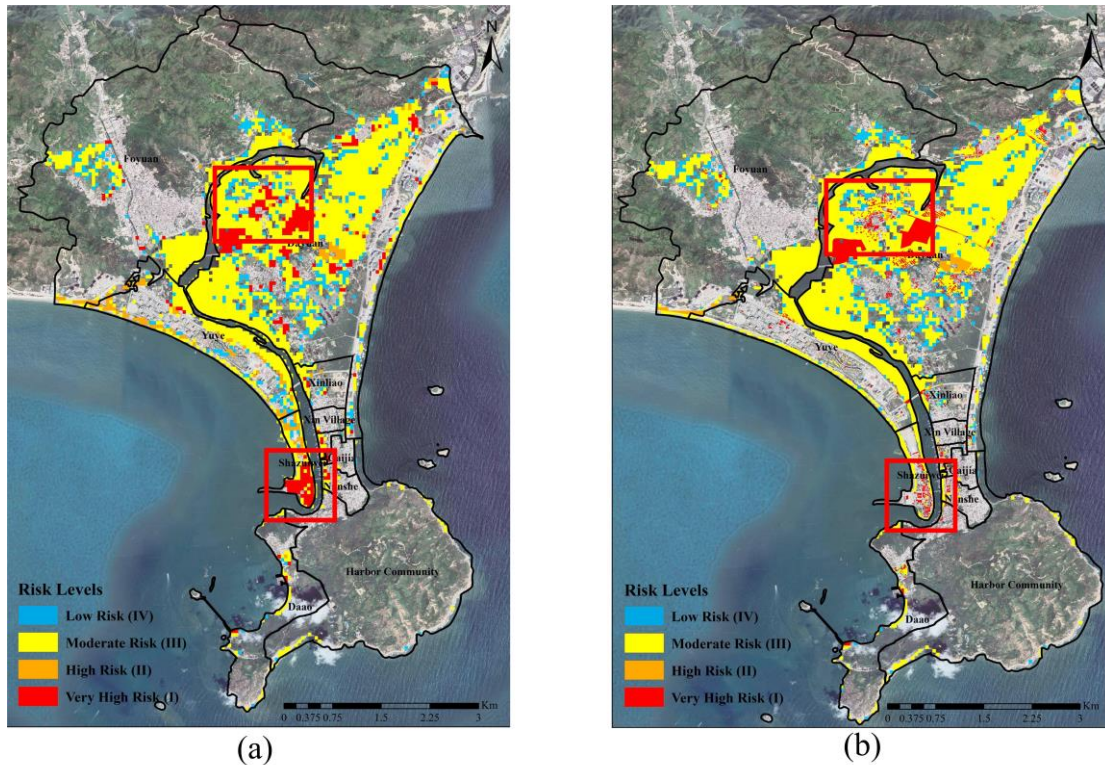

565 which was originally to assess the risk in the life cycle of purchase project (Garvey and  
 566 Lansdowne, 1998). An additional qualitative risk assessment is conducted using the risk matrix  
 567 method, incorporating improved land use data to highlight the superiority of building extraction in  
 568 flood risk assessment. The concrete representation of the risk matrix is shown in table 4.

569 **Table 4.** The concrete representation of the risk matrix

		<b>Vulnerability</b>			
		Low	Moderate	High	Very High
<b>Hazard</b>	Low	Low	Low	Moderate	Moderate
	Moderate	Low	Moderate	High	High
	High	Moderate	High	High	Very High
	Very High	Moderate	High	Very High	Very High

570  
 571 As is shown in Fig. 10(a), the concentrations of organic town of Dayuan village and  
 572 Shazuiwei makes it in very high vulnerability level. Under the circumstance of defined 880hPa  
 573 storm surge scenario, the inundation area spread inland which makes the majority area of Dayuan  
 574 is regarded as moderate risk, and a fraction of the only very high risk area is distributed in  
 575 Shazuiwei and north of Dayuan village. In the area of Yuye village, part of the south coastal area is  
 576 considered in moderate or high risk level. That is mainly because the majority area of Yuye is  
 577 defined as resort district except for a few areas of tidal flats, which is in high vulnerability.  
 578 However, after referring to the result of hazard assessment, buildings in the area are not actually  
 579 inundated, meaning the area should not be at risk level.

580 Through comparing the Fig. 10(a) and Fig. 10(b), the enhanced land use data in the present  
 581 research demonstrates a higher ability to recognize vulnerability elements, which the type is  
 582 buildings in the present research. The two red boxes in the figure highlight the noticeable disparity  
 583 between the original and current results. The present risk assessment provides more refined risk  
 584 assessment result compared to the original result, as the previously identified large hazardous  
 585 areas are replaced with more detailed and smaller zones. This refinement is conducive for  
 586 government or decision-makers to conduct disaster prevention measures, propose quick guidance  
 587 for personnel evacuation and organize rescue operations in the event of a disaster.

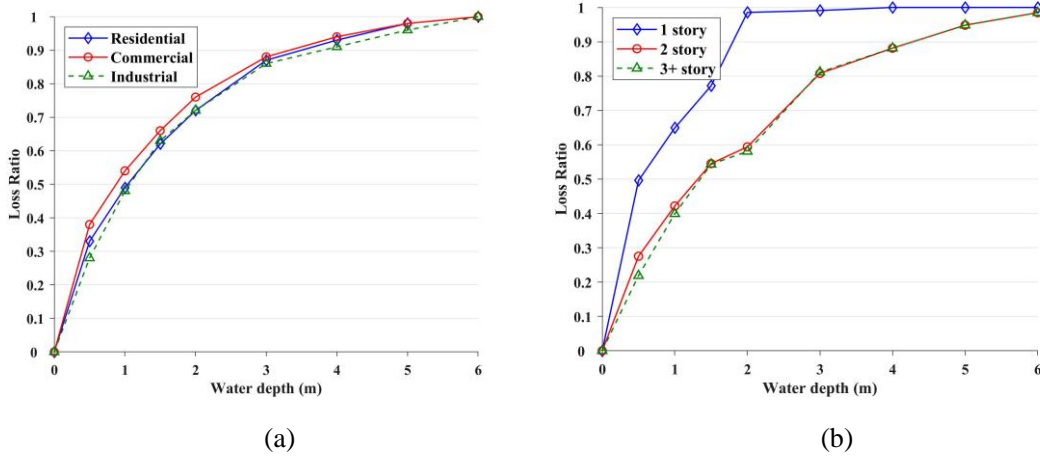

588  
 589 **Fig. 10.** The risk assessment maps before (a) and after (b) improvement for storm surge scenarios

 591 Google).

592  
 593 *4.4. JRC's depth-damage function adaption*

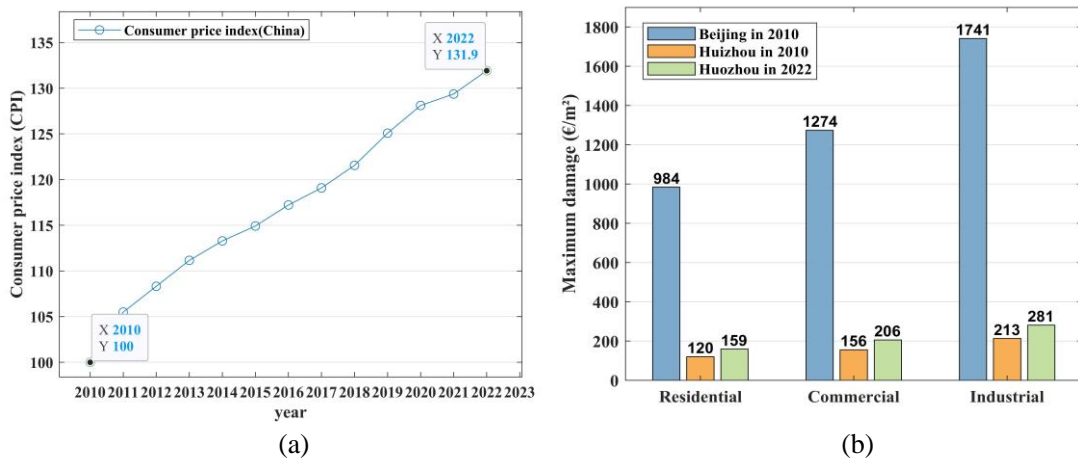

594 Fig. 11 illustrates the damage ratio given flood-depth after adjustment, respectively for one-,  
 595 two- and more than three-story residential buildings. After adjustment, the damage of one-story  
 596 residential building function is significantly enhanced, and the loss ratio reach 1 early, which is  
 597 explicable as 2m-depth flood almost submerges the entire building, resulting in a potential loss of  
 598 the maximum property value. On the contrary, the loss ratio for multi-story residential building is  
 599 decreased relative to the original function, it reaches the same level as in the original function  
 600 when the water depth reaches 5 meters. Furthermore, the function of a two-story residential  
 601 building is quite similar to that of a building with three or more stories. This can be attributed to  
 602 the flood's effect on buildings with six meters or less depth being nearly the same, on account of  
 603 the flood can't overwhelm the entire buildings.

604 The Joint Research Centre provides information on the maximum damages per square for  
 605 each type of building. This refers to the maximum monetary damage incurred when buildings are  
 606 inundated, which is the monetary damage value when the damage ratio in the depth-damage curve  
 607 reaches 100%. Although the maximum monetary damages are provided, they are computed for  
 608 Beijing in 2010. However, there is a substantial difference in the level of development between  
 609 Beijing and the study area. For better matching the financial level in study area, adjustment can be  
 610 achieved based on scaling the maximum monetary damage value with the GDP ratio according to  
 611 Huizinga (2007). Based on the 2010 GDP of Beijing of 14113558 million yuan and the GDP of  
 612 Huizhou of 172995 million yuan, the maximum monetary damage is adjusted by equal proportions.  
 613 Besides, the price level also needs to be adjusted to the 2022 price level. According to the World

614 Bank, the Chinese consumer price index (CPI) has changed from 100 in 2010 to 131.9 in 2022, the  
 615 tendency of variation and the adjusted maximum monetary damages are shown in Fig. 12.

616  
 617

621  
 622 **Fig. 12.** (a) The variation trend of Consumer price index released by World Bank; (b) The  
 623 maximum monetary damage per m<sup>2</sup> for each type of exposed elements in China (in 2010 and in  
 624 2022).  
 625

626 *4.5. Quantitative risk assessment*

627 Loss assessments of five storm surge scenarios are computed for return periods of 10, 20, 50,  
 628 100, and 1000 years, through employing the method in section 3. The estimate monetary damage  
 629 is summarized in Table 5.

630 The statistical data in Table 5 demonstrate an increase in the affected area and total economic  
 631 loss with an increasing return period. Comparing to the total affected area of 131533.12 m<sup>2</sup> and  
 632 the total economic losses of 9330517.49 euros with the 10-year return period, the  
 633 corresponding estimate result with 1000-year return period is 917437.99 m<sup>2</sup> and 68364923.25  
 634 euros, which is both approximately seven times higher. This indicates a proportional  
 635 relationship between the extent of regional impairment and the return period of a typhoon.  
 636 Although the impacted area for the 20-year and 50-year return periods exhibits relative  
 637 proximity as the different is 24118.26 m<sup>2</sup>, there is still a significant disparity in economic

638 losses. According to the inundation result above, that's because the inundation area of two  
639 return period is nearly the same except for the slight difference in the northeast of the study  
640 region, but the flood depth of 50-year intensified, which causes more monetary damage. In  
641 terms of inundated building types, in case that study area is characterized as a tourism and  
642 fish breeding area, the proportion of economic losses in industrial is relatively low. The losses  
643 of residential buildings and commercial buildings is comparatively close, up until the severity  
644 of storm surge reach 50-year return period. At this point, the losses experienced by residential  
645 buildings exceed those incurred by commercial buildings by more than double. The fact can  
646 be explained by the commercial buildings area mainly constructed by the seaside for better  
647 turnover therefore both types of waterfront buildings is impacted. However, as the severity of  
648 the typhoon worsens, more residential settlements inland are flooded, resulting in a swift  
649 increase in economic losses for residential buildings.

650 **Table 5.** The statistic result of the quantitative risk assessment for five defined typhoon scenarios.

Scenario	Elements	Area (m <sup>2</sup> )	Economic losses (€)	Total losses (€)	Probability	Risk (€)
10-year (940hPa)	Residential	94847.11	4910882.27	9330517.49	0.1	933051.75

	Industrial	5410.89	1161967.00			

651

652 Based on the economic losses estimation result for five storm surge scenarios, through using  
653 zonal statistics method on the data of administrative sub-zones in the study area, the quantitative  
654 risk assessment is conducted. The economic losses and spatial distribution of storm surge risk for  
655 ten sub-zones in five different scenarios are shown in Fig. 13. The zonation statistics result map of  
656 each sub-zone is defined at four different risk levels (very high, high, moderate, low). The  
657 classification of risk levels is obtained by categorizing all zonal statistic result based on quantiles.

658 As is shown in Fig. 13, Dayuan village is considered in very high risk for every defined  
659 typhoon scenario. Through analyzing the geographical characteristics of the study area, it can be  
660 found that although Dayuan is a relatively inland village, it's surrounded by the watercourse of the  
661 estuary of Double-Moon Bay. Due to the existence of flood control dam, both side of the bay offer  
662 a measure of protective effectiveness, which result in the water level rises in inland watercourse,  
663 and further causes flooding of residential buildings in Dayuan village, leading to massive financial  
664 losses. In contrast, Foyuan village is also a village with a relatively large area, the risk is at  
665 moderate level for 10, 20-year return period, and the level escalates to high for 50, 100-year return

666 period and reaches very high in 1000-year. Considering the presence of the knoll, the spread of  
667 inundation is hindered. However, as typhoon becomes more severe, the inundation hit the western  
668 buildings in the region, which led to the phenomenon of progressively escalating risk level. In  
669 terms of those villages with relatively smaller sizes, due to the protection of dam, Xinliao village,  
670 Xin village, Caijia village all are defined in relatively low risk level, although the regions with a  
671 high density of buildings. Shazuiwei and Yuye village in different return period are considered in  
672 different risk level, the cause of this phenomenon might be that apart from the higher density of  
673 buildings, the buildings in Shazuiwei are distributed in coastal area, combing the impact of  
674 inundation of both sides as it's located at the outermost part of the gulf. Consequently, the risk  
675 level in Shazuiwei remains consistently high as opposed to gradually increasing like in Yuye  
676 village. Although they are located at the outermost part of the study area, the quantitative risk level  
677 of Daa village and Harbor community is gradually increasing for different return period, but it's  
678 not as serious as the other village, which can be explained that these locations exhibit elevated  
679 topography.

680 Comparing the qualitative risk assessment result and the quantitative risk assessment result,  
681 the first difference to be noticed is that the two results focus on different scales. For the qualitative  
682 result, the emphasis is on delineating the regions in different risk levels, which leads to the  
683 prevention and control of priority areas. Whereas for quantitative result, the scale of the result is  
684 limited to the village level zoning, as the estimated monetary loss amounts are summarized at the  
685 village level. Furthermore, while the qualitative results suggest that certain regions may not be at a  
686 moderate or high risk level, the quantitative result reveals that the estimated monetary loss for  
687 those villages are not insignificant. In conclude, the qualitative risk assessment provides new  
688 results from a completely different perspective than qualitative risk assessment. The results can  
689 provide intuitive information about the potential monetary loss to the secondary government  
690 departments, thus to help provide constructive suggestions in terms of risk prevention and control.

691 The quantitative risk assessment and zonal risk maps can assist the government or decision-  
692 makers in recognizing the specific economic losses of each sub-zones, so it's helpful to identify  
693 the areas that are more susceptible to experiencing significant losses, which allows them to  
694 develop disaster prevention measures, for example constructing disaster prevention facilities,  
695 budget allocation for disaster prevention and planning evacuation strategies. Besides, establishing  
696 the quantitative risk for different typhoon periods can enhance the decision makers understanding  
697 of the potential vulnerability in each sub-zone, and facilitates the implementation of appropriate  
698 preventive and disaster relief measures facing different typhoon intensity.

699

 701 return period (a) 1000-year, (b): 100-year, (c): 50-year, (d): 20-year, (e): 10-year. The base map is  
 702 obtained from © GoogleMaps (map data © 2023 Google).

703 **5. Conclusions**

704 These years, the academic research on storm surge risk assessment has been greatly  
 705 developed due to climate change and financial growth in coastal area. However, the quantitative  
 706 risk assessment is inexecutable in the undeveloped area since on account of the lacks of building  
 707 characters and damage assessment data. Target at the question above, the purpose of this paper is  
 708 to propose a method for conducting refined storm surge risk assessment quantitatively based on  
 709 deep learning and GIS techniques. Firstly, the reliable coupled FVCOM-SWAN model is utilized  
 710 to simulate five defined storm surge scenarios. Facing the challenge of the absence of data, a deep  
 711 learning method TransUNet is applied to extract the building footprint data for refined extraction  
 712 of exposed elements, and buildings' height data is acquired through UAV. To compensate for that  
 713 the available depth-damage functions do not taking building's height into account, the functions  
 714 are adjusted for buildings with different floor and consequently to perform more refined monetary  
 715 losses calculations in five defined scenarios. Eventually, the quantitative risk assessment and  
 716 zonation maps of the study area are generated base on GIS techniques

717 The quantitative risk assessment result of the study region shows that on account of the  
 718 existence of estuary and the gathering of buildings, Dayuan village presents the high-risk level in  
 719 all defined typhoon scenario, and the economic loss risk is large. The flood control dam provides  
 720 protection of Xinliao village, Xin village, Caijia village, which prevents the regions suffering large  
 721 economic losses as the typhoon return period is 10-year and 20-year. However, the storm surges,  
 722 under the typhoon scenarios that the return period is greater than 50-year, can overwhelm the  
 723 existed dikes, and both the commercial buildings and residential buildings suffer heavy economic

724 losses. Therefore, it's necessary to make land use planning and adjustment especially in Dayuan  
725 and Shazuiwei as they are under very high-risk level to prevent the impact and losses caused by  
726 storm surges. Besides, the regions that is nearest to the sea doesn't mean they suffer greater  
727 potential economic loss, as the risk level of Daao village and Harbor community are considered at  
728 a relatively low level because of the topographical characteristics and the distribution of buildings.

729 In the context of global warming and increased climate extremes, the occurrence of large-  
730 scale typhoons has become more frequent, such as Typhoon Rammasun and Typhoon Meranti  
731 (corresponding to 100-year return period). Therefore, the modified typhoon parameters are utilized  
732 for simulation five typhoon scenarios, in order to assuming the different storm surge disaster  
733 situation in the future. On the basis of the above, the study provides a framework for refined  
734 quantitative storm surge risk assessment targeting the problem of acquiring exposure elements and  
735 the establishing multi-variable empirical depth-damage functions, as a consequence of missing  
736 data in underdeveloped regions. The generated results can help the decision-makers to identify the  
737 areas that are susceptible to experiencing significant losses efficiently, and help the respective  
738 authorities with disaster prevention, future land use planning and material deployment.  
739 Furthermore, it is important to remark that, the methodology of this paper has general applicability,  
740 since the applied models are publicly available. Thus, there is also potential for further application.  
741 For example, the framework can be applied in other coastal areas in China, as they have similar  
742 characters, which also means there is a possibility to utilize in larger scales. Furthermore, the  
743 framework can also be performed in other types of disasters, such as flood, earthquake, and  
744 mudslide. Consequently, the proposed methodology demonstrates an extensive relevance to the  
745 scientific community.

746 There is still room for improvement in this study. The current study relied on manual labeling  
747 in terms of distinguishing between functional areas to conduct risk assessment. In the future study,  
748 efforts will be made to distinguish the types of exposure elements in a more objective way, based  
749 on diverse data sources such as social media Point Of Interest (POI). Additionally, exploring the  
750 activity patterns of the population through multiple sources of data including taxi trajectories and  
751 smart cards can contribute to the consideration of population risks in different storm surge  
752 scenarios, thereby prompting more comprehensive risk assessments.

#### 754 **Data availability.**

755 Remote sensing images are obtained from Chang Guang Jilin-1 satellite. The dataset of wind field  
756 is generated by ERA5 and Holland method. The Administrative Boundary data is obtained from  
757 National geographic information public service platform. The datasets can be obtained from  
758 <https://dx.doi.org/10.6084/m9.figshare.24586605> (Yu, 2023). DEM data and UAV data are  
759 obtained from Department of Natural Resources of Huizhou Bureau, data sets are not publicly  
760 available due to the policy of the Natural Resources of Huizhou Bureau.
